The experiment indicates that the stabilized fibrin, that is, desmofibrin, is a product of two-step reaction: in the first step thrombin acting on fibrinogen, not necessarily in the presence of calcium, produces the fibrin and by acting on FSF in presence of calcium thrombin, produces an active fibrin-stabilizing factor.

In the second step, during reaction of fibrin with active fibrin-stabilizing factor, desmofibrin is formed.

The problem of the significance of calcium during the reaction of fibrin polymer with active fibrin-stabilizing factor has not yet been elucidated. Active fibrin-stabilizing factor created during the time of reaction with thrombin in the presence of calcium, after addition of sodium citrate, results in desmofibrin during the reaction with fibrin polymer.

With the same conditions, but with potassium oxalate added to the active fibrin-stabilizing factor, desmofibrin is not produced in the reaction with fibrin polymer.

The two-step formation of desmofibrin is as follows:

First step: (a) fibrinogen + thrombin → fibrin

$$(b)\ \text{FSF} + \xrightarrow[\text{Ca}^{++}]{\text{thrombin}} \text{active fibrin-stabilizing factor}$$

Second step:

$$\text{fibrin} + \xrightarrow[\text{Ca}^{++}\,(?)]{\text{active fibrin-stabilizing factor}} \text{desmofibrin}$$

The fact that the formula given above differs from other known findings[12] can be explained as being the result of using fibrinogen preparations containing FSF instead of the sol of fibrin monomer free from fibrin-stabilizing factor, for work on fibrin-stabilization.

Catalysis of Incorporation of ^{14}C-Uridine into Rat Lens Ribonucleic Acid by Rat Lens Enzyme System

MAMMALIAN lenses may now be considered to be centres of the active metabolism of protein on the basis of the recent findings of Devi, Lerman and Sarkar[1] on the existence in rat lens of a very active system which catalyses the incorporation of amino-acids into lens ribonucleic acid (RNA) and proteins, and on the basis of the occurrence of many proteases in rat lens as demonstrated by Zeller and Devi[2] and Devi[3,4]. The relatively high concentration of RNA in rat lens as reported by Dische and Devi[5] and its key role in protein synthesis as shown by various investigators[6,7] has stimulated us to examine whether or not there also exists in rat lens any system capable of synthesizing RNA.

Rats 6–8 weeks old and weighing approximately 100–120 gm. each were given intraperitoneal injections of 0·2 ml. of 2-^{14}C-uridine (specific activity $2·2 \times 10^6$ c.p.m.) prepared in normal saline. The animals were killed at different time-intervals after injection. The lenses from each rat were immediately removed and homogenized in 1 ml. of 0·25 M sucrose in the cold and to the latter 4 ml. of 5 per cent cold trichloracetic acid (TCA) were added. The TCA-insoluble material was afterwards washed three times with cold 5 per cent TCA, once with alcohol, once with methanol/chloroform/ether (2 : 1 : 1 proportion) mixture at 50° C. and then twice with ether. The TCA-insoluble, lipid-free material was plated and assayed for radioactivity as previously described by Devi, Lerman and Sarkar[1] in the gas-flow windowless counter with an efficiency of 30 per cent.

In experiments where the incorporation of ^{14}C-uridine into RNA was studied *in vitro*, the lenses of 10 such rats were pooled and homogenized at 0° C. in 10 ml. of cold 0·25 M sucrose medium containing 0·025 M potassium chloride, 0·035 M potassium bicarbonate and 0·004 magnesium chloride[8]. The reaction mixture

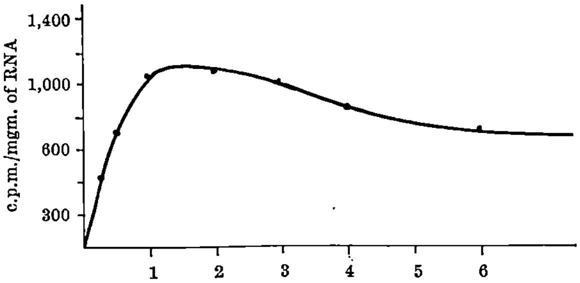

Fig. 1. Carbon-14 uridine incorporated into rat lens RNA (*in vivo*)

containing 0·5 ml. lens homogenate, 2 µmoles of adenosine triphosphate (ATP), 2 µmoles of Mg^{++}, 20 µmoles of *tris* buffer, *p*H 8·0, and 0·05 ml. 2-^{14}C-uridine, specific activity 0·55 × 10^6 c.p.m. in a total volume of 1 ml. was incubated for 30 min. at 37° C. The reaction was terminated by adding 4 ml. of cold 5 per cent TCA. The procedures for washing, plating, and counting were similar to those described above. In some experiments the insoluble material washed three times with TCA was heated in 5 per cent TCA at 90° for 15 min. and then centrifuged. 1 ml. of the TCA-extract obtained was dried and afterwards assayed for radioactivity. ^{14}C-uridine, when injected into rats, appreciable counts can be recorded in TCA-insoluble material. The incorporation reaches the peak within 60–90 min.; then very slowly and gradually declines. Even 24–48 hr. after injection, TCA-insoluble material shows 60–70 per cent of the radioactivity noted at 60–90 min. These results are shown in Fig. 1.

The ability of the lens homogenate to catalyse the incorporation of ^{14}C-uridine into lens RNA under various experimental conditions is shown in Table 1. This system requires ATP and is dependent on Mg^{++}. Omission of any one of the components from the reaction mixture results in a poor incorporation of ^{14}C-uridine into RNA. Incubation of the homogenate with (50 µgm./ml.) crystalline pancreatic ribonuclease (RNase) (Worthington) for 30 min. prior to the addition of ATP, Mg^{++}, ^{14}C-uridine and *tris* buffer renders the system inactive. If, on the other hand, the lens homogenate is first treated with 50 units of venom phosphodiesterase (Biochemical Research) and then incubated with the other components of the reaction mixture, the extent of uridine incorporation into RNA remains practically the same.

The lens homogenate, on exhaustive dialysis at 2–4° C. against 0·02 *M tris* buffer *p*H 7·4 containing 0·01 *M* ethylenediamine tetraacetate (EDTA), becomes inactive in catalysing the incoporation of ^{14}C-uridine into RNA, but the activity can be restored by adding Mg^{++} (Table 2). Mn^{++} can replace Mg^{++} to the extent of 70–80 per cent and Co^{++} to the extent of 35–40 per cent, while other divalent metallic ions such as Zn^{++}, Ca^{++} and Fe^{++} are comparatively poor activators. These metals do not, however, exert any inhibitory effect as the extent of incorporation of carbon-14 into RNA remains the same in the presence of these metals provided Mg^{++} is also present. All these divalent metallic ions begin to exhibit an inhibitory effect when their concentration is raised above 10 µmoles in the test system. It should be of some interest to recall and compare the remarkable effect of Co^{++} in promoting the incorporation of amino-acids into lens RNA and proteins and the strong inhibition of the Co^{++} effect exerted by Ni^{++} (ref. 1) with the effect these metals have on this system which lends support to the conception that Co^{++} is highly specific in protein synthesis.

Table 1. INCORPORATION OF ^{14}C-URIDINE INTO RAT LENS RNA (*in vitro*)

Components of the reaction mixture	c.p.m./mgm. of RNA
Complete system	11,650
Complete system − Mg^{++}	2,060
Complete system − ATP	4,625
Complete system + RNase (50 µgm./ml.)	2,850
Complete system + venom phosphodiesterase (50 units/ml.)	9,210

The complete system contained 0·5 ml. of dialysed rat lens homogenate, 2 µmoles of ATP, 2 µmoles of Mg^{++}, 20 µmoles of *tris*, *p*H 8·0 and 0·05 ml. of ^{14}C-uridine, specific activity 0·55 × 10^6 c.p.m.

Table 2. EFFECT OF METALLIC IONS ON THE INCORPORATION OF ^{14}C-URIDINE INTO RAT LENS RNA

Metals	c.p.m./mgm. of RNA	
(Mg^{++}, 2 µmoles, other metals, 5 µmoles)		
1. Lens homogenate + ATP + Mg^{++}	11,680	
2. Lens homogenate + ATP + Ca^{++}	2,250	
+ Mg^{++}		11,025
3. Lens homogenate + ATP + Fe^{++}	2,040	
+ Mg^{++}		10,965
4. Lens homogenate + ATP + Co^{++}	4,080	
+ Mg^{++}		12,005
5. Lens homogenate + ATP + Mn^{++}	9,294	
+ Mg^{++}		12,608
6. Lens homogenate + ATP + Zn^{++}	2,060	
+ Mg^{++}		10,985

The addition of chloramphenicol (50–100 µgm./ml.) does not block the incorporation of ^{14}C-uridine into RNA; but the addition of 5-bromouracil, 5-fluorouracil or 2-thiouracil (at a level of 40–50 µgm./ml.) inhibits the incorporation only to the extent of 25–35 per cent. No further inhibition is noted with higher concentration of these analogues of this pyrimidine. The purine analogues such as 8-azoguanine and 8-azoadenine cannot inhibit the incorporation of uridine into RNA more than 20–30 per cent.

These results clearly demonstrate the existence of an active system in rat lens capable of synthesizing RNA. Previously it was possible to demonstrate the presence of an active protein-synthesizing system in rat lens[1]. These results seem to be consistent with the assumption that in rat lens and also in lenses of other species of animals metabolism of proteins and nucleic acids is an active dynamic process.

Serum Lipids in Relation to the Intake of Alcohol and Sodium Chloride

THE question whether variation in the intake of alcohol or sodium chloride has any marked influence on serum lipids is of considerable interest in human pathology. Whereas several investigators have studied the long-term influence of these factors, especially on vascular changes, relatively few reports have been

published on the variations in serum lipids caused by a single dose of alcohol and by short periods of high or low intake of sodium chloride. The present communication deals with some experiments aimed at elucidating these problems.

Experiments with alcohol. Six persons participated in this experiment : 1 normal person, 30 years of age, and 5 geriatric patients. One dose (100–150 ml.) of brandy (45 per cent v/v) was given at 8 a.m. to the fasting person together with 4 plain biscuits (24 gm.). Blood samples were taken immediately before and 1, 4, and 6 hr. after. Total lipids, cholesterol and phospholipids were determined in all the samples. Alcohol was determined in the samples after dosing, determinations being carried out at the Institute of Forensic Medicine, University of Copenhagen, by courtesy of Prof. H. Gormsen.

Furthermore, in all samples prothrombin-proconvertin, serum transaminase, alkaline phosphatases and icterus index were determined, and thymol- and Takata-Ara tests were carried out. The liver function as judged by these examinations was normal and did not show any variation during the experiment.

The results of the serum lipid and alcohol determinations are presented in Table 1. In no case were significant changes in total lipids, total cholesterol and phospholipids observed after the ingestion of ethanol in the quantities used. This seems to be in agreement with observations of Grande *et al.*[1], who did not find any significant increase in serum cholesterol when 0·45 gm. ethanol/kgm./day was given for three weeks, and an increase of only 18 mgm. cholesterol per 100 ml. serum when 1·35 gm./kgm./day was given for one week. Under quite different conditions, namely acute alcoholism with damage to the liver, Epstein and Greenspan[2] found a reduction of the cholesterol esters in blood plasma.

Experiments with sodium chloride. Four geriatric patients participated in this experiment. They were given a diet low in sodium chloride (less than 0·5 gm. sodium chloride/day) for two weeks and thereafter the usual hospital food (5 gm. sodium chloride/day) plus 3 gm. sodium chloride in tablets/day for the following two weeks.

Serum total lipids, total cholesterol and phospholipids were determined once before the experiment, twice during each experimental period, and once after the experiment. The results were presented in Table 2. The values for total lipid, total cholesterol and phospholipids did not change significantly from one period to the other. This finding does not necessarily contradict the possibility that a diet rich in sodium chloride may contribute to the development of atheromatosis, as has been claimed, for example, in rats[3].

Eucollagen

As protein chemistry becomes more complex and large units become molecularly subdivided, new terms are required for adequate description. Prefixes such as α-, β-, pseudo- are well known. In collagen research, terms have been invented to cover new concepts, such as Orekhovich's procollagen[1], Banga and Balo's metacollagen[2] and the tropocollagen units of Schmidt, Gross and Highberger[3].

None of these terms was adaptable to the highly modified forms of collagen described by me[4], and so the term 'eucollagen' was used[5] in this connexion.

The *Shorter Oxford English Dictionary* describes 'Eu' as a prefix representative of Greek, used mostly in words of Greek derivation. ευ κόλλα λεν is derived wholly from the Greek and clearly means 'easily producing glue'. This is an exact property entering into the definition and the term was chosen for this precise reason.

Unaware, at the time, of the original publication[5] on eucollagen and of subsequent references[6] to this term by Kelly, Little and Courts; Reed and Stainsby Crosby and Stainsby; and by Tristram, a second interpretation of eucollagen was used by [the late] W. T. Astbury[7] to name a hypothetical limiting structure for collagen, in which glycine occurs at intervals of three residues and hydroxyproline at intervals of ten residues. This unit is considered to be responsible for the 28·6 Å. X-ray repeat.

So far as the modified collagen[5] is concerned, many of the properties suggest a retention of the collagen helical configuration but absence of segmented spacings. A substantial reduction in molecular chain weight to parent gelatin size occurs. The hydrothermal stability falls to a minimum value and the material undergoes transition to a random coil structure entirely by a hydrogen bond-breaking mechanism. It is suggested, therefore, that use of the term 'eucollagen' for such material is both etymologically and scientifically in order.

Some Properties of the Deoxyribonucleic Acid of Phage Alpha

WE wish to report some results concerning the unique properties of the deoxyribonucleic acid (DNA) isolated from the phage α grown on its host, *Bacillus megatherium*, strain Paris. This phage and its host have been studied by Drs. S. Aurisicchio, A. Celano, A. Coppo, P. Donini and F. Graziosi, and kindly supplied to us by them. These workers had found that the decay of phosphorus-32 incorporated in the DNA of the phage led to a time-dependent loss of viability similar to that of the phage φ*X*-174 (Graziosi,, F., personal communication). Since the DNA of the latter phage has been shown to be single-stranded[1], the DNA of phage α was expected to display similar properties. However, as will be indicated later, many of its properties resemble those of double-stranded DNA with the notable exception that, on denaturation, there are formed two denatured units with distinct buoyant densities in a cæsium chloride gradient.

After gathering and purification of phage α, DNA was isolated by the phenol method of Mandell and Hershey[2]. Using as much caution as possible to avoid shear degradation, a mean sedimentation coefficient of 40*S* (extrapolated to infinite dilution and corrected to water at 20° C.) was obtained for this type of preparation. Exposure to heat resulted in an absorbance–temperature profile similar in the sharpness of its rise of absorbance to that of the DNA of the *T* phages of *Escherichia coli*, with a T_m (midpoint of the rise of absorbance) of 86·5° C. in 0·15 *M* sodium chloride plus 0·015 *M* sodium citrate. This T_m corresponds to a base composition of 41 mole per cent guanine plus cytosine (ref. 3 and Marmur, J., and Doty, P., unpublished work). When phage α DNA is denatured and then renatured under optimal conditions[4], it exhibits an absorbance–temperature profile similar to that of the native; the curves can be superimposed to the extent of approximately 85 per cent in the region of the T_m.

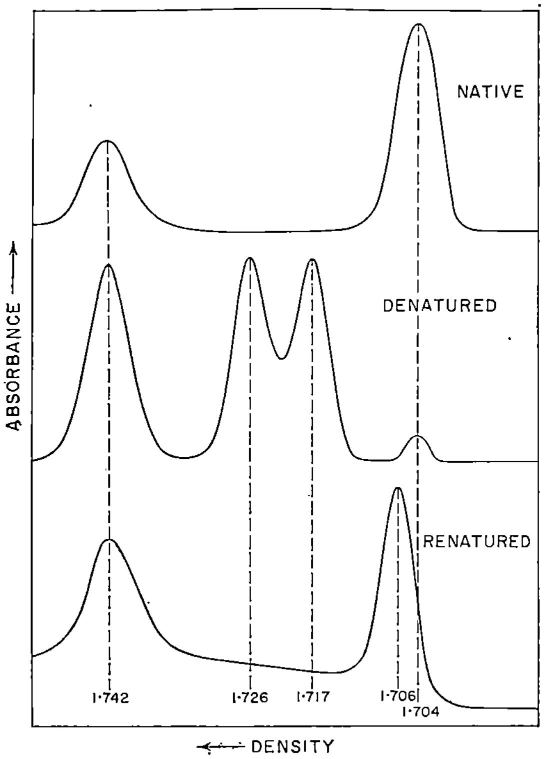

Fig. 1. Buoyant densities of native, denatured and renatured phage α DNA. Microdensitometer tracings were made of the ultra-violet absorption photographs taken after 23 hr. at 44,770 r.p.m. (25° C.). The density 1·742 represents that of the standard, *Pseudomonas aeruginosa* nitrogen-15 DNA, which is used to calculate the densities of the other bands

Native and denatured samples of phage α DNA were then examined for their properties in cæsium chloride density gradient centrifugations. The results are shown in Fig. 1. Native phage α DNA was equilibrated in a single band with a buoyant density of 1·704 gm./c.c. This density corresponds to a base composition of 44 mole per cent guanine plus cytosine (refs. 5, 6 and Schildkraut, C. L., Marmur, J., and Doty, P., unpublished work). However, a thermally denatured aliquot gave rise to two equal distinct bands with densities of 1·717 gm./c.c. and 1·724 gm./c.c. When the denatured material was renatured, again one band was obtained. The density of this band (1·706 gm./c.c.) is slightly higher than that of the native DNA, a result most likely due to the persistence of some denatured unmatched ends.

The two distinct denatured units, obtained on thermal denaturation (and on formamide denaturation as well), might result from a variety of factors. The two hypotheses which at the present time we favour as explanations of these results may be summarized as follows: (1) That there is a difference in the base compositions of the two units or strands which causes one or both of them to have a different density from that usually obtained for a DNA of this overall base composition (42·5 per cent, obtained by chemical analysis, Graziosi, F., personal communication). The Watson–Crick structure does not exclude this possibility even for deoxyribonucleic acids in which adenine = thymine and guanine = cytosine (as has been shown for this DNA, Graziosi, F., personal communication). (2) That an unknown material, *X*, is attached to one of the two units causing it to have a lighter or heavier buoyant density.

In considering the first hypothesis, it is possible to calculate the percentage of guanine plus cytosine for each of the denatured bands from their buoyant densities. This corresponds to 42 mole per cent for the lighter and 49 mole per cent for the heavier band. The lighter denatured band then has, by this calculation, a guanine plus cytosine content closely approximating that obtained by chemical analysis and by the T_m of the absorbance–temperature profile. However, the average composition calculated from the densities of the two bands (45 per cent) is close to that corresponding to the buoyant density measured for the native material. Since the lighter denatured band approximates the average base composition of the double-stranded material, we feel inclined to favour hypothesis (2). Some unknown material firmly attached to one of the strands causes it to exhibit a higher buoyant density, resulting in the two-band pattern observed by thermal and formamide denaturation. If only one of the two strands of the DNA molecule were essential for the replication of the phage, it would then be possible to explain the high phosphorus-32 suicide of the phage.

This investigation was supported in part by research grants (*RG* 7985, 13990 and *G* 16360) from the National Institutes of Health and from the National Science Foundation.

An Inhibitor of Liver Alcohol Dehydrogenase in Preparations of Reduced Diphosphopyridine Nucleotide

Different samples of reduced diphosphopyridine nucleotide (β-DPNH, Sigma Chemical Co.) have been found to give significantly different maximum rates of reduction of aldehyde catalysed by liver alcohol dehydrogenase. The crystalline enzyme was prepared from horse liver[1] and measurements of initial rates were made with a recording fluorimeter[1,2] at 23·5°. In Table 1 relative values of initial rates with $1 \cdot 3 \times 10^{-3}$ *M* acetaldehyde and 2×10^{-5} *M* DPNH in *p*H 6 phosphate buffer (ionic strength 0·1) are collated with assays of the samples of DPNH. The percentage by weight of anhydrous disodium salt was calculated from direct extinction measurements at 340 mμ (column 2), and also from the decrease of absorption of light at this wave-length ($\Delta E340$) accompanying complete oxidation of the coenzyme by excess acetaldehyde and liver alcohol dehydrogenase (column 3), using in each case the value 6·22 (ref. 3) for the millimolar extinction coefficient. The second value is taken to be the true DPNH content. The difference between the two values is due to the presence of a substance which closely resembles DPNH in both light absorption and fluorescence emission, but is not coenzymically active with liver (or yeast) alcohol dehydrogenase. The results indicate that the samples which give the higher initial rates have the greater coenzyme content and a smaller excess of total adenine over coenzyme (column 4). Ribose and total phosphate analyses were also made ; calculating the total adenine content from the extinction at 260 mμ (*p*H 7) and a millimolar extinction of 15 (ref. 4), the molar ratios of ribose and phosphate to adenine were 2·1 ± 0·1 for all the samples.

With butyraldehyde as substrate, similar differences in initial rates at *p*H 6 were found. At *p*H 7 the differences were smaller, and with acetaldehyde at *p*H 10 all the DPNH samples gave the same initial rates. With yeast alcohol dehydrogenase (Worthington Biochemical Corporation) the rates of reduction of acetaldehyde at *p*H 6 were the same for all the DPNH samples. It appears that the more impure samples at least contain a potent and relatively specific inhibitor of liver alcohol dehydrogenase in neutral and acid solution.

Table 1. ASSAY VALUES AND RELATIVE INITIAL RATES OF OXIDATION OF DPNH SAMPLES BY ACETALDEHYDE AND LIVER ALCOHOL DEHYDROGENASE AT *p*H 6·0

Sample	Assay, percentage DPNH(Na_2)		$E260/\Delta E340$	Initial rate (arbitrary units)
	$E340$	$\Delta E340$		
1*	73	66	3·6	57
2	78	73	3·0	68
3	85	80	2·85	96
4	88	81	2·75	100

* Sample 1 not designated as the β-isomer.

The following compounds were tested as inhibitors with negative results : nicotinamide and its oxidized and reduced N-methyl derivative, adenosine, adenosine di- and tri-phosphate, yeast adenylic acid, and α- and β-DPN. Digests of DPN and DPNH with nucleotide pyrophosphatase[5], which yield adenosine monophosphate and nicotinamide mononucleotide, were also not significantly inhibitory. Treatment of DPNH with 0·1 *N* hydrochloric acid and DPN with 0·1 *N* sodium hydroxide produced potent inhibitors, however ; both these treatments form adenosine diphosphate ribose[6], and this compound was isolated from acidified DPNH and from digests of DPN with the nucleotidase of *Neurospora crassa*[7]. A concentration of 8×10^{-6} adenosine diphosphate ribose produced 40 per cent inhibition in the rate of reduction of acetaldehyde at *p*H 6 under the conditions described here and using the purest DPNH preparation, but had no inhibitory effect at *p*H 10. It did not affect the reaction catalysed by yeast alcohol dehydrogenase at *p*H 6. Digestion of the compound with nucleotide pyrophosphatase destroyed its inhibitory power. Direct evidence of the presence of adenosine diphosphate ribose in DPNH samples has been obtained by paper electrophoresis, but it is not yet possible to say whether the amount is sufficient to account for the observations.

The remarkably potent and *p*H-dependent inhibition of liver alcohol dehydrogenase by adenosine diphosphate ribose has obvious possibilities for work on coenzyme binding. It also seems probable that discrepancies between the kinetic data for this enzyme[1,8,9], which were particularly large as regards the maximum rate of aldehyde oxidation in acid solution, were mainly due to the presence of different amounts of inhibitor in the coenzyme samples. Highly purified coenzyme samples are evidently essential for valid kinetic studies, especially if conclusions about the mechanism are to be drawn from relations between the forward and reverse rates and equilibrium constants[8,10,11]. It remains to be seen whether these observations and conclusions are relevant to other dehydrogenases.

I am indebted to Dr. N. O. Kaplan for a gift of α-DPN and to Dr. V. Massey for a preparation of *Neurospora* nucleotidase.

A New Universal Buffer System

DURING investigations of the effect of *p*H on the activity of certain enzymes it was found necessary to use a single buffer solution for measurements at widely different *p*H values. For various reasons the universal buffer solutions of Prideaux and Ward[1], and Britton and Robinson[2] were unsuitable, and so the following solution was devised, the *p*H value of

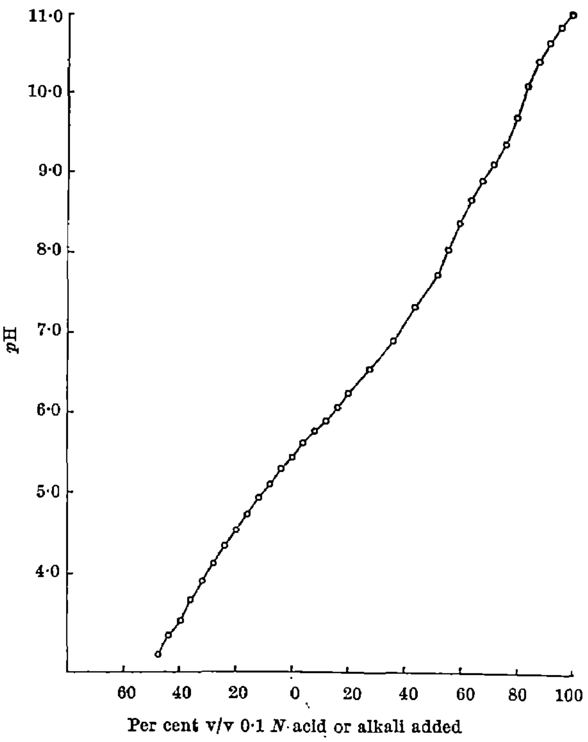

Fig. 1

which was found to vary almost linearly with added acid or alkali.

0·1 mol. of each of the following was dissolved separately in 250 ml. water, the solutions being mixed in the order shown just prior to use: sodium carbonate, 2-amino-2-methyl propan-1 : 3-diol[3] (Eastman-Kodak reagent); sodium dihydrogen orthophosphate; citric acid.

Van Slyke[4] and Britton and Robinson[2] deduce that in mixtures of buffer substances a constant buffering power over the working pH range will be obtained if the consecutive pK values of the acids involved differ by not more than 1·2. In the present system the pK values are deduced to be[3,5]:

1·0; 3·1: 4·7: 5·4: 6·4: 7·1; 8·8; 10·4 and 12·3.

These approximate to the ideal system, and the buffering power in fact remains nearly constant between pH 2 and 12 (Fig. 1).

RADIOBIOLOGY

Determination of Cæsium-137/Potassium Ratios in Diet and in the Human Body by Urine Analysis

A radiochemical method[1] has been developed for the determination of cæsium-137 in urine. Acidified urine containing cæsium carrier is passed through a column of ammonium phosphomolybdate mixed with an equal weight of asbestos to give adequate porosity. The ammonium phosphomolybdate acts as a highly selective cation-exchanger and retains the cæsium quantitatively, even at comparatively high flow-rates. Other cations, including sodium, potassium and the alkaline earths, are not retained to any significant extent. After all the sample has passed through the column, the ammonium phosphomolybdate is dissolved in sodium hydroxide solution and the cæsium precipitated as the cobaltinitrite. The removal of final traces of potassium and rubidium from the cæsium is ensured by its subsequent precipitation as the bismuth iodide complex and finally as the chloroplatinate, which is filtered, dried and beta-rays counted. The recovery of carrier normally exceeds 80 per cent. The sensitivity of this method makes it particularly useful for the determination of fall-out cæsium-137 in urine, as current concentrations are low and are likely to decline still further.

The cæsium-137 contents of seven urine samples collected in February, March and April 1961 were determined by this method. These samples were prepared by bulking at least 10 specimens obtained from individuals, mostly resident in Berkshire, with no known exposure to cæsium-137 other than fall-out levels in their diet. Potassium was estimated in the same samples by flame photometry. The results of these analyses are given in Table 1.

Table 1. CÆSIUM-137 AND POTASSIUM CONCENTRATIONS IN BULKED URINE SAMPLES

Date of collection	Cæsium-137 ($\mu\mu$c./l.)	Potassium (gm./l.)	Ratio ($\mu\mu$c./gm.)
21.2.61	29·9	2·47	12·1
1.3.61	21·1	2·00	10·6
7.3.61	26·8	2·73	9·8
14.3.61	24·3	1·73	14·0
20.3.61	24·6	1·66	14·8
10.4.61	26·2	2·07	12·7
28.4.61	21·7	2·07	10·5
	Mean 24·9	Mean 2·10	Mean 12·1

In vivo cæsium-137/potassium ratios were determined by Rundo, J. (private communication, 1961) in 14 residents of Oxfordshire and Berkshire during March 1961. The mean value for this group was 36 $\mu\mu$c./gm., which is almost exactly three times the value for this ratio in urine given in Table 1. Values for the ratio :

$$\frac{\text{cæsium-137/potassium in the body}}{\text{cæsium-137/potassium in urine}}$$

have also been determined for a number of individuals by Rundo and by Miller and Marinelli[2]. These varied from 1·9 to 4·6, indicating that individuals may show a considerable departure from the average value of 3 obtained in the present comparison.

As both cæsium and potassium are completely absorbed from the human gastro-intestinal tract, the cæsium-137/potassium ratio in urine will be equal to that in the diet and should also be one-third of that in the body, under equilibrium or near equilibrium conditions. This is in agreement with the measurements of McNeill and Trojan[3], who measured the cæsium-137/potassium ratio in the diet of Toronto residents and in the residents themselves, using a γ-spectrometric technique. They found that the body/diet ratio was 3: 1.

The analysis of bulked urine samples appears to provide a simple method for assessing current cæsium-137/potassium ratios in both diet and the human body, so long as dietary-levels are not changing too rapidly. By analysing a bulked sample, the difficulty in selecting representative aliquots of various items of diet for analysis is avoided.

The possibility of monitoring strontium-90 in diet by urine analysis has been proposed by Schulert[4], whose measurements show that the strontium-90/calcium ratio in diet is approximately twice that in the urine. Both strontium-90 and cæsium-137 may be estimated on the same sample by adding strontium and cæsium carrier to urine before passing it through the ammonium phosphomolybdate column. While cæsium is retained on the column, both strontium and calcium pass through and may be co-precipitated from the effluent as the oxalates. Separation of the strontium from the calcium and determination of the strontium-90 can then be effected by well-established techniques.

We wish to thank Mr. W. H. A. Raymond of the Medical Research Council Radiobiological Unit, Harwell, who carried out potassium determinations in the urine samples.

Effect of Irradiated Normal Tissues on the Growth of Mouse Carcinoma

In 1932 it was observed by Geoffrey Keynes[1], working on the disappearance of human mammary carcinoma by surrounding the growth with radium needles, that on cutting out a piece of the tumour after the needles had been in place for ten days, some of the malignant cells were alive and became grafted in the overlying biopsy skin-incision, although the rest of the tumour from which the piece had been removed eventually disappeared. This suggests that the surrounding normal cells might have been acted on by the radiations so as to continue to pour out a chemical substance which led to the death of the cancer cells[2].

It was decided to search for evidence of the presence of such substances in irradiated normal tissues. The material tested has been bovine and rabbit muscle, lamb's thymus and mouse meat. The irradiated tissue was supplied either solid as food or in water as a drink. The tumour used was one of two mice carcinomata, Bashford 63 (also labelled *X*), or Compton 22, which arose in our laboratory spontaneously and so far has not been described. The general method of experimenting was to implant grafts from the same fragment of tumour subcutaneously into 10 mice. From these animals, 1–5 were taken at random for testing the irradiated material. The others were kept as controls. Both control and test animals were fed on the pellets customarily used in laboratories, but the test animals had either (*a*) the irradiated material, if solid, added to the ground-up pellets or (*b*) had a watery extract of the irradiated material substituted for their drinking water. There was no restriction of the amount the animals were allowed to eat or drink.

Experiments showed that unirradiated meat or meat extracts added to the normal diet of the mice had no effect on tumour growth; and that animals receiving irradiated food showed no alteration in weight compared with the controls.

In 23 experiments of this nature, 16 by the feeding procedure and 7 by administering the material by drinking, the results were as follows: (*a*) in 6 there was no evidence of inhibition; (*b*) 17 showed disappearance of the growth or inhibition in some degree.

Among the failures was a drinking experiment where the material had been heated to 80° C. In three others the material had received doses of 1,000 r., 6,000 r. and 7,500 r., which we consider as inadequate, while in one, although the dose given to the food 120,000 r. was suitable, the animal was fed for only 3 days. For the sixth failure we have no explanation.

Experiments 619 (feeding with lamb's thymus, radiation dose 600,000 r.) and 664 (drinking experiment with a watery extract of beef muscle, radiation dose 150,000 r.) are examples of findings.

Experiment 619 (Fig. 1) illustrates the disappearance of 3 treated tumours and, while feeding was proceeding, inhibition in 2 others.

In the experiment 664 (Fig. 2), No. 2 was treated from the fifth day after implantation of the graft, for 7 days. The tumour disappeared. No. 1 was allowed to grow until the eleventh day and then given the drink for 7 days. It showed some initial shrinking in size but then resumed growth and caught up with the controls by the eighteenth day. This suggests that there is a simple relation between the amount of active agent necessary to cause disappearance of the growth and the weight of the tumour (proportional to r^3 in the case of a sphere). Below this critical amount, inhibition only can occur and the growth of the tumour soon gets the upper hand. The amount of active agent in our extracts is likely to be small, so that the animal may not drink enough to absorb the critical amount for disappearance of the tumour.

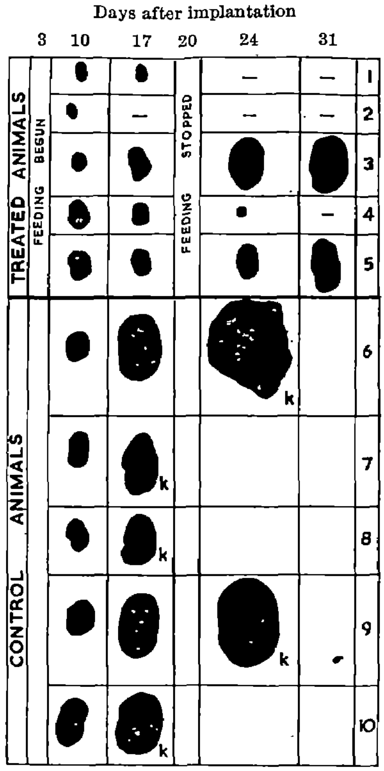

Fig. 1. Experiment 619, tumour 63. *K*, killed for tumour propagation purposes

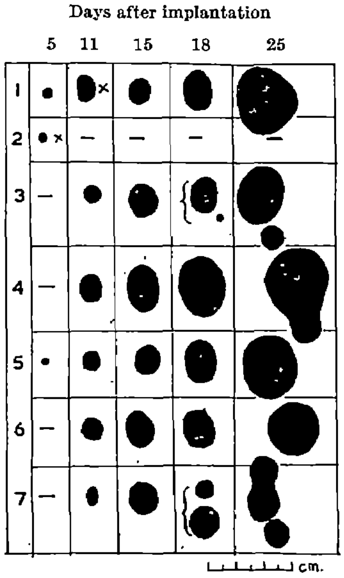

Fig. 2. Experiment 664, tumour *X*. *X*, treated animals ; the other animals are controls

Graphs of the rate of tumour growth in controls and in treated animals where the tumour is inhibited but does not disappear show the same general character; but the growth-time curve for the inhibited tumour shows a variable delay before it turns upward.

Assuming the tumours to be spherical in shape and that the inhibitory effect is due to direct destruction of tumour cells, theoretical curves have been plotted for different amounts of active agent given. It appears that for complete disappearance of a tumour a dose is required which will destroy at least 37 per cent of it.

The inhibitor seems to be diminished in activity by heating above 60–65° C. and destroyed by an X-ray dose greater than from 10^6 to 2×10^6 r.

A similar phenomenon in plants has been reported from the U.S.S.R. A. M. Kuzin[3] has found evidence that irradiating the normal cells of a plant produced substances which had an inhibitory effect on cell division in other parts of the plant which had not been exposed to X-rays. He isolated from the irradiated part a mixture of polyphenols which proved to be the active substance.

PHYSIOLOGY

Spontaneous Spike-Discharges of Vascular Smooth Muscle

I reported in refs. 1 and 2 that trans-membrane potentials of smooth muscle fibre of the small blood-vessels, distributed in frog tongue and web, had been studied with the aid of an intracellular micro-electrode technique. The results of these experiments were as follows: (1) The resting potential of smooth muscle fibres was found to be negative on the inside, against the external medium; the mean value was − 40·5 ± 5 mV. and fluctuations of the resting potential were rarely observed. (2) Single spike-potentials were evoked by single induction shocks, which were about 60 mV. in magnitude and 200 msec. in duration.

Though these potentials usually had the shape of simple spikes, some of them showed the so-called 'complex shape'[3,4] provided with some humps on the phase of either depolarization or repolarization, or on both, and showed graded response. Another type of action potential was obtained from smooth muscle fibres in the remarkably contractile region of the bifurcation of small blood-vessels or in blood capillaries that were highly sensitive to electrical or chemical stimulation; in this type the magnitude was about 60 mV. and the duration 50 msec. This evidence suggested that there were two sorts of muscle fibres, distinguishable in contractility, in the small blood-vessel system.

(3) The mean value of the resting potential of endothelial cells in blood capillary wall was − 47 ± 3·7 mV., but spike-potential, elicited by electrical stimulation, had not been observed.

In the present work, the spontaneous spike-discharges of vascular smooth muscle of frog were observed with the intracellular micro-electrode. The recordings *in situ* were carried out in the following

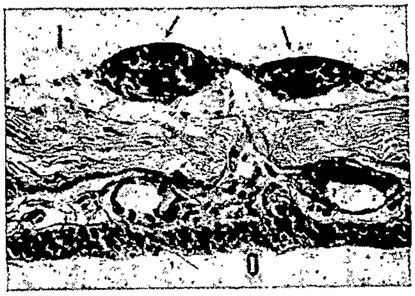

Fig. 1. Photomicrograph showing a transverse section of a blood-vessel in the skin of the lateral abdomen of a frog. Note the absence of visible connective tissues in the surface of the blood-vessels. The arrows mark blood-vessels (venules containing red-stained corpuscles). *I* and *O* are the inside and outside respectively of the skin. Stained with hæmatoxylin–eosin. (× 100)

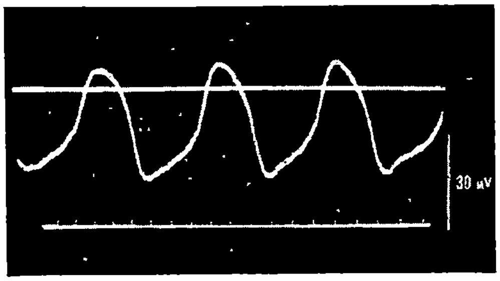

Fig. 2. A series of the spike-discharges recorded intracellularly from a vascular smooth muscle fibre (venule). In this record the resting and action potential are −26 and 36 mV. respectively. The spikes show an overshoot of about 10 mV. and a time-course of about 200 msec. Note the initial slow potential (pre-potential), from the summit of which the spike arises. The horizontal line indicates zero potential. Calibration, 30 mV.; time mark, 30 msec.; temperature, 29° C.

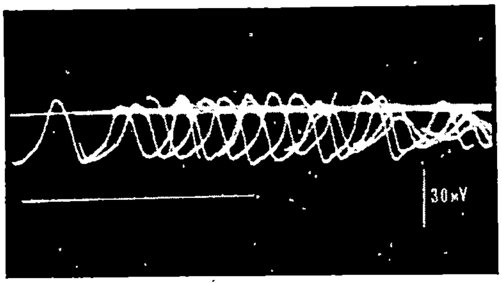

Fig. 3. Typical record of spike-discharges obtained from a muscle fibre with an intracellular micro-electrode during spontaneous activity (arteriole). This continuous record was taken repeatedly with several sweeps on a slow-moving film. The horizontal line indicates zero potential. Calibration, 30 mV.; time mark, 30 msec.; temperature, 26° C.

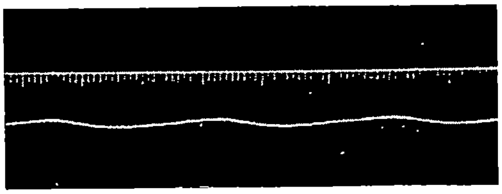

Fig. 4. A vascular pulsation curve recorded from the same specimen as in Fig. 3, in which the period is about 900 msec. This curve is shown to compare with the time-course of the spike. Time mark, 30 msec.

way: the frog was immobilized by fixing the dorsal side down with a metal cover in a lighted chamber. The skin of the abdomen was incised both along the mid-line and at the flank so as to be turned over, and was spread out under moderate tension on a cork board immersed in Ringer solution. A micro-electrode was then inserted into the blood-vessel wall from the outside with the aid of a Peterfi-type micro-manipulator under the binocular microscope. The micro-electrode filled with 3 M potassium chloride solution was used to record the potential, a relatively high-resistance micro-electrode (35–50 $M\Omega$) being used for the purpose of minimizing injury to the muscle cell. For the arteriole, the tip of a micro-electrode had to be thinner than for the venule, in order to penetrate the wall safely. For the convenience of good penetration small blood-vessels, with very thin connective tissue membrane covering the surface as shown in Fig. 1, of 50–100μ in diameter, were selected. The control of vascular pulsation was made possible by applying adequate pressure to the proximal part of the same blood-vessel at some distance from the point of impalement.

All experiments were carried out at temperatures between 25° and 32° C. When the tip of a micro-electrode penetrated into a muscle fibre of a small blood-vessel, the resting membrane potential showed a negativity against the external medium, the value of which was about − 25 mV. During the observation, repetitive bursts of spike-discharges occurred sometimes spontaneously at regular spike-intervals, and lasted for several seconds or longer. The typical record is shown in Fig. 2. In this record the resting and action potentials were − 26 and 36 mV. respectively, the resting potential being measured at maximum polarization between one spike and another. The action potentials had an overshoot of about 10 mV. and a time-course of about 200 msec. They were invariably provided with an inflexion of the rising phase. This indicated that the spike configuration consists of two components, namely, an initial slow potential and a large simple spike.

The slow potential resembled in appearance pre-potentials of other smooth muscles (tænia coli[3], pregnant uterus[5], etc.) or excitatory post-synaptic potentials of various neurones[6,7]. The spike-potential recorded appeared to be conducted excitation in view of the initial slow potential and it is probable that the excitation is propagated from one unit to another to some extent in the blood-vessel. It is with this point taken into account that the mechanism of vascular activity is now under investigation by me.

With the spike-discharges, there was a progressive decrease of the amplitude towards the end, finally reaching a certain depolarization-level of the resting potential. Though the spontaneous discharges were observed in both arterioles and venules, no significant difference was noted between them.

Stimulation of Motor Nerve Terminals

KNOWLEDGE of prejunctional events in neuromuscular transmission is at present indirect in origin and largely speculative in content. This is because there has been no method of directly recording from, or stimulating, the very small motor nerve endings. Using a glass micro-electrode in the isolated rat diaphragm phrenic nerve preparation we have succeeded in stimulating single nerve fibres very close to, or at, the neuromuscular junction. The recording chamber and bathing solution have been previously described[1].

The stimulating electrode (filled with 4 M sodium chloride, 1·5–3μ tip and 1–3 megohm resistance) was located at neuromuscular junctions by using it to record extracellular end-plate potentials in curarized ($2\text{–}4 \times 10^{-6}$ gm./ml.) or magnesium-poisoned (11 m.mole/l.) preparations (Fig. 1*A*). With this method extracellular end-plate potentials are recorded only when the tip is very close to the junction. When localized in this way the electrode was connected to two Grass stimulators which delivered pairs of pulses separated by varying intervals (1–200 msec.). These pulses were recorded across a known small resistance in the stimulating circuit and monitored on the C.R.O. screen. In response to stimulation small all-or-nothing potentials could be recorded in the phrenic nerve (Fig. 1*B*). The position of the electrode tip was very critical in that movements of only 10–15μ sideways or upwards caused the response to stimulation to be lost. Moving the electrode downwards resulted in impalement of the muscle fibre. As the diameter of the neuromuscular junction in the rat diaphragm is 20–30μ (ref. 2) we feel that we are stimulating structures very close to the nerve terminals.

The changes in threshold after one supra-threshold conditioning stimulus have been examined in both magnesium-poisoned and curarized preparations. The results (Fig. 1*C*) indicate a refractory period of 1·5–3 msec. followed by a period of supernormality lasting 15–30 msec. There is often a slight subnormality for about 50 msec. after the supernormal period (Fig. 1*C*). Following 2–5 conditioning volleys the period of supernormality is reduced and the subnormality increased in magnitude and duration. These excitability changes of the terminals are very similar in time course to those described for the parent fibres, the mammalian *A* fibres[3]. After a brief (0·1 msec.) sub-threshold conditioning pulse changes in threshold—an initial fall and later recovery—can be detected for 2·5–3·0 msec. in both magnesium-poisoned and curarized preparations.

We have further found that the excitability of the terminals can be markedly altered by drugs. A comparison of magnesium and curare at the same neuromuscular junctions has shown that curare reversibly reduces the supernormal period found after one conditioning stimulus both in curarized and magnesium-poisoned preparations. Prostigmine in concentrations as low as 10^{-7} gm./ml. produces a reversible increase in refractory period followed by an increase in the magnitude and duration of the supernormal period (Fig. 1*C*).

These findings are of interest in two connexions. First, prolongation of the refractory period and thus presumably of the spike potential in the terminals suggests that part of the effect of prostigmine on the end-plate potentials is caused by a prolongation of

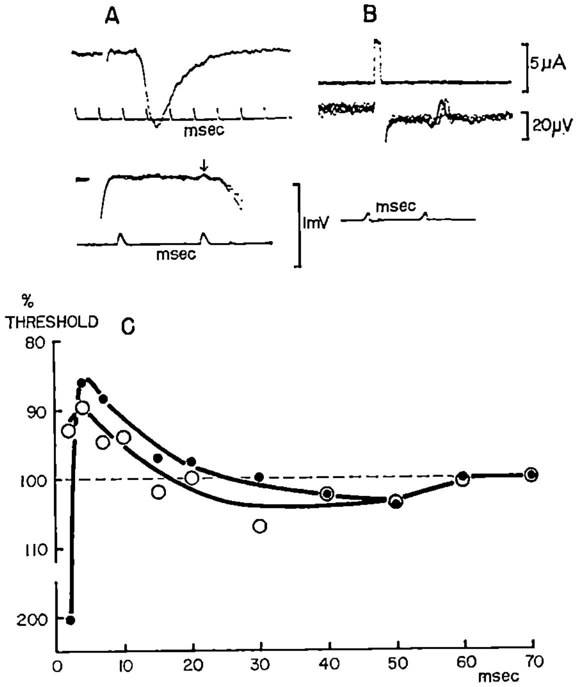

Fig. 1*A*, Extracellular end-plate potentials recorded with a 4-*M* sodium chloride electrode, neuromuscular transmission being depressed by magnesium chloride 11 m.mole.; *B*, action potential in phrenic nerve in response to threshold stimulation (with square pulse of 0·06 msec. duration) at same neuromuscular junction as 1*A*; *C*, changes in threshold after one conditioning stimulus. Ordinate: threshold current at given interval as percentage of unconditioned threshold current. Abscissa: interval between conditioning and testing pulses. ○, magnesium chloride 11 m.mole values before and after prostigmine bromide, averaged; ●, magnesium chloride 11 m.mole and prostigmine bromide 2 × 10^{-6} gm./ml.

the period of transmitter release. Secondly, the prostigmine-induced increase in negative after-potential provides an adequate mechanism for the initiation of the antidromic discharges found in motor nerves after intra-arterial administration of this drug[4].

Potential Changes produced by Application of Current Steps in Motoneurones

IN cat spinal motoneurones, when current steps are applied across the membrane through the intracellular micro-electrode, the membrane potential changes in an approximately exponential way, but with a certain deviation. Thus, the soma-dendritic membrane of the motoneurone has been assumed to behave as a resistance and a capacitance in parallel[1,2], and the deviation has been attributed to the cable-like property of dendrites, the dominance of which in forming the effective surface area of motoneurones has been emphasized recently[3]. As will be described, however, the potential produced by current steps in motoneurone membrane shows a considerable overshoot, which has so far been overlooked because the current steps used previously were generally too brief to reveal the later decline of the potential. This electrical behaviour of the membrane suggests that the equivalent electrical circuit of the membrane is not a simple resistance-capacitance network.

Single micro-electrodes filled with 3-mole/l. potassium chloride solution were inserted into motoneurones in the lumbosacral region of the cat spinal cord. Rectangular currents were applied to the impaled cell membrane through the micro-electrode, and changes in the membrane potential thereby induced were recorded through the same micro-electrode by compensating for the voltage set up across the micro-electrode resistance. The applied current was monitored by the potential drop across a 10-M.ohm resistor inserted in series between the micro-electrode and the 100-M.ohm resistor, the latter being connected to the current generator. After d.c. amplification, the potential changes in the membrane were recorded photographically from a cathode ray oscilloscope trace.

Fig. 1 *A* and *B* shows an example of the potential change thus induced by rectangular current pulses of about 50 msec. duration. The current strength was about half the rheobase for initiating the *IS–SD* spike potential. Both depolarizing (*A*) and hyperpolarizing (*B*) potentials rose in an approximately exponential way to a maximum at about 15 msec., there being a later decline during the continuation of the currents. After cessation of currents, the membrane potentials rebounded in the opposite direction before returning to the original level, as seen with slower sweep velocity in Fig. 1 *C* and *D*. In Fig. 1 *E* and *F* the potential induced by current steps reached a steady level in about 100 msec. after the summit at about 15 msec. The rebound, after current ceased, followed a course similar to that of the initial hump at the onset of the current. The potentials caused by depolarizing and hyperpolarizing currents were virtually mirror images. In these records, care was taken to eliminate distortion by electrode polarization[1]. Traces in Fig. 1 *G–L* were obtained just after the withdrawal of the micro-electrode to the extracellular position by applying the same currents used in *A–F*, and they showed that electrode polarization was not responsible for the overshoot at the current onset and the undershoot when current ceased. The net changes in the membrane potential are illustrated in Fig. 1 *N* by subtracting the extracellularly recorded electrode polarization from the corresponding intracellular potential in the same motoneurone as shown in Fig. 1 *E* and *F*. Measurements of the threshold changes give further evidence that these observed potential changes are taking place across the cell membrane. Short depolarizing pulses (duration, 0·2 msec.) were applied to the membrane through the micro-electrode. The threshold strength was measured as the current exciting the cell in about 50 per cent of the trials[1,2]. The decrease or increase of the threshold strength of pulses during the depolarizing or hyperpolarizing current steps is plotted in Fig. 1 *M*. As shown by dashed lines through the plotted points, the change of the threshold was closely related to the observed change in the membrane potential in *N*.

Changes in membrane potential resembling those of Fig. 1 have been observed constantly in all fifteen

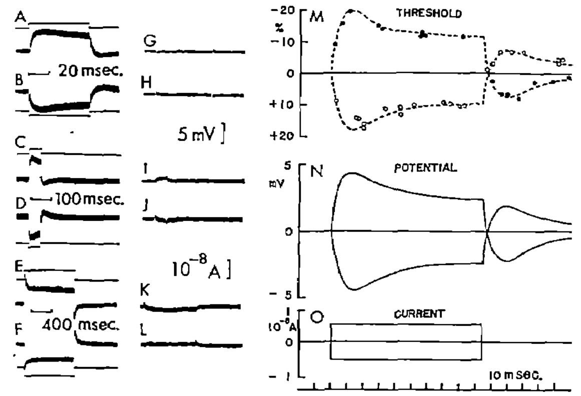

Fig. 1. *A* to *F*, depolarized (*A*, *C*, *E*) and hyperpolarized (*B*, *D*, *F*) potentials in the cat motoneurone membrane were induced by rectangular current pulses. The applied currents were registered in the companion traces of each record. *G* to *L*, electrode polarization recorded in the extracellular position by applying the same currents that were used for obtaining the intracellular records arranged to the left in *A–F*. *M*, Increase (+) and decrease (−) of the threshold strength of short pulses during conditioning by hyperpolarizing (○) and depolarizing (●) currents which are shown in O. *N*, change in the membrane potential by the conditioning currents. Note that records *A–D* were obtained in a different cell from that for *E*, *F*, *M* and *N*. The voltage and current calibrations apply to the appropriate records *A* to *L*

motoneurones examined so far. When current steps of from 2 × 10^{-9} amp. to 6 × 10^{-9} amp., in each case corresponding to about half the rheobase for each motoneurone, were applied, the polarized potential reached the summit at 16 msec. on the average (range, 10–22 msec.) after the onset and then declined by 30 per cent on the average (range, 17–46 per cent) of the peak value in the following interval of about 100 msec. This electrical behaviour of the motoneurone membrane may be explained by assuming that an inductive reactance is involved in the membrane, as has been proposed for squid giant axon[4,5], and for frog nerve[6]. Since the over- and under-shoots of polarized potentials are considerable, the analysis of the time-course of the rise or fall in potential caused by the current steps can no longer be based on the previously assumed resistance-capacitance model. The small undershoot following the monosynaptic excitatory post-synaptic potential, which summates to a large undershoot after a repetitive series of post-synaptic potentials[7], appears to be another example of the undershoot described here. During a depolarizing steady current, the change in membrane threshold is correlated accurately with the change in the membrane potential and is not strictly an example of accommodation of the membrane as has hitherto been assumed[1,2].

Effects of Corticotrophin, Hydrocortisone and Methopyrapone on the Circulating Eosinophiles in Man

2-METHYL-1,2-*bis*(3-pyridyl)-1-propanone (methopyrapone) has been shown to stimulate the secretion of corticotrophin (ACTH) in the pituitary by inhibition of production of cortisol. 11-Desoxycortisol (compound *S*) is a precursor of cortisol and 11β-hydroxylation of compound *S* converts it into cortisol. Methopyrapone (*SU*-4885) inhibits 11β-hydroxylation of 11-deoxycortisol[1]. The result is the rise of compound *S* and fall of cortisol in the adrenal cortex and the blood. Secretion of corticotrophin or its administration by the parenteral route stimulates the adrenal cortex. The resultant release of hydrocortisone and other glucocorticoids from the adrenal cortex causes a marked eosinopenia. A clinical trial was undertaken to evaluate and compare the effects of exogenous administration of ACTH and hydrocortisone and endogenous secretion of corticotrophin by methopyrapone. This work is a part of our neuroendocrinological investigation of the role of methopyrapone and phrenotropic drugs in man[2].

Twenty normal human subjects volunteered for clinical trial. One group of five received 25 units of ACTH parenterally, the second group of five, 80 mgm. hydrocortisone equally divided, orally and parenterally, and the third group of five, 1 gm. methopyrapone orally and 1 gm. dissolved in 250 ml. 0·9 per cent saline infused in 1 hr. Five subjects acted as controls. Using phloxine as a staining medium, circulating eosinophile counts of the venous blood were done just before and 3 hr. after administration of the drug.

Table 1 shows the analysis of variance of control versus drugs and among drugs, and is significant in the comparisons. Tables 2–5 indicate the percentage fall in the circulating eosinophiles 3 hr. after the administration of the drug. The mean percentage fall was 83·3 with ACTH, 80·7 with hydrocortisone, 24·4 with methopyrapone and 1·8 in controls. In one control there was a rise of 22 per cent in the circulating eosinophiles.

Previous work has shown that the parenteral administration of 25 units of ACTH in man resulted

in a mean percentage fall of 62·2 in circulating eosinophiles in 3 hr. Hydrocortisone in 80-mgm. dosage also caused a mean fall of 75·6 per cent[4]. The results of the present experiment indicate the similar significant eosinopenic response to the exogenous ACTH and hydrocortisone. An infusion of 1 gm. methopyrapone in 250 ml. 0·9 per cent saline in 2 hr. has been reported to raise 17-hydroxycorticoids in bloods significantly within 4 hr.[5]. The rise in 17-hydroxycorticoids is attributed to uninhibited pituitary secretion stimulating the production of Porter-Silber chromogens.

The eosinopenic response to ACTH and hydrocortisone is uniformly high and without significant difference (Tables 2 and 3). The eosinopenic response to methopyrapone versus control is significant, but low in comparison with that for groups treated with ACTH and hydrocortisone (Tables 4 and 5). Methopyrapone stimulates the secretion of corticotrophin in the pituitary to such an effective level as to cause a significant fall in the circulating eosinophiles.

We acknowledge the receipt of ACTH from Armour, hydrocortisone from Merck, Sharp and Dohme and methopyrapone from Ciba. We wish to thank Dr. E. I. Burdock for help with biometrical work.

Precorticotrophin in Blood

The existence of precorticotrophin, precursor of corticotrophin, has been demonstrated by Dasgupta and Young[1]. Extracts of ox anterior pituitary, otherwise inactive, acquire a corticotrophic activity detectable by Sayers' test (adrenal ascorbic acid depletion) when the medium is acidified (*p*H 3) or when urea (3–8 *M*) is added to it. These findings have been confirmed by Dixon *et al.*[2], who observed the presence of precorticotrophin in pig pituitary also (personal communication). Earlier, Moruzzi *et al.*[3] reported the presence of an 'inactive' form of corticotrophin (activable by treatment with oxycellulose) in the blood of patients suffering from various types of adrenal insufficiency, including Addison's disease; they called it 'activable' corticotrophin. The possibility that 'precorticotrophin' may be comparable with 'activable' corticotrophin and that the former may be in circulation even under normal physiological conditions was discussed by Dasgupta[4]. The present report is concerned with the actual demonstration of precorticotrophin in normal rabbit blood.

When fresh serum obtained from normal rabbit blood is diluted 15–20 fold by adding 0·9 per cent sodium chloride solution no activity is detected when tested by the method of Sayers as modified by Chowdhuri[5]. The modification consists of using morphinized (morphine sulphate 1·5 mgm. per 100 gm. body-weight by subcutaneous route 2–3 hr. prior to administration of test doses) rats as test animals instead of hypophysectomized ones. When, however, the serum is either acidified with 2 *N* hydrochloric acid to *p*H 3 or treated with urea (3 *M*) and then diluted, adrenal ascorbic acid depleting activity is found to be present in the final test solutions (Table 1).

In a second series of experiments, instead of fresh serum, freeze-dried serum was used as the test material. The solid residue left after freeze-drying serum is dissolved in distilled water such that 1 ml. of the solution corresponds to 2 mgm. of the solid. The clear solution is divided into three portions. The first portion is left untreated, the second portion is acidified to *p*H 3 and the third is treated with urea (3 *M*). Each of these three portions is next separately diluted 20-fold with distilled water and its adrenal ascorbic acid depleting activity determined. Whereas no corticotrophic response is produced by the untreated solution, those treated show definite corticotrophic activity (Table 1).

These results provide evidence suggesting the existence in normal blood of a precorticotrophic factor inactive *per se* but giving rise to corticotrophin under the influence of *p*H adjustment (*p*H 3) or urea.

The extent of dilution (15–20 fold) of the serum was determined by trial such that the concentration of endogenous corticotrophin present in the serum was reduced to a very low value and caused no depletion of adrenal ascorbic acid. However, the same serum, despite dilution, was found to maintain the concentration of endogenous precorticotrophin at a sufficiently high level as to give in consequence of *p*H adjustment or treatment with urea a positive response in the Sayers test. The serum, therefore, seemed to be behaving in this respect in a manner analogous to the

Table 1. Mean Response in Sayers' Test produced by Normal Rabbit Serum

	Fresh serum			Freeze-dried serum		
	Untreated (control)	Adjusted to *p*H 3	Treated with urea	Untreated (control)	Adjusted to *p*H 3	Treated with urea
Mean response (ascorbic acid change mgm./100 gm. adrenal) ± Standard error	−4·4 ± 3·34 (20)	−95·7 ± 13·00 (14)	−87·2 ± 8·82 (10)	−0·125 ± 4·86 (8)	−92·0 ± 23·96 (5)	−55·6 ± 16·18 (5)

Figures within parentheses indicate the total number of observations. Test solutions were injected intravenously at a dose of 0·25 ml./100 gm. body-weight.

extracts of ox anterior pituitary prepared by Dasgupta and Young[1], Dixon *et al.*[2] and Dasgupta[4].

Since the freeze-dried serum residue redissolved in distilled water behaved like fresh serum under the same experimental conditions (Table 1), it appears that the precorticotrophic factor of blood survives a single freezing treatment. Moreover, the serum sample was prepared 4–6 weeks before biological testing and this indicates that the circulating precorticotrophic factor is fairly stable in dry conditions.

I am grateful to Dr. B. Mukerji, director, and to Dr. A. B. Kar, assistant director, for their interest in this work.

PHARMACOLOGY

Augmentation of Toxicity of Monoamine Oxidase Inhibitor by Thyroid Feeding

THE administration of desiccated thyroid or thyroxine modifies the susceptibility of animals to the poisonous effects of a number of substances. Thyroid hormone is known to increase the toxicity of fluoride[1], endotoxin[2], alloxan[3], cocaine[4], morphine[5], anoxia[6,7], ozone[8], dinitrophenol[9] and adrenaline[10,11]; furthermore, it prolongs the action of certain barbiturates[12]. Conversely, a diminished sensitivity to the toxicity of a number of nitriles has been reported[13,14].

As a consequence of certain work on subacute thyroid and monoamine oxidase inhibitor interaction, apparent augmentations were observed in the mortality of hyperthyroid rats receiving high daily parenteral doses of a hydrazide (iproniazid) or a non-hydrazide (*N*-methyl-*N*-benzyl-2-propynylamine hydrochloride; '*MO*–911') enzyme inhibitor. The latter drug was first described by Taylor *et al.*[15,16]. To evaluate this possible hormonal sensitization, four groups of fasted male rats (Wistar strain) (172 gm. mean weight), eight animals to a group, were injected intraperitoneally with doses of '*MO*–911' differing by 0·03 log unit. Four other groups (127 gm. mean weight), previously made hyperthyroid by a 7-day desiccated thyroid (2 per cent) *ad lib.* diet, were injected in an identical manner. Nine hyperthyroid rats (130 gm. mean weight) were injected solely with normal physiological saline solution and served as controls. All animals were housed at a temperature of 25–27° C. and were provided prior to monoamine oxidase inhibitor medication with oral vitamin A and D (oleum percomorphum) supplementation at 3-day intervals. The acute toxicity results are given in Table 1.

Table 1. ACUTE TOXICITY OF 'MO–911'

Treatment	Dose (mgm./kgm.)	Response (12 hr.)	Dead (per cent)
'MO–911' intraperitoneal	187·5	4/8	50·0
	175·0	2/8	25·0
	163·0	3/8	37·5
	152·4	2/8	25·0
'MO–911' intraperitoneal + thyroid (2 per cent) diet	187·5	8/8	100·0*
	175·0	8/8	100·0*
	163·0	8/8	100·0*
	152·4	8/8	100·0
Thyroid diet controls + 0·14 ml. normal saline intraperitoneal	—	0/9	0

* All deaths within 2 hr. of dosing.

Because a perfect statistical analysis of the respective LD_{50}'s was not possible due to the limited number of animals employed and the one group aberrantly responding to '*MO*–911' at 175 mgm./kgm., only an approximation to this dose for the enzyme inhibitor in the euthyroid animals could be made; this value was found to be 183·5 ± 15·0 (*S.E.*) mgm./kgm. using a graphic method of analysis[17]. It should be noted that in the thyroid-'*MO*–911' treated group all deaths, except one at the 152·4 mgm./kgm. level, occurred within 2 hr. These results show rather conclusively that the acute intraperitoneal toxicity of '*MO*–911' in hyperthyroid rats is markedly increased and that the LD_{50} of the drug lies well below 152 mgm./kgm. in these circumstances.

The cause of this augmented lethality is not easily understood, but because of the early onset of malaise and death, a direct sensitivity to the toxic effects of the monoamine oxidase inhibitor molecule *per se* seems to be the most likely explanation. However, these effects may be possibly related to monoamine oxidase inhibition coupled with the similar enzymatic *in vivo* effects of the thyroid feeding[18,19] resulting in an acute liberation of unbound catecholamines, a diminished ability of the animal to cope with stress and a predisposition to fatal thyrotoxicosis. In any event, this potentiation of toxicity may well explain the reported psychotherapeutic incompatibility of simultaneous medication with an irreversible amine oxidase inhibitor and thyroid extract[20,21].

A more detailed account of these experiments will be published elsewhere.

The '*MO*–911' was generously provided by Dr. G. M. Everett, of Abbott Laboratories, Chicago.

High Concentration of (−)-Noradrenaline in *Portulaca oleracea* L.

Portulaca oleracea L. is one of the plants reputed to be of value in the treatment of cardio-vascular diseases in Jamaican folk-lore[1]. It was therefore examined for the possible occurrence of pharmacologically active substances.

A crude protein-free extract was prepared as follows: the fresh plant was macerated in cold 2 *N* hydrochloric acid with a Waring blender. Protein was precipitated by adding ethanol (to approximately 75 per cent) and the supernatant was evaporated at low temperature, under reduced pressure, and in the absence of oxygen to remove the ethanol. The concentrate was diluted with water to an appropriate volume. A strong pressor response was observed when this crude extract was injected intravenously into a dog anæsthetized with nembutal. Because of this response, the possibility of the presence of catechol amines was examined.

The crude extract was examined by paper chromatography using three solvent systems as indicated in Table 1, common catechol amines being used as markers. When the paper was developed with potassium ferricyanide reagent[2], four spots were observed. Three of these spots corresponded to markers of dopa, noradrenaline, and dopamine while the fourth spot is as yet to be identified. The areas of these spots on chromatograms demonstrated approximately equal quantities of noradrenaline and dopamine to be present while the amount of dopa was much smaller.

In order to separate these catechol amines the following procedure was used: the crude protein-free extract was adjusted to *p*H 4 with 10 per cent sodium hydroxide solution and passed through a column of 'Dowex 50–*x*4' (hydrogen form). The catechol amines in the column were eluted with 2 *N* hydrochloric acid. The fraction which contained mainly noradrenaline was subjected to chromatography on sheets of Whatman 3*MM* paper using *n*-butanol/acetic acid/water (4: 1: 5) as the solvent system. The appropriate strips from these sheets (located by trial cuttings developed with the ferricyanide reagent) were cut and eluted with 2 *N* hydrochloric acid. The eluates were pooled and were freeze-dried to a brown powder which gave a single spot on the paper in the same position as a marker of noradrenaline. Quantitative comparison of the extracted material with synthetic noradrenaline hydrochloride on paper revealed that equal amounts of each gave comparable spot areas.

Table 1. PAPER CHROMATOGRAPHY OF CATECHOL AMINES OF THE CRUDE EXTRACTS OF *Portulaca oleracea* L.

System	R_F value						
	Spot I	Dopa	Spot II	Noradrenaline	Spot III	Dopamine	Spot IV
n-Butanol/acetic acid/water (4 : 1 : 5)	0·21	0·21	0·34	0·34	0·41	0·42	0·61
Phenol–water (HCl vapour)	0·16	0·14	0·23	0·23	0·41	0·41	0·54
n-Butanol–0·5 *N* HCl	0·17	0·18	0·12	0·12	0·20	0·20	0·33

The biological activity of the extracted material was then examined. It was found to give a pressor response comparable with that of an equal amount of synthetic (−)-noradrenaline hydrochloride when administered intravenously into dogs anæsthetized with nembutal. This result not only supports the chromatographic evidence for the identity of noradrenaline but also suggests that the noradrenaline present is the biologically active (−)-isomer.

Dopa and dopamine are known to be common plant constituents, but noradrenaline in plants has only been reported previously in banana, plantain, and in potato[3–5]. However, the concentration of noradrenaline found in *Portulaca* is much greater than that in any of these plants. Both by paper chromatography and biological estimation it was found that one of the crude extracts contained noradrenaline approximately equivalent to 2·5 mgm./gm. of fresh plant. It is of interest to note that the concentration of noradrenaline in this plant might be greater than that extractable from suprarenal glands of mammals.

This work forms part of a pharmacological and chemical analysis of some West Indian medicinal plants and is supported by the Tropical Products Institute, Department of Scientific and Industrial Research.

HISTOCHEMISTRY

Sialic Acid as a Structural Component of Some Mammalian Tissue Cell Surfaces

WHEN human erythrocytes are treated with trypsin, a sialomucopeptide is liberated from their surfaces[1]. It is a common observation that a mucoid material is liberated from mammalian cells by trypsin treatment; the release of this material is associated with a considerable loss of cellular dry mass[2], and alteration of the stickiness of cells for various surfaces *in vitro*[3]. Attempts to investigate the chemical nature of the liberated mucoid[4] have been largely unsuccessful, partly owing to the lack of sensitivity of the tests, and partly because the mucoid cannot be obtained free of cells.

In view of the possibility that the structure of ovine salivary gland mucoprotein put forward by Gottschalk[5] is a general model for the molecular arrangement of mucoprotein at the cell surface, it is important to know whether sialic acid is present at the surfaces of mammalian tissue cells, and if so whether it occurs as a structural element as opposed to a cellular excretion.

A method has recently been developed for measuring the strength of attachment to glass of tissue cells in culture[6]. It consists of growing cells covered by a fluid medium, in circular culture vessels; a rotating disk is lowered into the fluid covering the cells and a shearing stress, transmitted through the fluid, tends to detach the cells from their glass substratum. With a knowledge of the angular velocity of the rotating disk, the viscosity of the culture medium, the distance separating the bottom of the rotating disk from the cells, and the distance of the cells from the centre of the disk, it is possible to apply accurately reproducible and approximately known detaching pressures to the cells. The cells are counted before and after the application of the shearing stresses, and the percentage of cells detached is determined.

It was found that when a cell is removed from a glass substratum under these conditions, separation is not cleanly at the cell surface/substratum interface, but occurs in the cell surfaces, parts of which are left on the glass[7]. Thus this type of peeling-test provides a measure of the cohesiveness or shear-strength of cell surfaces, rather than measurement of the strength of adhesion between cell and substratum. This differentiation between cohesion and adhesion is in accordance with work done in other fields[8,9].

Recently, an attempt has been made to identify structural components in the cell surface, by incubating cultures with enzymes and determining the resulting change in the shear-strength of the cell surfaces as reflected in the percentage of cells detached by various shear stresses.

For these experiments three 'permanent' strains of cells were used, two (16*R* and 16*C*) obtained from late rat fœtal skin and the other from bovine kidney cortex, and also freshly isolated fibroblasts from rat fœtal skin. It was found that in all these cultures crude receptor-destroying enzyme (Burroughs Wellcome) obtained from *Vibrio choleræ*[10,11] weakened the cohesive strengths of the cellular surfaces. These experiments were not entirely satisfactory as a means of identifying sialic acid, however, since this crude enzyme preparation may also contain a mucinase, a trypsin-like enzyme, and an *N*-acetylneuraminic acid aldolase, as well as 0·01 per cent 'Thiomersal' (sodium ethyl-mercuri-thiosalicylate) preservative.

A very small amount of pure recrystallized neuraminidase[12] was then obtained, which was just sufficient to do one series of confirmatory tests on the 16*R* strain of cells. The cells were grown on glass in synthetic medium 199 (Glaxo) plus 15 per cent bovine serum for 18 hr.; they were washed gently with Hanks's balanced saline solution at *p*H 6·9 and counted in delineated areas. Neuraminidase (10,000 units per ml.) in Hanks's fluid was then applied for 60 min. at 37° C., after which the cells were exposed to a shearing stress of approximately 32 dynes/cm.^{2} for 60 sec. and again counted. 16 observations, each on groups of 200–300 cells, were made on the experimental cultures, and eight on the controls which were incubated with Hanks's fluid only. In the neuraminidase-treated group 37·7 per cent ± 2·3 (*S.E.*) of cells were detached as opposed to 21·0 per cent ± 6·0 in the control group. A *t*-test made on the data gave the following results: $t = 3{\cdot}13$, d.f. $= 22$, $0{\cdot}01 > P > 0{\cdot}001$.

The crystalline neuraminidase used in the present experiments has been very carefully prepared and is very specific in its action[13], which is 'the hydrolytic cleavage of the glycosidic bond joining the keto group of *N*-acetyl-neuraminic acid to D-galactosamine'[14].

It is therefore concluded that sialic acid is an important structural component of the cell surface in one strain, and possibly also in the three other cell types treated with the crude enzyme preparation only.

My thanks are due to Dr. G. L. Ada of the Walter and Eliza Hall Institute, Melbourne, for providing me with the sample of crystalline neuraminidase. I am also indebted to my colleague, Dr. Mary R. Daniel, for providing me with the cells.

HÆMATOLOGY

Immunoelectrophoretic Examination of Agammaglobulinæmia

IT is now well established that congenital agammaglobulinæmia is associated with multiple serum protein deficiencies; the sera of these patients lack $7S$ γ-globulins, $19S$ γ-globulins or β_2M globulin, and β_2A globulin[1]. Good *et al.*[2,3] have recently reported that the sera of patients with agammaglobulinæmia contain three proteins not found in normal human sera and they have termed them β_2K, β_2E and γ_1A globulins; their work was performed with antiserum from a horse immunized against human serum by Dr. P. Grabar. A review of our own immunoelectrophoretic patterns as well as those of Grabar *et al.* has failed to reveal any protein constituent other than C-reactive proteins in the sera of agammaglobulinæmic patients which is not ordinarily detectable in normal sera. Consequently the work reported here was undertaken to re-investigate this matter.

The micromethod of Scheidegger was used for immunoelectrophoresis of sera from normal and agammaglobulinæmic individuals[4]. Electrophoresis was carried out for 3½ hr., at 10 V./cm. in an agar gel containing a borate buffer of 0·1 ionic strength at *p*H 8·6. Following electrophoresis, horse antiserum against whole human serum obtained from Dr. Grabar was placed in a long well cut into the agar to one side of the patient's serum but parallel to the axis of the electrophoresis, and horse antiserum against human γ-globulin prepared by us was placed in an identical well placed on the opposite side of the patient's serum (Fig. 1). Both electrophoresis and the diffusion of antisera into the agar occurred at room temperature. The immunoelectrophoretic patterns were then observed at regular intervals for 48 hr.

Fig. 1 shows that all the bands of precipitation which were obtained with agammaglobulinæmic sera were also obtained with normal sera. The band corresponding to β_2K was elicited with both antisera,

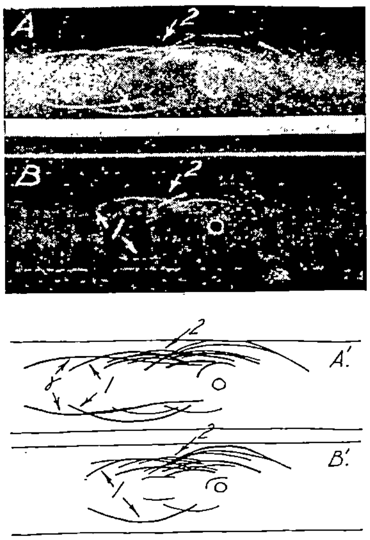

Fig. 1. Immunoelectrophoresis of sera from a normal person (*A*) and from a patient with congenital agammaglobulinæmia (*B*); the arrows marked '1' indicate the protein designated β_2K, those marked '2' indicate that designated β_2E or β_2X and those marked 'γ' indicate the γ-globulins. Figs. *A'* and *B'* are tracings of the precipitation bands seen in Figs. *A* and *B*. Antiserum in the well at upper edge of each figure was horse antiserum versus whole human serum and antiserum in lower well was horse anti-human γ-globulin. Time for diffusion of antiserum was 24 hr.

but the β_2E band was evident only with the antiserum against whole human serum. The identity of the β_2K line formed by each of the two antisera was established by the merging of the ends of these curvilinear precipitation bands. The distance of the vertex of the β_2K band from the electrophoretic axis was the same with both normal and agammaglobulinæmic sera, which suggested that the concentration of the protein component in both sera was similar.

One ml. aliquots of each antiserum were adsorbed with either 0·15 ml. of normal human serum or with 0·15 ml. of a 1:10 dilution of normal human serum. In both instances the adsorbed antisera no longer formed β_2K or β_2E bands with either normal or agammaglobulinæmic sera. These results indicated that normal serum contained β_2K and β_2E globulins in quantities sufficient to remove their respective antibodies from the horse antisera.

The protein which had been designated γ_1A by Good *et al.* had previously been noted by Heremans, who labelled this band of precipitation γ_x-globulin[5]. Heremans noted its occurrence in a variety of pathological states and has shown that it is probably C-reactive protein. The French workers had also noted the band of precipitation designated as β_2E by Good and had variously labelled this band β_2X or β_2B; Heremans stated that it was present in all normal sera which are fresh. A protein corresponding to that called β_2K globulin by Good *et al.* was demonstrated by Scheidegger in the sera of normal persons as well as in the serum of a patient with a dysgammaglobulinæmia characterized by the absence of β_2A and β_2M globulins from the serum. The same horse antiserum against human γ-globulin that we used in the present work had been used in Scheidegger's study[6].

These findings indicate that there is no definite evidence as yet for the presence of abnormal globulins in the sera of patients with agammaglobulinæmia or for the presence in such sera of globulins not demonstrable in normal persons.

Nature of the Coating Globulin causing a Positive Antiglobulin Consumption Test

The direct antiglobulin consumption test has been developed in several laboratories and has been applied chiefly to the detection of antibodies that sensitize thrombocytes and leucocytes[1–6].

The test is based on the following principle: Pure, thoroughly washed suspensions of leucocytes and thrombocytes obtained from the blood to be examined are added to an antiglobulin serum of known titre and are left at room temperature for 30 min. The supernatant fluid is then tested for its antiglobulin titre against red blood cells coated with incomplete anti-*D* antibodies. If the cells have been sensitized *in vivo*, a significant drop in the antiglobulin titre occurs, while normal cells do not cause any reduction in titre.

The nature of the coating globulin causing a positive antiglobulin consumption test of thrombocytes and leucocytes has not been defined (ref. 6 and Dausset, J., personal communication), although some attempts have been made in this connexion with the globulin coating of red blood cells causing a positive Coombs test[7,8]. In the present work some experiments are reported which suggest that the coating substance causing a direct antiglobulin consumption test of thrombocytes and leucocytes may be a normal plasma protein attaching itself to the cells under certain conditions. The coating substance must not be an antibody produced as a result of an antigenic stimulus.

Preparation of the anti-human globulin serum, the coating of erythrocytes with incomplete anti-*D* antibodies, the anticoagulant and the washing fluid, as well as the separation of the cells from the blood, were performed as described in ref. 6.

The direct antiglobulin consumption test[6] was performed with some minor changes. To two tubes, each containing 0·5 ml. of anti-human globulin serum, 0·1 ml. of repeatedly washed thrombocytes and 0·1 ml. of repeatedly washed leucocytes, respectively, were added and re-suspended in the serum by gentle shaking. The respective blood cell concentration of the samples in the antiglobulin serum was as follows: thrombocytes 50,000–100,000/mm.^{3}, and leucocytes 40,000/mm.^{3}. The tubes were kept at room temperature (20°–25° C.) for 30 min. They were then centrifuged for 10 min. at 3,000 r.p.m. and the supernatants titrated against $O\ Rh^+$ erythrocytes, 'sensit-

ized with incomplete anti-*Rh* antibodies. The titre was expressed in terms of the last tube showing macroscopical agglutination.

Whole blood taken into siliconized syringes containing disodium sequestrene as anticoagulant in a proportion of 1 : 9 was divided into aliquots of equal amounts. From the first the thrombocytes and leucocytes were separated immediately and washed three times. The second sample was kept for various times at either 6° C., 25° C. or 37° C. before the cells were separated and washed. The direct antiglobulin consumption test was then performed at the same time on the cells which had been separated at once from the blood and on those that were incubated before separation. Results of such experiments are summarized in Table 1. It will be seen that a direct relationship could be demonstrated between the temperature, time of incubation and the degree of the antiglobulin consumption. If the cells were immediately separated from the blood after its withdrawal, the antiglobulin test was always negative, while the test became positive after keeping the blood for 4–6 hr. at 37° C. or 8–10 hr. at room temperature and more than 10 hr. in the refrigerator.

Table 1 gives typical results of one such experiment. Twenty blood samples from normal healthy donors were examined and all of them showed similar results, although the degree of the globulin coating *in vitro* of the thrombocytes and leucocytes varied significantly from sample to sample.

The results reported indicate that leucocytes and thrombocytes may absorb *in vitro* plasma proteins, which adhere to the cells very strongly, so that even repeated washings do not separate them. The absorbed protein causes a positive direct antiglobulin consumption test, indistinguishable from the test obtained when cells are sensitized *in vivo* due, presumably, to an immune mechanism.

It is tempting to believe that the globulin coating of the leucocytes and thrombocytes *in vitro* was achieved as a result of some damage to the cell in its abnormal surroundings. The fact that at 37° C. the sensitization by autoplasma proteins was quicker than at 6° C. points to the same conclusion.

If the results obtained *in vitro* may be compared with *in vivo* processes, we may assume that bacterial toxins, breakdown products of drugs, high temperature or any other damage to the cells in the body may change them in such a way as to prepare them to absorb irreversibly normal autoplasma proteins.

The finding, therefore, of a positive antiglobulin consumption test indicates only that the cells are coated with globulin, which may either be an antibody or a normal protein absorbed on a damaged cell.

The clinical significance of the coating as a result of an antibody or the coating as a result of the interaction of the cells with normal autoplasma proteins is not yet clear, although it may be very similar.

This work has been aided by a grant from the Leukemia Research Foundation, Chicago.

PATHOLOGY

Development in Mice of Prolonged Non-specific Resistance to Sarcoma Implant and Staphylococcus Infection following Repository Injection of Lipopolysaccharide

Previous reports have indicated that the injection of lipopolysaccharides (endotoxin) of Gram-negative organisms exert a profound effect on many vital functions of an animal[1,2]. Particularly striking has been the development of a non-specific resistance against infection[3,5]. More recently, resistance against implantation of malignant tumours has also been demonstrated following treatment with agents stimulating the reticulo-endothelial system, including lipopolysaccharides[6,7]. However, use of lipopolysaccharides clinically has, so far, been frustrated in view of the hazards of fatal shock and/or infection, since the action of the endotoxin is biphasic[4]. For several hours following the injection of the lipopolysaccharide, resistance to infection is markedly decreased, but if the animal survives the shock and other physiological derangements, the resistance to infection is increased manyfold. The administration of lipopolysaccharide is particularly hazardous in experimental animals with latent or low-grade infections, converting these into acute processes often terminating in death[8].

To overcome the hazards of shock and the decreased resistance developed during the negative phase, which is an expression of excess dosage or limited tolerance, it was thought advisable to administer the lipopolysaccharide in repository form. Prepared as a water-in-oil emulsion in which mineral oil is the outer phase, the endotoxin is released slowly owing to the poor metabolism of the oil.

It is the purpose of this communication to summarize the results of experiments with emulsified lipopolysaccharide, in which single large doses (2–4 × *LD* 50) were injected into mice, with the survivors being challenged afterwards in small groups at varying intervals, either by a sarcoma 180 implant, or by an intravenous injection of a virulent staphylococcus. Tables 1 and 2 show the number of animals originally injected with lipopolysaccharide and the number that survived; the number of days post-injection when challenged; the number of survivors for each group; controls (mice receiving the same challenge but pre-treated only with saline); and the increases in the size of the liver and spleen of the endotoxin-treated animals as compared with

* *E. coli* lipopolysaccharide *O*26 (*B*6 Difco). 110 mice injected with 2 mgm./0·1 ml. of emulsion—67 survived.

† One of each of the treated and control groups was killed before challenge.

the controls. One of each group was killed on the varying days of challenge for these measurements, without challenge by either implant or infection.

Analysis of Tables 1 and 2 shows the following: The intramuscular injection of emulsified endotoxin in 1-mgm. doses resulted in the death of only 5 out of 135 animals. On the other hand, 2-mgm. doses resulted in the loss of 43 of 110 mice injected initially. Deaths here, however, cannot be attributed solely to the dosage since on other occasions the same dosage of better emulsions (droplet size 1–2μ) did not kill. The emulsion employed in this instance had shown droplets of about 4μ, which may have contributed to the higher number of deaths.

Resistance against implantation of the sarcoma becomes evident in the pre-treated animal when challenged on the second day post-injection, reaching a peak about the 30th day, and maintaining this resistance as long as 92 days (Table 1). Resistance against the *Staphylococcus* challenge was more striking since 114 of 115 control animals died, whereas the survival-rate in the sarcoma implantation was 20 per cent in 3 control groups. The highest peak of resistance (80 per cent) was noted against sarcoma implant, whereas the resistance against the *Staphylococcus* reached a peak of 60 per cent. However, when consideration is given to the dose of lipopolysaccharide administered and the survival-rate of the control animals, the resistance against the infection becomes most significant.

The enlargement of both liver and spleen following a single repository injection is noteworthy, since the development of non-specific resistance is asserted to be due to the stimulation of the reticulo-endothelial system[3]. These experiments show, however, that resistance is displayed long before there is maximum enlargement of these organs.

The Effect of Various Diets upon Sexual Maturity of Mice

It was demonstrated previously that eggs are carcinogenic in mice[1]. On the other hand, it was found that chicks maintained on an egg diet become sexually mature and the hens begin to lay eggs 6–8 weeks earlier than the controls (chicks of the same breed maintained on a Purina mash diet[2]). The question was consequently raised whether these two phenomena, carcinogenicity and sexual precocity, are caused by a single, or by two different components of the egg. It was important, therefore, to determine the effect of egg-yolk and egg-white upon sexual maturity of mice and compare it with the carcinogenic effect.

Mice of the *T.M.* strain were used in the present experiments. This is an inbred strain of mice developed in the School of Tropical Medicine, and in the 13 years of its existence no malignancies were observed. On a diet supplemented with eggs, however, the mice of this strain developed as high an incidence of cancer as the *A* strain[2]. The mice were divided into 4 groups and at the age of 4 weeks they were placed on the following diets. Group 1, the control, was maintained on the Rockland rat diet, no supplement. For the other 3 groups the Rockland rat diet was supplemented with raw egg-yolk (group 2), hard-boiled egg-white (group 3), or a mixture of lard, cholesterol and sugar (group 4). One egg-yolk, one egg-white or half a gm. of lard mixed with 50–100 mgm. of cholesterol and with half a gm. of sugar were given daily per cage containing 8 mice. The mice of the 4 groups were bred and their offsprings, which were maintained on the same diets, were used in the present experiments.

The age of the mice at the time they gave birth to the first litter varied considerably. As shown in Table 1, the mice of the second group, on the Rockland rat diet supplemented with raw egg-yolk, were the most precocious. They gave birth to the first litter at the average age of 66 days, or 8 days earlier than the controls. On the contrary, the mice on the diet supplemented with egg-white were delayed in their sexual development; they first reproduced at the average age of 94 days, or 21 days later than the controls. These differences between the two experimental groups and the controls appear to be highly significant. The mice of the fourth group, on the diet supplemented with lard, cholesterol and sugar, first reproduced at the average age of 75·4 days, or one

day later than the controls. This difference, however, does not seem to be statistically significant.

In summary, the yolk of eggs accelerates sexual development, while the white slows it down. Since preliminary results of other experiments indicate that not only the egg-yolk but also the egg-white is carcinogenic, the conclusion can be drawn that the carcinogenic and sex-stimulating substances in eggs are not the same. There is, however, the possibility that a single substance, present in both the egg-white and egg-yolk, is carcinogenic and stimulates sex development, but a second factor present in the egg-white inhibits sexual maturity thus masking the latter effect. Recently, work has been started with alcohol and ether extracts of whole eggs and of yolk. Some of the mice on the alcohol extract have already died of cancer. The same extract, however, does not seem to cause precocious sexual development, which indicates that our first assumption is correct; namely, that there are two different substances in eggs, one carcinogenic and the other one stimulating sex development.

Effect of Alpha-Amylase on the Ehrlich Mouse Ascites Tumour

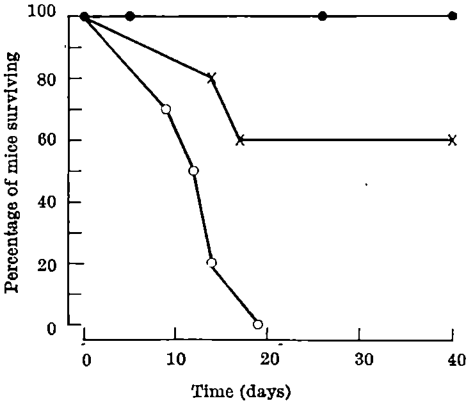
EVEN after incubation in saline at 37° for as long as 24 hr., about $8{\cdot}5 \times 10^{6}$ Ehrlich ascites tumour cells will produce tumour and cause death in 20–26 days when re-injected into new hosts. As part of an attempt to pin-point *in vitro* specific types of damage and then to test the virulence of these damaged cells by subsequent inoculation into mice, Ehrlich ascites tumour cells were exposed to the action of the enzyme α-amylase.

A number of white Swiss mice were inoculated intraperitoneally with 0·3 c.c. of fresh ascitic fluid. After seven days, the ascitic fluid was withdrawn, centrifuged for 10 min. at 4,000 rev./min. and then washed three times with triple volumes of 0·85 per cent saline. 1 c.c. of these preparations of packed tumour cells contained about 34×10^{7} cells (counted in a routine hæmocytometer and diluted in 0·1 per cent citric acid). The packed cells were suspended in twice their volume of saline and incubated at 37° in a water-bath equipped with a shaker following the addition of 25 mgm. of α-amylase (three times recrystallized, Worthington) in 0·5 c.c. water for each 34×10^{7} cells. The control cell flasks received 0·5 c.c. distilled water; 500 units of penicillin per c.c. of incubation mixture were always added. After 3 and 7 hr. respectively, the cell suspensions were diluted with saline, so that 1 c.c. contained $8{\cdot}5 \times 10^{6}$ cells. This amount was injected intraperitoneally into 15 white Swiss mice (weight 20–22 gm.) and their survival-times were followed.

A representative experiment is shown in Fig. 1. Six such experiments were carried out. Mice injected with the 0-, 3- and 7-hr. control mixture showed approximately the same survival-rates, apparently because of the large inoculum of tumour cells (at 0 hr. about 1/10 of this amount would have sufficed for production of ascitic tumour). All mice died of ascites tumour within 20 days after inoculation and 50 per cent mortality occurred on about the twelfth day. Mice injected with cell preparations incubated with α-amylase for 3 hr. showed a 40 per cent tumour mortality within 40 days. Increasing the incubation time with enzyme to 7 hr. resulted in a further loss of virulence, since none of the mice inoculated with these preparations developed an ascitic tumour within 40 days. β-amylase was found to have no effect on the virulence of these tumour cells.

Cell counts carried out at the beginning and end of the incubation showed no appreciable change in number of cells.

DNA and RNA were determined at 0 hr. and after 7 hr. incubation by Schmidt and Thannhauser's method[1]. The DNA phosphorus ranged from $1{\cdot}6$ to $2{\cdot}2 \times 10^{-9}$ mgm./cell and the RNA phosphorus from $3{\cdot}5$ to $4{\cdot}9 \times 10^{-9}$ mgm./cell in different preparations. No appreciable decrease in the tumour cell DNA and RNA content was noted in any experiment.



Percentage survival of mice inoculated with the following cell mixtures. ○—○, Untreated cells incubated for 7 hr.; ×—×, cells incubated with α-amylase for 3 hr.; ●—●, cells incubated with α-amylase for 7 hr.

Cytological preparation from representative incubation mixtures were stained by the Papanicolaou technique and examined without knowledge as to the treatment previously given. Depending on the appearance of their nuclei, cells were considered to be either viable or non-viable. There was no appreciable difference in the proportion of non-viable cells between preparations made from the 0-hr. control mixture and those made after 3 hr. incubation, either with or without α-amylase. There was, however, a marked increase in the ratio of non-viable to viable cells both in the treated and untreated mixtures after 7 hr. incubation. The difference between the two groups at 7 hr. was slight ; about 30 per cent of the control preparations appeared to have remained viable compared with about 20 per cent of the cell suspensions treated with amylase.

Because of the frequent assumption that viable cells are resistant to eosin, all these cell suspensions were examined by Schrek's method[2]. The 0-hr. preparations contained 93–95 per cent, the 7-hr. control preparation about 80–90 per cent and the 7-hr. preparations incubated in the presence of α-amylase about 80–95 per cent resistant to eosin cells. No appreciable amount of material giving a positive reaction with periodic acid–Schiff reagent was found in cell smears from any of the preparations.

Regardless of the unaltered DNA and RNA contents or the lack of apparent cytological distinctions between treated and untreated cells, the tumour cells were impaired in their growth ability after incubation with enzyme for 3 or 7 hr., even after they were returned to an optimal nutritional milieu.

These experiments suggest that a polysaccharide containing 1,4 glycosidic linkages may be important for the virulence of Ehrlich ascites tumour cells.

Evidence that the L-Asparaginase Activity of Guinea Pig Serum is responsible for its Antilymphoma Effects

THE inhibitory action of guinea pig serum on the cells of three transplantable mouse and rat lymphomas *in vivo* was described some years ago in papers from this Laboratory[1,2]. In a continuation of this work, evidence has now been found that the L-asparaginase activity of guinea pig serum is responsible for the antilymphoma effect. The evidence has been obtained in two ways: first, by a study of the induction of resistance to guinea pig serum by 6*C3HED* cells grown in tissue culture; and secondly, by a direct comparison of L-asparaginase activity in various preparations of guinea pig serum with their tumour inhibitory properties.

It was found that 6*C3HED* cells obtained from ascites tumours, and shown to be sensitive to inhibition by guinea pig serum, could be cultivated relatively simply in Eagle's medium[3], which contains L-glutamine, but no L-asparagine. For an initial period of 2–4 weeks growth of the cultured cells was poor, as indicated by a low rate of acid production and diminished cell counts, but with adaptation to the medium the cultures became considerably more vigorous. When, however, cells from the 9 cultures examined were removed after 2–4 weeks incubation and implanted into *ZBC* mice the tumours produced all showed complete resistance to guinea pig serum. Furthermore, the tumour cells having once acquired resistance maintained this character permanently both in prolonged culture and in serial transplantation through *ZBC* hosts. In these features, and particularly in the complete degree of resistance to guinea pig serum, the cultured cells strongly resembled resistant sublines of 6*C3HED* cells obtained by Kidd and Holmquist from tumours treated *in vivo* with small quantities of guinea pig serum[4].

However, the presence of L-asparagine in the medium profoundly modified the characteristics of the culture. In four separate experiments cultures were prepared in parallel using Eagle's medium and a modification containing 200 mgm./l. of both L-glutamine and L-asparagine. The cultures grown in Eagle's medium behaved in the manner already described, initially they grew poorly and when tumour cells were tested after 3 weeks in culture they proved to be fully resistant to guinea pig serum. But in the modified medium growth was more vigorous from the beginning. Cells from the four cultures have been implanted into mice after periods of 12, 11, 9 and 9 weeks incubation respectively. They remain fully sensitive to supression by guinea pig serum.

Modifications of Eagle's medium were also prepared to contain L-aspartic acid, L-alanine, L-arginine, glycine, L-histidine, L-leucine, L-lysine, L-methionine, L-phenylalanine, proline, and L-tyrosine at concentrations of 200 mgm./l. But in these, cultures showed the same growth lag as observed in the original medium and the development of guinea pig serum resistance was completely uninfluenced.

These experiments therefore show the intimate relationship between the metabolic changes induced in 6*C3HED* cells by the absence of an external source of L-asparagine, and the development of resistance to guinea pig serum.

Now guinea pig serum is a particularly rich source of L-asparaginase activity, as was shown by Clementi[5], but activity was not detected in the sera of numerous other species examined. Similarly, Kidd[1] found that antilymphoma activity was confined to guinea pig serum. A comparison of these two activities in preparations derived from guinea pig serum showed a striking correspondence.

Electrophoresis of guinea pig serum by a modification of the starch-block technique of Kunkel and Slater[6] showed that L-asparaginase activity was confined to the α_2 globulin fraction. When eluates from the starch block were injected into groups of 3 *ZBC* mice immediately following the subcutaneous implantation of 5 × 10^4 6*C3HED* cells of the original guinea pig serum sensitive line into each groin, a marked delay in the appearance of tumours occurred in animals receiving fractions which possessed L-asparaginase activity. No other fraction produced any tumour inhibition. Thus, from the fractionation shown in Fig. 1, eluates in tubes numbered 27–30 caused a delay in the first tumour appearance of 3, 5, 7, and 4 days respectively, compared with untreated controls and animals receiving other eluates, in which tumours first appeared in all groups by the

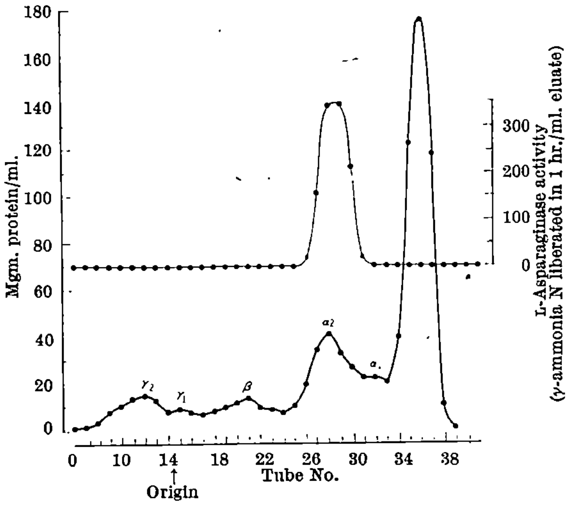

Fig. 1. Electrophoretic pattern of guinea pig serum (in 0·1 *M* veronal buffer, *p*H 8·5) with the localization of L-asparaginase activity

11th day following implantation. Fractions possessing L-asparaginase activity produced complete suppression of many tumours and others appeared at irregular intervals after considerable delay.

Further experiments were performed to examine the stability of L-asparaginase activity in samples of guinea pig serum to changes in temperature and *p*H. Assays of residual enzyme activity provided an accurate correlation with the effectiveness of these samples in producing tumour inhibition.

Ainis *et al.*[7], using the Murphy-Sturm lymphosarcoma, showed that serum from new-born guinea pigs possesses only very weak antilymphoma activity. This finding was confirmed using lymphoma 6*C3HED*. Assays of neonatal serum showed that L-asparaginase activity was only present at 3–15 per cent of adult values.

These experiments provide strong evidence that the inhibitory action of guinea pig serum on 6*C3HED* cells is due to its L-asparaginase activity. It is probable that the antilymphoma action on other sensitive cell strains is by a similar mechanism, and indicates that a distinct form of L-asparagine metabolism is possessed by this group of tumours.

These findings will be published in detail elsewhere. Further experiments are in progress to prepare more highly purified enzyme preparations and to examine the function of L-asparagine in tumour cell metabolism.

I am grateful to Dr. John G. Kidd for his advice and encouragement and to Mrs. P. Moy for much valuable technical assistance.

BIOLOGY

Excretion of Inulin by Malpighian Tubules

In an earlier investigation[1] it has been shown by the use of isotopically labelled compounds that the wall of the Malpighian tubule of the stick insect is permeable to urea and to certain sugars and amino-acids. At that time labelled inulin was not available.

Five Malpighian tubules of the stick insect *Dixippus morosus* were isolated in drops of medium containing one part of stick insect Ringer, one part of stick insect serum, a small quantity of the antibiotic oxytetracycline and inulin labelled with carbon-14 at a concentration of about 0·2 per cent. Urine was collected as described elsewhere[1]. The count-rates of equal volumes of urine and medium were compared (Table 1).

Table 1

Tubule	Urine (*U*) (c.p.m.)	Medium (*P*) (c.p.m.)	*U*/*P*
1	406	8,679	0·047
2	331	8,828	0·038
3	363	9,165	0·040
4	431	9,984	0·043
5	582	9,752	0·060
			Mean = 0·046

In subsequent experiments urine and medium were examined by paper chromatography for evidence of metabolization of inulin; no evidence was found.

The *U*/*P* ratio for inulin may be compared with the *U*/*P* ratios for other carbohydrates: glucose, 0·75; fructose, 0·58; sucrose, 0·58 (ref. 1). On the theory that soluble constituents of the medium enter the urine by diffusion through the wall of the Malpighian tubule[1], this much lower *U*/*P* ratio for inulin is understandable in view of its much greater molecular weight.

Composition of the Skin Follicle Population in Seven Rajasthan Sheep Breeds

Early workers found that the wool follicles of domestic sheep are mainly arranged in groups of three primaries with their associated secondaries[1]. The existence of a number of groups with only two or one primary (*P*) follicles was also recognized. The proportion of these 'incomplete' trio groups was considered to be so small as to make a negligible difference in the primary lateral/primary central (*PL*/*PC*) ratio. Ross[2] found a *PL*/*PC* ratio of 1·9, hence most workers have assumed the *PL*/*PC* ratio to be equal to 2.

Counts of trio, couplet, and solitary groups, and the number of associated secondary (*S*) follicles were made at superficial levels on whole sections of biopsy skin samples (taken with a trephine, 1 cm. in diameter) of about two-year-old ewes, of seven Rajasthan breeds. The results are given in Table 1.

Table 1. PERCENTAGES OF DIFFERENT FOLLICLE GROUPS, S/P AND PL/PC FOLLICLE RATIOS, AT MID-SIDE OF RAJASTHAN SHEEP BREEDS

Breed	No. of sheep	Percentage of total number of groups				Mean S/P ratio					PL/PC
		More than 3	Trio	Couplet	Solitary	More than 3	Trio	Couplet	Solitary	All follicles	
Chokla	7	1·8	64·0	12·6	21·6	2·02	2·54	2·65	2·99	2·58	1·41
Magra	7	0·2	60·2	15·5	24·1	2·75	2·26	1·98	2·49	2·28	1·36
Nali	7	2·7	62·8	13·9	20·6	1·22	2·58	2·57	3·00	2·55	1·45
Jaisalmere	8	0·2	64·3	17·7	17·8	3·87	2·46	2·40	3·36	2·53	1·46
Marware	6	0·4	63·1	12·9	23·6	2·25	2·12	2·14	2·66	2·19	1·39
Malpura	7	0·3	46·3	19·6	33·8	1·75	1·78	1·57	1·78	1·74	1·12
Sonadi	8	0·2	37·3	23·6	38·9	1·00	1·14	1·01	1·19	1·13	0·98

The ratio of PL to PC follicles varies from 0·98 to 1·41 in these Indian breeds and is consistently lower than the figure 1·9 observed by Ross[2] in New Zealand Romney N-type sheep. Further, the proportions of trio groups, which varies from 37 to 64 per cent, is much lower than the figures of more than 90 per cent for Romney N-type sheep (Ross[2], quoted by Fraser and Short[3]).

In the hairy group (Malpura and Sonadi) the PL/PC ratio, the mean S/P ratios and percentage of trio groups is lower and of couplet and solitary groups is higher than in the carpet wool group (Chokla, Magra, Nali, Jaisalmere and Marware).

The trio percentage is higher in the carpet wool group and lower in the hairy wool group than the total of couplet and solitary groups. In these hairy breeds, the trio arrangement is apparently not a predominant feature of the grouping of the P follicles.

As adult maturity is approaching, it becomes progressively more difficult to establish the essential arrangement of the primary follicles in their original trio, couplet or solitary configuration. Hence these results need to be corroborated by qualitative and quantitative histological examination of appropriate pre-natal material, from the different breeds, covering the transition from the pre-trio to the post-trio stage in development of follicle population.

In general, the mean S/P ratio of the solitary groups is greater than that of both couplet and trio groups. Differences in S/P ratio between trio and couplet groups are usually small compared with the differences between solitary and trio or couplet groups.

The mean follicle densities of Sonadi (lowest among these breeds) are compared with those of Chokla (highest) in Table 2.

The PC density can be taken as indicating the density of follicle groups, and hence it is seen that the increase in total follicle density from Sonadi to Chokla is associated with substantial increases in both PL follicles (57 per cent) and S follicles (228 per cent) per group, but a much smaller (14 per cent) increase in the density of the groups themselves. The total population of both P and S follicles has also increased from Sonadi to Chokla, with only a very small increase (7 per cent) in the total number of follicle groups.

Stephenson[4] speculated that "central primary anlagen, once present, may inhibit the initiation of new central primaries within a certain radius". The initiation of new PC follicles may possibly depend on skin expansion taking place simultaneously at the required rate. Since PC follicles directly influence the initiation of PL follicles, for a given rate of skin expansion, the rate of formation of P follicles may vary from different positions, and such variation may also occur between different fœtuses. It may be that variations in formation of P follicle are greater for lateral than for central primaries.

Table 2

	PC	PL	S	$PC + PL + S$
Chokla	1·6	2·2	9·5	13·3
Sonadi	1·4	1·4	2·9	5·7
Sonadi adjusted to body-weight of Chokla	1·5	1·5	3·2	6·2

Two probably independent mechanisms seem to influence the number of S follicles per P: one which provides for an increase of S follicles in those breeds with higher PL densities and another which allows the initiation and development of more S follicles around couplet and solitary primaries.

Sex Composition of Lamprey Populations

SINCE 1947 records have been kept of the size and sex composition of annual spawning populations of *Lampetra planeri* in the River Yeo in Somerset. In a previous communication[1] it was reported that up to 1954 there had been marked variations in the sex ratio from year to year and that in general these changes were associated with fluctuations in the relative abundance of this small isolated population. Observations made in subsequent years have confirmed the existence of a positive correlation between abundance and the ratio of males to females; that is, the bigger the population the larger has been the proportion of males. This trend is emphasized in Fig. 1, where the total annual catches have been plotted against the number of males and females separately and the corresponding regression lines fitted to the observations. The lowest observations, which lie close to the intersection of the two regression lines, give sex ratios of 1·2 ♂/♀ for the smallest populations of 50–60, while the highest observed sex ratio of 3·4 corresponds to a relative population of about 200.

In the course of the work on the landlocked sea lamprey (*Petromyzon marinus*) in the Lake Huron–Michigan watersheds, undertaken by the U.S. Depart-

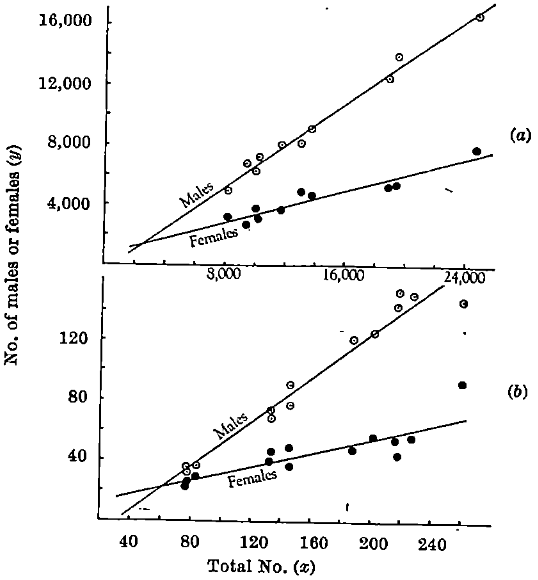

Fig. 1. Changes in the sex ratio of lamprey populations with relative abundance. *a*, *P. marinus* (Oqueoc River, 1944–57): males, $y♂ = -468+0{\cdot}71x$; females, $y♀ = 632+0{\cdot}27x$. *b*, *L. planeri* (R. Yeo, 1947–60): males, $y♂ = -9{\cdot}0+0{\cdot}74x$; females, $y♀ = 10{\cdot}5+0{\cdot}25x$

ment of the Interior, Fish and Wildlife Service, a somewhat similar situation has come to light in the upstream-migrants of this parasitic species. The data on relative abundance and sex composition for the Oqueoc River, supplied by Dr. V. C. Applegate, have been plotted in the same way as the observations on *L. planeri* (Fig. 1) and the corresponding regression coefficients calculated. The similarity in the curves is indeed remarkable; for the male *planeri* the slope of the regression line as given by the regression coefficient *b* is 0·74 compared with 0·71 for *P. marinus*, while the corresponding values for the females are 0·25 and 0·27 respectively. The correspondence is the more striking when it is borne in mind that, whereas the observations on *P. marinus* are based on very large numbers (8,000–24,000), the information on the brook lamprey populations has been limited to annual catches of 50–200.

In view of this correspondence, it is tempting to search for a common explanation for these changes in the sex composition of the spawning populations. However, it is important to recognize that the pattern of changes in relative abundance have been somewhat different in the two species. In the brook lampreys of the Yeo, there have been no continuous upward or downward trends in population size, but rather a series of annual fluctuations with a distinct tendency for large and small populations to follow one another. In the Great Lakes, on the other hand, there appears to have been a continuous increase in the lamprey population during 1944–49 and during this period the relative abundance increased from an estimated 3,300 in 1944, to 24,600 in 1949. In this phase, the sex ratio also increased from 1·65 ♂/♀ in 1947 to 2·13 in 1949. The highest sex ratios were recorded from 1950–52 (2·56—2·58 ♂/♀) but in subsequent years the excess of males tended to decrease and in 1957 the sex ratio was 1·56, that is, slightly lower than in 1947, when records were first made. Although there have been fluctuations in relative abundance, the general trend of the population during the period 1950–57 has been downwards.

Such a close parallel in the sex composition of spawning populations is the more surprising in view of the great divergence in the life-cycle of the two species. Whereas in *L. planeri* spawning takes place within about six months of metamorphosis, in *P. marinus* a period of parasitic life in the Great Lakes, of about two years duration[2], is interposed between metamorphosis and spawning. The existence of a similar relationship between sex ratio and population size, in spite of geographical differences and diversity of life-cycle, suggests that whatever factors may be responsible, their operation should be sought in those phases of the life-cycle which are common to both species. Moreover, since any attempt to account for this relationship must start from the assumption that the sexes are present in approximately equal proportions during the larval stages[3], this would appear to limit the causal period to the critical stage of metamorphosis or to the period of sexual maturity.

The observed variations in the sex ratio could conceivably be explained by assuming that the mortality-rate is dependent on density and higher in the female lamprey than in the male, but while this would be plausible in the large parasitic populations of *P. marinus*, it is unlikely that it could apply to the small Yeo population of brook lampreys which do not feed in the adult state. Moreover, in view of the differences in environment and size of the two forms, similar patterns of mortality due to predation could almost certainly be excluded.

In a detailed study of the brook lamprey population of the River Yeo, which will be published elsewhere, it has been suggested that the spawning class consists of more than one age group and that fluctuations in abundance may be due to differences in the annual recruitment of these age groups. If this hypothesis is extended to include a differential recruitment of the two sexes with respect to their age class, it is possible to explain the sequences of high and low populations and high and low sex ratios which have been observed in brook lamprey populations during 1947–60. A similar situation, it is thought, might exist in the landlocked sea lamprey, a possibility which could be verified by determining the distribution of the sexes in large numbers of the downstream migrants.

I should like to acknowledge with gratitude the help received from Dr. V. C. Applegate of the U.S. Department of the Interior, Fish and Wildlife Service, both in supplying specimens and in furnishing the information on the sea lamprey.

Isolation of *Plasmodium knowlesi* from Philippine Macaques

Between October 1959 and November 1960 blood films were examined for parasites from 164 Philippine long-tailed macaques (*Macaca irus*) at the University of California Medical Center. Ten of the animals were found infected with species of *Plasmodium*. Morphological investigations suggested that several species were present either as single infections or, in several monkeys, as multiple infections. Sub-inoculations into uninfected monkeys were used to help determine the species. Blood from two animals (*MK* 116 and *MK* 119, originally from the Cebu area of the central Philippines) was also sent to the Laboratory of Parasite Chemotherapy in Memphis. This communication has been prepared primarily to record the isolation of *Plasmodium knowlesi* from one of the Philippine macaques. This finding represents a considerable extension of the known range of this parasite which is transmissible to man experimentally and perhaps also in Nature.

On November 15, 1960, 2 ml. of infected blood (scanty plasmodia on thick films) from *M. irus*, *MK* 119, were injected intraperitoneally into an uninfected immature rhesus (*M. mulatta R* 614). Daily blood films from *R* 614 remained negative, and after three weeks it appeared that the transfer had been unsuccessful. On December 5, 1960, *R* 614 was sub-inoculated by intraperitoneal injection of 2 ml. of blood, this time from *M. irus MK* 116. Again the blood was only lightly infected with plasmodia. On the following day a patent plasmodial infection appeared in *R* 614 (5 parasites/1,000 red cells). It later became clear (see later) that this infection was caused by parasites inoculated from *MK* 119 three weeks earlier. The infection evidently became patent as the result of the stimulus due to foreign protein of the second injection of *M. irus* blood.

From December 6 until the work was terminated, blood films were made from *R* 614 every four hours. During a nine-day period beginning on the first post-inoculation day, the plasmodia followed a well-defined 48-hr. asexual cycle with maturation of schizonts being a maximum in the early morning hours, between 1 a.m. and 5 a.m. The blood parasites during this phase of the infection were characteristic of *Plasmodium cynomolgi*, a parasite which has been recorded from Philippine macaques on at least one previous occasion (Garnham, P. C. C., personal communication). Parasitæmia rose to a peak of 75 parasites/1,000 red cells on the eighth day after the *MK* 116 inoculation. On the ninth, tenth, and eleventh days after this inoculation, the parasite counts were much lower, but gametocytes were prominent, at one time comprising 62 per cent of the total count of parasites.

On the eleventh day after inoculation, as the *P. cynomolgi* infection rapidly waned, a second species of *Plasmodium*, morphologically characteristic of *Plasmodium knowlesi*, suddenly appeared. It became apparent later that this second parasite resulted from the *MK* 116 sub-inoculation. The parasites of this species appeared in rapidly increasing numbers during the next three days. Two complete 24-hr. asexual cycles were observed, with maximum maturation of schizonts at about midday. On the evening of the fourteenth day after inoculation, the parasite count was 160/1,000 red cells. The monkey was severely anæmic, pale, and listless. At this time virtually all parasites in the blood-stream appeared to be *P. knowlesi*. 1 ml. of blood was inoculated into a clean *M. irus* (*MK* 117, previously treated with chloroquine and primaquine) to preserve the strain. This transfer was successful. At the same time 50 mgm. of sulphadiazine was administered intramuscularly in an attempt to save the life of the rhesus. This was unsuccessful; the monkey died from the overwhelming *P. knowlesi* infection during the night.

At the same time that these investigations were carried out, *P. cynomolgi* was isolated from *MK* 119 blood at the Memphis laboratory (confirming the suspicion that this species in rhesus *R* 614 had been derived from the first sub-inoculation), and *P. knowlesi* and *P. inui* were isolated from *MK* 116 blood. *P. knowlesi* became patent in Memphis rhesus *X* 509 five days after injection of blood from *MK* 116. For about a week small numbers of parasites were present. A very heavy *P. knowlesi* infection then developed which was successfully treated with chloroquine (50 mgm. a day intramuscularly for three days). Prior to treatment a second rhesus (*X* 536) was inoculated from *X* 509 and *P. knowlesi* infection developed rapidly. Treatment was carried out with sulphamerazine (250 mgm. a day by stomach tube for five days). The *P. knowlesi* parasites disappeared and typical *Plasmodium inui* became evident. Quartan periodicity was demonstrated by segmenter counts of daily blood films.

While *P. inui* was not detected in California rhesus *R* 614 in the face of the vigorous *P. knowlesi* infection, three of the nine other *M. irus* found infected appear to have plasmodia morphologically resembling *P. inui*. *P. inui* has been isolated from Philippine macaques on at least one previous occasion[1].

Plasmodium knowlesi has been recorded previously only from Malaya. The present report extends the known range of the parasite considerably. It is of interest, however, that a variant of *P. knowlesi* was discovered in Formosan macaques (*M. cyclopsis*) by Yokogawa *et al.* in 1941[2]. This variant, *Plasmodium knowlesi* var. *arimai*, was reported to have a 24-hr. asexual cycle, but to be only slightly or moderately pathogenic for rhesus monkeys, and non-infective for man. The Philippine strain of *P. knowlesi*, although not studied in man as yet, is certainly highly virulent in the rhesus and thus appears to be more closely related to the Malayan strain than to the Formosan variant.

Further work on these plasmodia is in progress at both laboratories; for convenience they have been termed the Cebu strains of *P. knowlesi*, *P. inui*, and *P. cynomolgi* respectively.

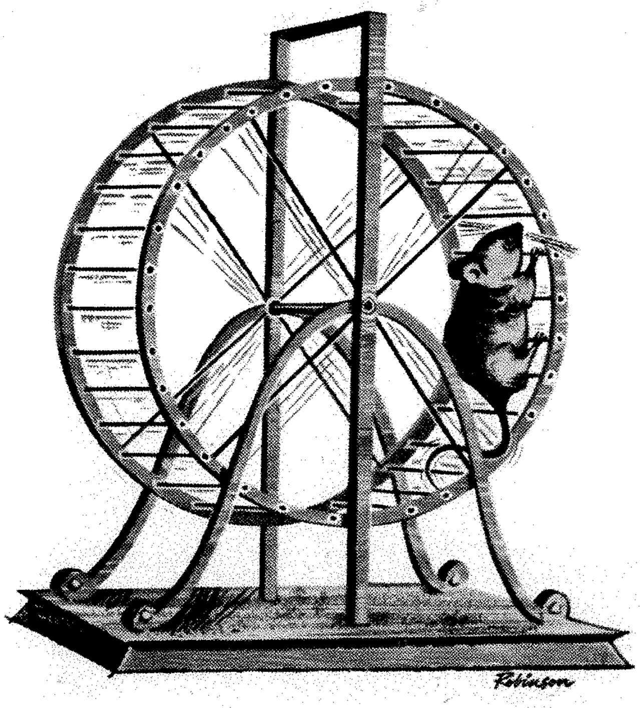
Excretory Ducts in the Genus *Notopterus* (Lacepede)

THE reduction in size of the cœlom in the genus *Notopterus* has resulted in certain interesting modifications of the alimentary canal, swim-bladder, kidneys and gonads. An anomalous feature has also been observed in the organization of the kidney ducts and urinary bladder.



IT'S A SMALL WORLD

AND MARCHON SURFACTANTS PLAY A BIG PART IN IT

The mouse runs hard in order to stay in the same place. That is how Marchon keeps its lead in the detergent industry. The Marchon factory at Whitehaven produces an ever-increasing range of detergent raw materials to meet the expanding—and exacting—needs of industry all over the world. Marchon is, of course, able to keep its leading position because it supplies high quality materials at economic prices.

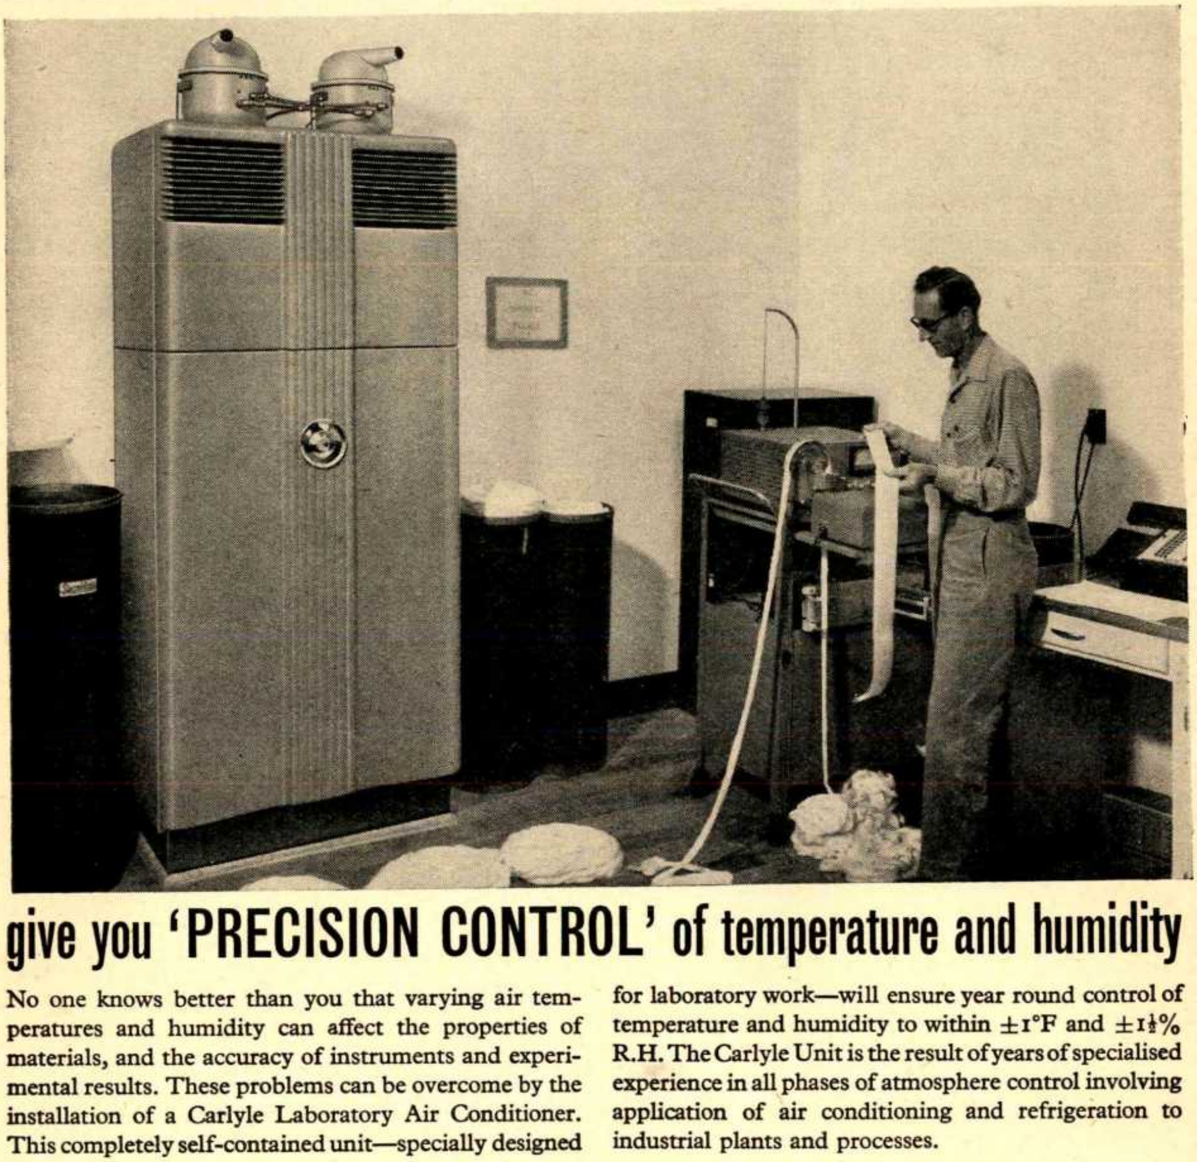
CARLYLE
LABORATORY CONDITIONERS



give you 'PRECISION CONTROL' of temperature and humidity

No one knows better than you that varying air temperatures and humidity can affect the properties of materials, and the accuracy of instruments and experimental results. These problems can be overcome by the installation of a Carlyle Laboratory Air Conditioner. This completely self-contained unit—specially designed for laboratory work—will ensure year round control of temperature and humidity to within ±1°F and ±1½% R.H. The Carlyle Unit is the result of years of specialised experience in all phases of atmosphere control involving application of air conditioning and refrigeration to industrial plants and processes.

Capacities from 29,000 to 80,000 Btu/hr

Larger capacities are also available on special order. We shall be glad to co-operate with organisations in recommending the unit most suitable for their purpose.

CARLYLE

CARLYLE AIR CONDITIONING & REFRIGERATION LTD

1 King Street, St. James's, London S.W.1 Tel: WHItehall 5356

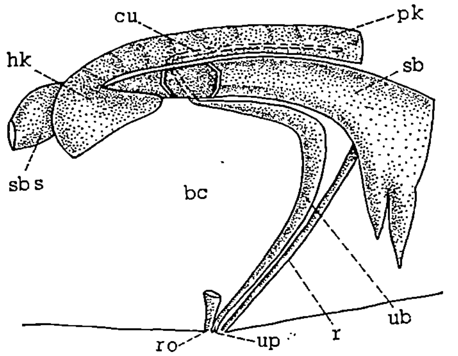


Fig. 1. Lateral view of the excretory organs and swim-bladder in *Notopterus*. *bc*, body cavity; *cu*, common ureter; *hk*, head kidney; *pk*, posterior kidney; *r*, first radial bone; *ro*, rectal opening; *sb*, swim-bladder; *sbs*, sub-spherical sac of swim-bladder; *ub*, urinary bladder; *up*, urinogenital papilla

The typical teleostean excretory organ consists of a pair of kidneys lying retroperitoneally beneath the vertebral column. Each kidney is differentiated into an anterior non-excretory part, the head kidney and a posterior functional part, the mesonephros. The ureter of each kidney proceeds backwards along the dorsal surface of the cœlom to open independently into the urinary bladder. In *Notopterus*, however, the ureters lie deep within the kidney. The two ureters join posteriorly to make a U-shaped bend whence a common, relatively thick-walled ureter runs forward superficially over the entire length of the left mesonephros. The common ureter then enters the swim-bladder, which lies immediately below, courses along its inner partition wall and pierces its tunica and fibrous peritoneal wall to open into a long, curved, tubular urinary bladder which extends as far as the middle of the body cavity.

The fusion of the ureters into a long common duct, its recurrent course along the kidney cephalad and its passage through the swim-bladder before it opens into the urinary bladder in both *Notopterus notopterus* and *Notopterus chitala*, the two available species in India, have not been reported earlier. The arrangement of the ureters and urinary bladder differs fundamentally from that of the typical teleostean excretory ducts.

Bridge[1], who worked on the swim-bladder of *Notopterus borneensis*, did not mention this feature. Also, Srivastava[2] and Dehadrai[3,4], who worked on the swim-bladder of *N. chitala*, failed to notice its association with the excretory system. It is inferred that an intense compression of the body and reduction of the cœlomic cavity have necessitated this change in the organization of kidney ducts and urinary bladder in the genus.

My sincere thanks are due to Dr. M. Chandy for her guidance and to Prof. B. R. Seshachar for helpful suggestions. I am also grateful to the Colombo Plan Authorities for the award of a Technical Co-operation Scheme Fellowship.

Stimulants of Cell Division in Developing Fruits

STIMULANTS of cell division have been detected in a number of plant tissues, but little progress has been made in identifying the active substances involved[1]. Work on tobacco pith tissue culture[2] has recently shown that apple fruitlets collected while undergoing cell division contain particularly active stimulants of cell division. We have confirmed this, obtained further information about these stimulants and found that fruitlets of other species are also rich sources of factors stimulating cell division. Some properties of the factors in plum fruitlets have been determined.

The method of detection of these stimulants used in our experiments depended on observing the growth by cell division of explants from secondary phloem of carrot roots in the presence and absence of fruit extracts. Liquid culture methods[3] were employed. Ferric sodium ethylenediaminetetraacetate[4,5] was used as source of iron. All media contained 2 p.p.m. of indole-3-acetic acid, were adjusted to *p*H 6·4 and sterilized by autoclaving. Apple fruitlet extracts were active only in the presence of indole-3-acetic acid.

Sturmer Pippin apple fruitlets showed evidence of an active factor promoting cell division at the time of probable cessation of division (30 days from fertilization[6]) and again 24 days later. Activity was also detected in Granny Smith fruit 58 days from fertilization. No such activity, however, was detected in Sturmer Pippin fruit 110 days from fertilization or in mature fruit. The continued presence of stimulants of cell division in apple fruitlets after the cessation of intense cell division suggests that division is not regulated solely by the presence or absence of such stimulants. We have some evidence that extracts of more mature fruit inhibit the stimulative activity of the fruitlet extracts.

Stimulants of cell division were present in unfertilized fruitlets about to drop and in unfertilized fruitlets artificially held on the tree (by spraying with 2-benzthiazolyloxyacetic acid). Thus, while the development of an apple fruit is normally dependent on successful fertilization of a flower, the presence of stimulants of cell division in the developing receptacle is not entirely dependent on fertilization. Yet excision of the developing seeds, which are known to yield active extracts, renders the growth in sterile culture of fruitlet explants more dependent on the supply of a stimulant of cell division. Hence the developing fruit may depend in part on the developing seeds for a supply of such stimulants. The presence of stimulants has also been detected in other parts of the developing apple cluster (cluster base, fruitlet stalks and petals) and at times in leaves.

The presence of stimulants of cell division in fruitlets of other species collected within a period of 30 days from fertilization has been detected by the same method. In cold 70 per cent ethanol extracts of plum (diameter 7–11 mm.), peach (5–8 mm.) and pear (6–10 mm.) the activities equalled or exceeded that in similar apple fruitlet extracts and were about 40–50 per cent that of coconut milk. Less marked activity was detected in quince and pumpkin fruitlet extracts. No activity was detected in extracts of immature avocado or tomato fruit.

Some properties of the active substances in plum fruitlets have been determined. When the 70 per cent ethanol extracts were evaporated *in vacuo* at

† After growth for 21 days; each value is the mean for 20 explants.

40° C. and the residue extracted with water, all the activity was located in the water-soluble fraction. The activity of this fraction could not be accounted for by its content of amino-acids or chlorogenic acid, substances reported[1,7] to stimulate slightly the growth of carrot tissue. Attempts to concentrate the activity of this fraction by adsorption on, and elution from, charcoal were unsuccessful, even when the strongly adsorbing sites were blocked with palmitic acid. Extraction of an aqueous solution of the water-soluble fraction three times with a double volume of ethyl acetate at *p*H 3·2 yielded an aqueous phase (fraction *AP*) with enhanced activity and organic phases (fraction *EP*) containing factors which retarded both cell division and cell enlargement. The influence of these fractions on the growth of carrot explants is indicated in Table 1.

Fraction *EP* was rich in polyphenolic compounds, two of which have been tentatively identified by paper chromatography as catechin and *epi*-catechin. These two substances have been found to retard the growth of carrot tissue. The phenolic components of fraction *EP* may account for the inhibitory action of this fraction. Ethyl acetate extraction would appear to be a simple, effective method for removing some growth inhibitors from plant extracts containing natural stimulants of cell division. (*Note added in proof.* Sumicki and Kawarda have also used ethyl acetate for this purpose, *Plant Growth Regulation*, 483; Iowa State Univ. Press, 1961).

Extraction by butanol and ion-exchange investigations have both provided evidence for the presence in the plum extract of at least two synergistic factors promoting division. Fraction *AP* was further fractionated by running first through 'Zeo-Karb 225' (H) and then through 'Amberlite *IR*-4*B*' or 'De-Acidite *G*' (free base). Activity was confined to the fraction obtained by elution of the 'Zeo-Karb' with 1·5 *N* ammonia after first removing adsorbed material with 70 per cent alcohol, and to the fraction not adsorbed on either resin. Activity of each was slight, but in combination they yielded 90 per cent of the original activity.

The factors in plum fraction *AP* differ from kinetin both chemically and biologically. Extraction with diethyl ether at *p*H 7 yielded inactive ether extracts, all the activity being accounted for by the extracted aqueous phase. Kinetin would be extracted by ether[8]. Fraction *AP* will not replace kinetin in satisfying the non-photosynthetic red-light requirement of *Spirodela oligorrhiza* (analogous to that of *Lemna minor*[9]) and in this respect resembles coconut milk. The factors in plum extract also resemble those in coconut milk in that they can be divided by ion exchangers. However, the 'neutral' fraction from coconut milk is itself completely inactive[1], whereas that from plum extracts promotes division slightly. The activity (increase in cell number per unit dry weight) of plum fraction *AP* is ten times that of coconut milk.

Flower Initiation in Kent Wild White Clover (*Trifolium repens* L.), under Controlled Environmental Conditions

Field experiments on seed production in white clover carried out here during 1958–60 have emphasized the importance of time of flowering in relation to grazing management[1].

Under natural field conditions the first signs of flower initiation can usually be seen during the third week in April, although in spaced plants flower initials are laid down earlier. During this period longitudinal sections of the apex of the stolon show the developing inflorescence as a flattened mass of meristematic tissue in the axil of the subtending leaf close to the growing point of the stolon. This meristematic region rapidly develops into a cone-like structure, differentiating individual florets from the base upwards[2,3].

Little critical work has been done on the environmental factors controlling flower initiation in white clover. Laude[4] investigated the effect of photoperiod on flowering in Ladino white clover, and compared plants overwintered outdoors with plants overwintered in heated glasshouses. Cains[5] has observed the effects of seed vernalization on flowering in white clover. Britten[6] has shown that warm-day, cold-

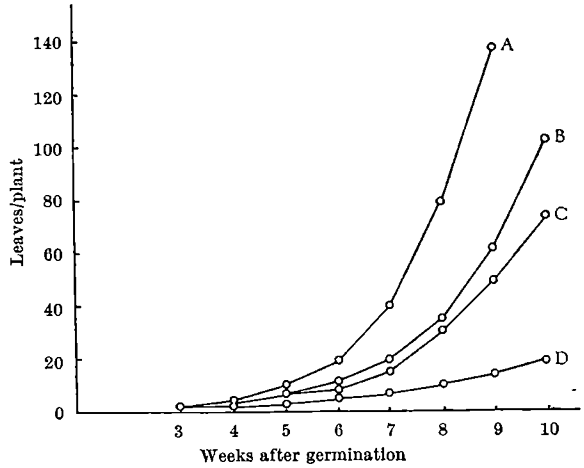

Fig. 1. Photoperiod and vegetative growth. Vegetative growth, measured as leaves per plant, of white clover seedlings grown under four different photoperiods. *A*, 24 hr. continuous illumination; *B*, 20 hr. a day; *C*, 16 hr. a day; *D*, 8 hr. a day

Table 1. Photoperiod and Flowering

Photoperiod	Time to first-flowering (days)	No. of inflorescences per plant
24 hr.	67	8·0
20 hr.	102	5·0
16 hr.	115	2·0
8 hr.	—	0·0

night temperatures can promote flowering in certain 'non-flowering' clones of white clover.

In the present investigations the effect of photoperiod and vernalization on the growth and development of wild white clover plants has been investigated, using controlled growth-room conditions (unpublished results).

Length of day has been found to be the chief environmental factor controlling flowering in white clover. When plants were grown from seed under photoperiods of 8 hr., 16 hr., 20 hr. and continuous illumination at 500 foot-candles and 65° F., flower initiation was observed only in plants in photoperiods of 16 hr. or more. In day-lengths greater than 16 hr. there was a quantitative response in both vegetative growth (Fig. 1) and reproductive development (Table 1) reaching a maximum under continuous illumination. This long-day flowering response in white clover confirms the findings of Laude[4], although he obtained relatively little difference in response to photoperiods of 15½ hr. or greater.

Cold temperatures during seed germination were not found to be essential for subsequent flowering, since some plants grown from non-vernalized seed completed their full cycle of development under long-day photoperiods. However, seed vernalization at 38° F. for 15 days resulted in earlier flowering and increased the number of inflorescences per plant, when grown on under natural long-day photoperiods in the early summer. Vernalization at 38° F. for longer, or shorter, periods than 15 days appeared to depress flowering ability.

Preliminary results for the interaction of seed vernalization and photoperiodism suggest that vernalization becomes more important in promoting flowering in the shorter photoperiods. In this respect, white clover appears to behave similarly to subterranean clover, as reported by Evans[7].

Once flowering has taken place, vegetative plant material has been induced to flower again by limited periods of cold temperature. Vegetative stolon cuttings were given successively longer periods of cold temperature in an unlit refrigerator at 38° F. When grown afterwards in the growth-room at 65° F., flowering occurred earliest under long-day photoperiods from plants which had received 1–2 weeks of cold temperature.

Under field conditions there would appear to be a positive flowering response as a result of the cold temperature received during the autumn and early winter. Plants that had received successively longer periods of natural low temperature during the autumn tended to flower earlier when brought into the growth-room and grown under long-day photoperiods at 65° F. This effect of cold temperature appeared to be satisfied by the beginning of January, since plants brought in thereafter showed little further increase in flowering response.

In the field it has been observed that some plants initiate flowers early in the spring and continue producing flowers for several weeks, whereas other plants may start flower initiation later in the spring and continue flowering for only a few days. This wide range of response is probably genetical and offers considerable scope for plant selection for time of flowering.

These findings have shown that Kent wild white clover is a long-day plant and that flowering can be stimulated by limited periods of cold temperature.

MICROBIOLOGY

Metabolic and Genetic Investigations of Nutritionally Exacting Strains of *Staphylococcus pyogenes*

Coagulase-positive strains of *Staphylococcus pyogenes*, taken at random from material phage-typed at Hammersmith Hospital and at the Central Public Health Laboratory, Colindale, were tested for their nutritional character. All but 50 of the 926 strains grew well on a defined medium (based on that of Fildes *et al.*[1]) containing valine, leucine, glycine, proline, aspartic acid, methionine, phenylalanine, arginine, histidine, cysteine, thiamine and nicotinic acid in a glucose-citrate-salts-agar base. Of the 50 exacting strains, all but 4 grew on the medium further supplemented as follows : tryptophan, 12 strains ; threonine, 6 strains ; alanine, 4 strains; tyrosine, 3 strains; lysine, 2 strains; tryptophan and tyrosine, 9 strains; tryptophan and *iso*leucine, 2 strains; tryptophan and biotin, 2 strains; threonine and glutamic acid, 1 strain; biotin, 2 strains; riboflavine, 1 strain; hypoxanthine, 2 strains.

Non-exacting variants were obtained from many of the exacting strains when large inocula were plated on the defined medium. The strain requiring threonine and glutamic acid gave variants able to dispense with threonine, and others able to dispense with glutamic acid, but none able to dispense with both amino-acids. This suggests that the two requirements result from two genetic lesions, each capable of repair by mutation. Some strains yielded only small-colony-type non-exacting variants, like those resulting from suppressor mutations in some nutritionally exacting mutants of *Salmonella typhimurium*.

Of the strains responding to tryptophan, some responded to anthranilic acid, indole or tryptophan, some to indole or tryptophan, some only to tryptophan; these categories correspond to classes of auxotrophic mutants in *Salmonella typhimurium* with blocks at different points in the biosynthetic path to tryptophan. None of the strains requiring both tryptophan and tyrosine responded to shikimic acid, the common precursor of the three aromatic amino-acids (of which phenylalanine was present in the standard medium); furthermore some of these strains utilized indole, and some indole or anthranilic acid, in place of tryptophan. It is therefore unlikely that they owe their double requirements to a single block in the synthesis of the aromatic amino-acids.

Of the 7 strains responding to threonine, or threonine plus glutamic acid, 2 only responded to homoserine, a precursor of threonine and methionine in *Escherichia coli*[2]. These 2 strains, but not the other 5, failed to grow on threonine-supplemented defined medium from which methionine had been omitted. These 2 strains, needing either threonine and methionine or homoserine, are, we infer, unable to convert aspartic acid to homoserine; and the other 5 threonine-requiring strains unable to convert homoserine to threonine.

We attempted to obtain non-exacting forms from the exacting strains by phage transduction, using typing phage 53, and other typing phages serologically related to it, obtained by growth on their respective propagating strains, all of which grew on our defined medium; Morse[3] showed that phage 53 obtained by induction of a lysogenic strain transduced fermentation and drug-resistance characters. Transduction of the non-exacting character was observed in all the strains responding to threonine, and in some with requirements for tryptophan, tyrosine, alanine, lysine or hypoxanthine. In the threonine-exacting strains with a phage-bacterium input ratio of 5 : 1 about 10^{-7} transductant colony was obtained per phage particle; the rate was lower in the other strains. No minute colonies, such as result from abortive transduction, were seen.

Phage 53 was grown on the two strains responding to threonine or homoserine, and on spontaneous non-exacting variants of them. When either of the exacting strains was treated with phage grown on the other, the yield of non-exacting colonies was only about one-fifth of that evoked by phage grown, instead, on the non-exacting variant. We infer that these 2 strains have non-identical genetic lesions, at sites very closely linked so that their probability of co-transduction is about 0·8. As phage 53 could not be grown on the 5 strains responding only to threonine these strains could only be used as receptors. When any of the 5 was treated with phage grown on either of the 2 strains responding to threonine or homoserine about half the colonies obtained by plating on defined medium supplemented with homoserine had the requirement for homoserine (or threonine) of the donor strain. We infer that the sites of the genetic lesions in the 5 threonine-requiring strains are closely linked to the sites in the homoserine-responding strains, so that the probability of co-transduction is about 0·5.

Thus examination of the minority of strains of *Staph. pyogenes* which are nutritionally more exacting than the majority has provided evidence that the biosynthetic paths to tryptophan and to threonine are similar to those in *Salm. typhimurium* and *Esch. coli*; and that typing phage 53 and some serologically related phages can transduce various nutritional characters. The observed linkage between loci for successive steps in the conversion of aspartic acid to threonine has been found also in *Salm. typhimurium*[4].

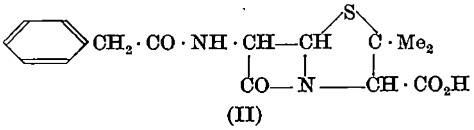
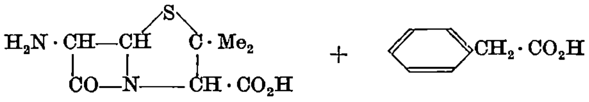
A Method for isolating Bacteria capable of producing 6-Aminopenicillanic Acid from Benzylpenicillin

BATCHELOR *et al.* discussed the isolation of 6-aminopenicillanic acid (I) from a submerged culture of *Penicillium chrysogenum*[1]. Recently, it was shown that (I) could be prepared by the microbial hydrolysis of benzylpenicillin (II)[2–4].



(II)



(I) (III)

While engaged in the study of resolving amino-acids by metabolism or hydrolysis of soil bacteria on acyl derivatives of DL-amino-acids[5–7], we have found that more than eight strains (*KT* 514, *KT* 513, *KT* 515, etc.) of soil bacteria capable of producing (I) from (II) by metabolism or enzymic hydrolysis could be isolated from four different field areas by using a synthetic medium containing (II) as the sole source of carbon.

The constituents of the culture medium used in the experiments are as follows : potassium benzylpenicillin, 0·93 gm. (0·0025 mole) ; NH_4Cl, 0·1 gm.; K_2HPO_4, 0·1 gm. ; $MgSO_47H_2O$, 0·05 gm. ; 1 per cent $CaCl_26H_2O$, 2 drops ; 1 per cent $FeCl_36H_2O$, 1 drop ; distilled water, 100 c.c. ; *p*H 7·0–7·2. All strains (*KT* 514, *KT* 513, *KT* 515, etc.) could be cultivated successively in the synthetic medium containing phenylacetic acid (III) as well as (II) as the sole source of carbon. They seemed to be rod-shaped in the phenylacetic acid medium, but they had a tendency to form filaments in the benzylpenicillin medium.

When 18·6 mgm. of potassium benzylpenicillin was incubated with 20 mgm. of bacterial acetone powder in 2 c.c. of 0·1 *M* potassium phosphate buffer at *p*H 7·8 and 37° C. for 4 hr. in the presence of toluene, the reaction mixture was found to contain 1·12–0·17 mgm. (that is, 10·4–1·6 per cent of the theoretical quantity) of (I), and (III) (Table 1). (I) was determined by treating a centrifuged sample with phenylacetyl chloride and bio-assaying the (II) formed by a plate diffusion assay. (III) was tested by the method of Pan *et al.*[8].

When ammonium chloride was removed from the benzylpenicillin medium, *KT* 514, *KT* 513, *KT* 515, and *KT* 512 could not or only just be cultivated, and then they scarcely utilized (I) as the sole source of

Table 1. PRODUCTION OF 6-AMINOPENICILLANIC ACID FROM BENZYLPENICILLIN BY HYDROLYSIS OF BACTERIAL ACETONE POWDER

Strains of soil bacteria	6-Amino-penicillanic acid (per cent)	Phenyl-acetic acid	Strains of soil bacteria	6-Amino-penicillanic acid (per cent)	Phenyl-acetic acid
KT 502	2·6	+	*KT* 513	2·3	+
KT 504	6·5	+	*KT* 514	1·6	+
KT 510	5·2	+	*KT* 515	10·0	+
KT 511	10·4	+			
KT 512	7·8	+	*KT* 517	2·6	+

Table 2. Production of 6-Aminopenicillanic Acid from Benzylpenicillin by Metabolism of Bacteria

Strains of soil bacteria	Fermentation time (day)	6-Aminopenicillanic acid (per cent)
KT 514	3	6·0
KT 513	3	5·5
KT 515	3	3·7
KT 512	3	1·5

carbon in the presence of ammonium chloride. Consequently, it is to be understood that *KT* 514, *KT* 513, *KT* 515, and *KT* 512 may produce (I) from (II) by utilizing (III), which was formed from (II) by the action of their 'penicillin acylase', as the sole source of carbon and ammonia as the sole source of nitrogen. A loop of the culture fluid was inoculated into 5 c.c. of the culture medium containing potassium benzylpenicillin and incubated at 25° C. for three days. The fermentation liquor contained 1·62–0·4 mgm. (that is, 6·0–1·5 per cent of the theoretical amount) of (I) (Table 2). The production of (I) was assayed by the microbiological determination mentioned here.

Thus, a new method to isolate bacteria capable of producing (I) from (II) was established.

Leptospirosis of White Laboratory Rats

Leptospiral infection of white laboratory rats was first reported by Uhlenhuth and Zimmermann[1]. Later it was observed in some stocks in Germany, Holland and Denmark[2]. The infection seemed to be present inapparently in white rats, although some observers emphasized the high incidence of albuminuria in these populations. The examination of single isolated strains and the results of serological screening tests suggested *Leptospira icterohaemorrhagiae* as the causative agent. It was generally assumed that the infection originated from wild rats in the animal house. Human cases were regularly detected in these institutes showing mainly the picture of Weil's disease with a high fatality-rate.

Our investigations in Hungary in 1959 and 1960 showed that leptospiral infection often occurs in large stocks of Wistar rats. The animal sera gave positive sero-reactions of high titre with the sero-types of the *icterohaemorrhagiae* sero-group; with other serotypes only occasional cross-reactions were present. The frequency of sero-positivity varied in the different populations, but in some stocks it ranged to 100 per cent in old animals. The positive sero-reactions indicated that the rats were carriers and *Leptospirae* could be easily cultured from the kidney of these animals. Study of the isolated strains showed that they represent one sero-type, which is closely related to the sero-types of the *icterohaemorrhagiae* sero-group, but they could be differentiated in cross-absorption tests. Therefore the name *Leptospira budapest* was given this sero-type, indicating the place of the first description.

Epidemiological investigations suggested the endemic spread of the infection in different white rat populations. In agreement with our former observations, typical *icterohaemorrhagiae* strains could be isolated from wild rats in Hungary and *Leptospira budapest* was encountered hitherto only in white laboratory rats.

The widespread incidence of leptospiral infection in white rats directs attention to the paramount importance of this problem in institutions where white rats are regularly used for experimental and routine work. Epidemiological surveys and serological screening tests generally revealed human cases in such places, occurring mainly among personnel of the animal house. The presence of the infection in the stocks may affect the experimental results in diets, kidney and liver function tests, determination of the basal metabolism and in histological examinations.

GENETICS

Stabilizing Selection for Heading Time in a Bulk-Hybrid Population of Barley

Several workers[1-3] have recently pointed out the importance of the stabilizing type of natural selection, in which the intermediate phenotype has an adaptive advantage over the deviants from such a centrally located norm, thus resulting in a rather stable population mean and a continually diminishing population variance. Robertson[4] has analysed the theoretical implications of two different models of stabilizing selection: the intermediate optimum model of Wright[5], where the more fit individuals are phenotypically intermediate, and the homeostatic model of Lerner[6], in which the favoured individuals are more fit since they are heterozygotes. The latter model involves true overdominance at one or more loci governing fitness or its various components. Hence, it would be of interest to investigate an actual example of stabilizing form of selection for its fit to one or the other model. The present communication summarizes evidence for stabilizing selection for heading time (recorded as the number of days before the first spike comes out of the flag leaf) in a bulk-hybrid population of barley that was derived from a composite cross and propagated over 18 generations under natural self-fertilization without conscious selection, and it further provides some information on the discriminating choice between the two models.

The experimental material consisted of the random samples of single plants in the bulked F_3, F_5, F_6, F_{13}, F_{15}, and F_{18} generations along with all the thirty

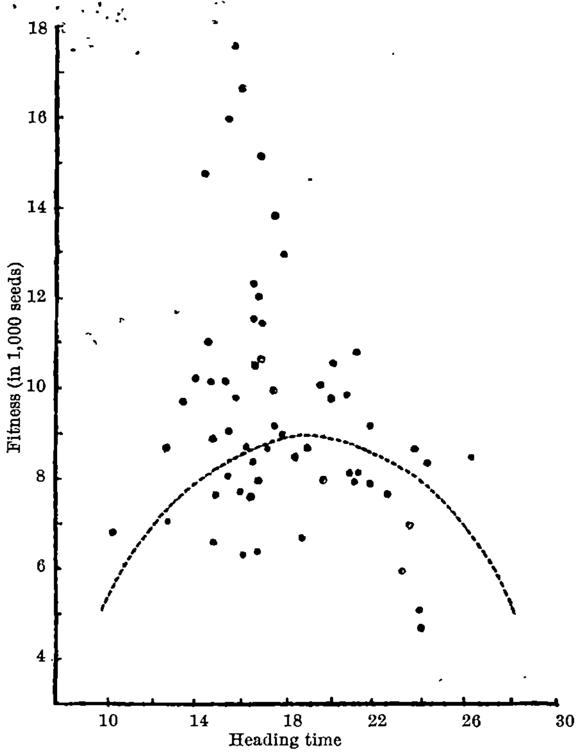

Fig. 1

parents of the composite cross, all planted together in a five-times replicated randomized block design. Table 1 gives the estimates of overall generation means and variances. A relatively small change in the mean towards earliness together with a consistent and striking diminution of the variance clearly suggest a strong pressure of stabilizing selection for intermediate metric values of heading date, since in absence of selection, theoretically, continued inbreeding is expected to bring about an increase in total variance through having subdivided a population into many familial lines. Wright[7] showed that with all genetic variance additive, the among-family-means and within-families variances are simple, linear functions of the inbreeding coefficient, F, such that $\sigma_m{}^2$ (among-families variance) $\propto 2F$, and $\sigma_w{}^2$ (within-families variance) $\propto (1-F)$. The relative proportions of $\sigma_m{}^2$ and $\sigma_w{}^2$, as estimated from progenies of 63 randomly chosen individuals in each of the F_3, F_6, F_{13}, and F_{18} generations, are given in Table 2. For sake of comparison, their estimates from the thirty parental cultures are also included. The values of $\sigma_m{}^2$ indicate a steady decrease in the amount of genetic heterogeneity due to the extinction of certain families under inbreeding and selection. The within-families variance, $\sigma_w{}^2$, is smallest in the parental (P) generation, and although it decreased slowly with inbreeding generations, yet F_{19} gave a higher value of $\sigma_w{}^2$ than P, an interesting observation that might be accounted for by a certain amount of heterozygosity being retained by natural selection even after as many as 18 generations of 98–99 per cent selfing occurring in this material[8]. The frequency distribution for the individual progenies shows only continuous variation which might imply that perhaps none of the segregating and overdominant loci could be singled out as being the major one. It is significant to note, however, that earlier, Jain and Allard[8] reported evidence for a distinct heterozygote advantage at four different marker loci segregating in the present material. The homeostatic model of stabilizing selection deals with precisely such truly overdominant loci.

Table 1. ESTIMATES OF OVERALL GENERATION MEANS AND VARIANCES

Statistic	Generation F_3	F_5	F_8	F_{13}	F_{15}	F_{18}
Mean (days)	18·86	16·94	17·42	16·27	16·47	16·42
Variance	31·76	24·06	25·14	21·75	21·05	18·00

Table 2. ESTIMATES OF AMONG-FAMILIES ($\sigma_m{}^2$) AND WITHIN-FAMILIES ($\sigma_w{}^2$) VARIANCES

Statistic	Generation F_4	F_7	F_{14}	F_{19}	P
$\sigma_m{}^2$	745·61	462·58	528·13	398·36	1,280·97
$\sigma_w{}^2$	10·70	9·80	8·91	7·10	5·28

A further consequence of the homeostatic model can be verified from the present experiment. As pointed out by Robertson[4], unlike its alternative model, the homeostatic model implies that homozygosis would never be complete and that the fitness (measured by the number of seeds produced) and mean heading time of a family would not be correlated. The fitness – heading time graph for F_{19} progenies (Fig. 1) actually shows a very wide scatter of points with reference to the parabolic curve expected under the intermediate optimum model. The absence of any significant correlation here may therefore be taken as further evidence for heterozygote advantage as the basis of stabilizing selection. A detailed report of this experiment is hoped to be published elsewhere.

I wish to thank Mr. C. A. Suneson of the United States Department of Agriculture for providing the seed material, and Prof. R. W. Allard of the University of California, Davis, for his helpful supervision and criticism. This work was carried out at the University of California, Davis, California.

Pulmonary Tumours and Group VII in the House-Mouse

CERTAIN aspects of the experiments reported in Dr. J. A. H. Tatchell's recent communication[1] are likely to result in misunderstanding of the genetic nature of the inheritance of susceptibility to pulmonary tumours in mice. Heston[2] has established that the inheritance of susceptibility to pulmonary tumours in mice is multifactorial in nature and therefore the further investigation of this problem requires an approach designed to take this into account. The experiment reported by Dr. Tatchell does not appear to do so.

I agree that Heston's[3–5] evidence proves the presence of a factor in linkage group VII, but it has not been shown that this is the only factor influencing susceptibility to pulmonary tumours in this linkage group; nor has the possible existence of background effects resulting from segregating loci present in other linkage groups been taken into account. The validity of estimating the recombination frequency depends on the supposition that the classification by the presence or absence of tumours corresponds with the segregation of a single Mendelian gene, and Dr. Tatchell has not given any supporting evidence for this. Even if the classification resulted in a 1 : 1 segregation in backcross matings, this in itself would not be sufficient evidence because, as Wright[6] showed in a well-known paper on polydactyly in guinea pigs, a polygenic character with a threshold, and all-or-none expression, can "simulate one-factor Mendelian heredity to a remarkable extent" in F_1, F_2 and backcross segregations. But the single-factor interpretation "breaks down completely in the tests of the supposed segregants". In addition, because of the segregation of genes at other loci, some mice with the linkage group VII gene may have no tumour, and some mice without the gene may have tumours. Dr. Tatchell states that there was certainly some degree of misclassification but does not indicate how much. Without a knowledge of the accuracy of the classification it is impossible to estimate the true recombination frequency: the results obtained are equally compatible with either loose linkage and accurate classification or close linkage and inaccurate classification.

A further complication is that the treatment used resulted in a 50 per cent loss of experimental animals, which appears to be excessively high; no information is given as to whether or not this loss is randomly distributed between the mutant groups. If the loss were not randomly distributed, so high a mortality might have seriously affected segregation ratios and the apparent recombination frequencies.

In my opinion consideration of these criticisms leads to the conclusion that the approach that Dr. Tatchell has used in this experiment is not valid for this character.

[6] Wright, S., *Genetics*, **19**, 537 (1934).

THE points raised by Dr. Bloom were either fully covered in my communication or else were unsuitable for inclusion in a preliminary account.

I stated that Heston's work *suggests* the presence of one major factor in linkage group VII without excluding minor factors; I did not claim that there is definitely only one factor involved, and I pointed out that his work does not exclude some interaction.

I agree that a polygenic character can "simulate one-factor Mendelian heredity to a remarkable extent", but Fisher's[1,2] later work on polydactyly in mice has clearly shown not only that a major gene can be isolated from its modifiers by refined genetic techniques but also that the demonstration of linkage with another factor is unassailable confirmation of its existence. He has also shown the necessity for having both phases before the evidence for linkage itself is conclusive. This is precisely why I have stated, on one hand, that the lack of linkage between the possible factor (*Tm*) and sex, where both phases are available, is proved, while on the other hand, the putative linkage between *Tm* and group VII, where the coupling phase only is available, is still uncertain. The further experiments in this series are an attempt to give the second phase (repulsion), as stated in my communication. This attempt is itself a test of "the single-factor interpretation" because the repulsion heterozygotes will be "supposed segregants", and thus, if they in turn give single-factor ratios, this will be evidence, additional to linkage, of the presence of the major factor.

The degree of modification of *Tm*, and thus the degree of misclassification, should also be more accurately measured by this further experiment. However, misclassification on the scale proposed by Dr. Bloom would already have been revealed by the more critical analysis which, as I have stated, I will give in my more detailed account. As this analysis agrees well with the simpler treatment, I felt that the latter was more suitable for publication in a preliminary communication, particularly as this was the only one used by previous workers. With minimal misclassification and sufficient numbers, it may now be claimed not only that Heston's "association" with group VII is strongly confirmed but also that, with the choice of factors having reduced known weight interaction, the case for linkage is strong enough to be worth pursuing.

I regret that my footnote to Table 2 did not indicate that the apparently high mortality-rate was due to my having to kill large numbers of my stock because of circumstances beyond my control and unconnected with the experiment. It includes also, of course, the low random litter mortality present in any breeding stock. The mortality-rate after injection was, in fact, extremely low.

In my opinion the application of genetic techniques and mathematical analyses used successfully in other apparently polygenic situations is essential to the discovery of a single major factor in cancer work and that no advance in this direction can be made without it.

Distribution of X-ray- and Nitrous Acid-induced Mutations in the Genetic Fine Structure of the ad_7 Locus of *Schizosaccharomyces pombe*

GENETIC research of the past ten years has shown that the classical gene can be subdivided by mutation, recombination and function. The region of a chromosome which determines the production of one enzyme can be inactivated by mutation at many independent sites which are separable by recombination. One well-known example is the *r*II region of phage *T*4 (ref. 1. For other genes analysed in micro-organisms see Pontecorvo[2] and Demerec and Hartman[3]).

In fungi, one of the most extensive intragenic recombination analyses has been performed by Leupold in the ad_7 locus of the yeast *Schizosaccharomyces pombe*[4a-c]. Leupold has obtained 153 ad_7 mutants by ultra-violet irradiation. These mutants need adenine for growth and accumulate a red pigment. Most of the ultra-violet mutants cannot grow without adenine at any temperature tested, but six mutants are sensitive to temperature (no growth at 25° C., growth at 35° C.). Using intragenic recombination analyses, Leupold has constructed a linear map of the ad_7 locus (Fig. 1*a*). The ultra-violet mutants are not randomly distributed on the map. There are a few 'hot spots', and the mutation sites appear to be concentrated in several parts of the map. Each ultra-violet mutant seems to be a 'point mutation'.

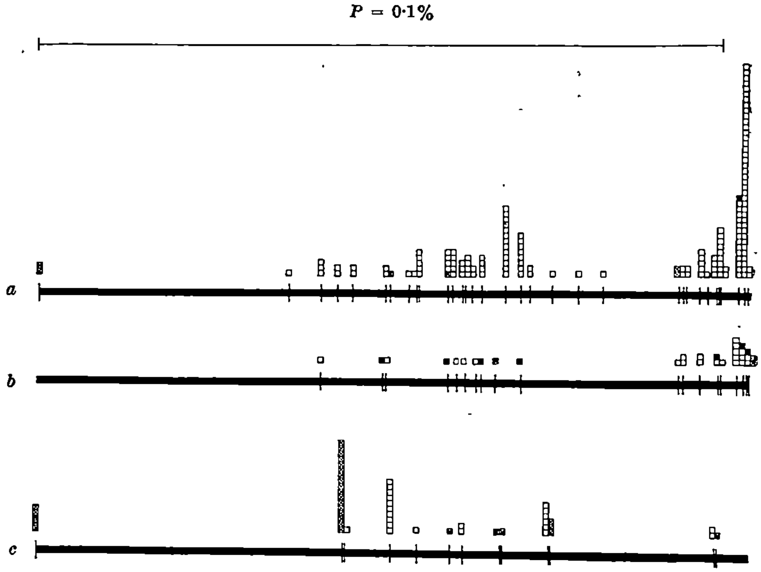

Fig. 1. Map of the ad_7 locus of *Schizosaccharomyces pombe* showing the distribution of the mutants induced by *a*, ultra-violet light (according to Leupold (ref. 4*c*); *b*, X-rays; *c*, nitrous acid. The map has a length of about 0·1 Morgan unit. ☒, Temperature-sensitive; ■, mating type

It was of interest to test the action of other mutagenic agents on the ad_7 locus. First, I chose X-rays. They are known to produce chromosomal aberrations, for example, deletions, and I wanted to see whether gross changes of corresponding types are produced on the intragenic level as well. Secondly, I chose nitrous acid. Nitrous acid causes inactivation and mutations in tobacco mosaic virus[5], bacteriophages[1,6], and bacteria[7]. *In vitro*, it deaminates the purine and pyrimidine bases of the ribonucleic acid[5] and deoxyribonucleic acid (DNA)[8]. Thus nitrous acid is a very interesting mutagen which is able to react directly with the genetic substance by a known mechanism. With respect to the ad_7 locus, one would expect to obtain mutations which are distributed evenly within the map, without the expression of 'hot spots'. In bacteriophage *T*4, however, Benzer[1] has found that the intragenic distribution of nitrous acid-induced *r*II mutants is non-random, suggesting that mutation-rates at individual sites may depend not only on the nature of the base pair involved but also on its position with respect to neighbouring base pairs. In cellular organisms, the situation is complicated further by the fact that the mutagenic action of nitrous acid may in part be an indirect one, affecting the DNA through changes in metabolism rather than by a direct deamination of its amino-bases.

In my X-ray experiments most of the mutants were produced with 180 keV. X-rays at a dose of 30,000 r. For the experiments with nitrous acid we used cells which were starved for 6 hr. in saline. The cells were incubated in acetate buffer *p*H 4·0 plus 0·03 *M* sodium nitrite at 30° C. for 3–5·25 min. This results in an inactivation of about 40–90 per cent. The treated cells were plated on yeast-extract agar. Following incubation at 30° C. the plates were scored for red colonies. I obtained 32 ad_7 mutants with X-rays and 51 with nitrous acid. The mutants were examined by the methods described by Leupold[4a]. The results of the intragenic recombination analyses are represented in Fig. 1*b* and 1*c*.

Each of the 32 X-ray mutants appears to occupy just one site only, no multi-site mutations having been obtained; they have to be considered as 'point mutations'. The distribution of the mutants in the map is similar to that of the ultra-violet mutants. Thus, no striking difference is observed in the distribution of ad_7 mutants induced with ultra-violet light or X-rays. Seven X-ray mutants have not only mutated in the ad_7 locus but also from mating type + to mating type −. It is not yet clear whether there is any causal connexion between the ad_7 mutations and the mutations concerning the mating type.

The ad_7 mutants obtained with nitrous acid are quite different from the ultra-violet and X-ray mutants. 29 out of the 51 mutants are sensitive to temperature. It is very striking that they show pronounced 'hot spots' different from those of the ultra-violet and X-ray mutants (Fig. 1*c*). It should be mentioned especially that no nitrous acid-induced mutations were found at the 'hot spots' on the right end of the ultra-violet map, and that a 'hot spot' of temperature-sensitive mutants is present in the left part of the map, at a site at which neither ultra-violet nor X-ray mutations has been observed.

The fact that nitrous acid-induced mutants show 'hot spots' may be interpreted as indicating that, under our experimental conditions, the nitrous acid has not attacked the DNA directly or only partially so. The mutagenic action of nitrous acid may to a certain degree be an indirect one, inactivating the ad_7 locus at specific sites partially different from those attacked by ultra-violet and X-rays.

The greater part of the work reported was performed during a research visit at the Institute of General Botany, University of Zurich, Switzerland, and has been supported by grants of the Deutsche Forschungsgemeinschaft, the Schweizerische Nationalfonds, and the Julius-Klaus-Stiftung, Zurich.

FORTHCOMING EVENTS

Thursday, September 14—Friday, September 15

Society of Chemical Industry, Food Group (at the Royal Society of Medicine, Wimpole Street, London, W.1), at 9.30 a.m. daily—Symposium on "Recent Advances in Processing Cereals".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Experimental Officer (with a general degree with zoology, botany and chemistry) in the Department of Insecticides and Fungicides—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 15).

Lecturer (with high academic qualifications and also teaching or research experience) in Inorganic and Physical Chemistry—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (September 15).

Lecturer (with suitable academic and/or industrial experience) in Mathematics—The Secretary, Royal College of Science and Technology, Glasgow (September 16).

Scientific Officers/Senior Scientific Officers (with a first- or second-class honours degree in a science or engineering subject, and a wide and intelligent interest in scientific matters and an aptitude for administrative work) at the Headquarters Office of the D.S.I.R., Regent Street, London, for scientific administrative work—The Establishment Officer, Headquarters Office, D.S.I.R., 5–11 Regent Street, London, S.W.1, quoting HQ.4 (September 16).

Assistant Hydrographer (marine zoologist or a geographer with suitable training and experience), for work in connexion with an investigation by a small team of the physical, chemical and biological conditions of inshore waters, with particular reference to the biology of sessile marine organisms—The Registrar, University College of North Wales, Bangor, North Wales (September 18).

Director of Combined Studies in the Faculty of Science, to supervise admissions to and the progress of students in the courses leading to the newly instituted degree in which two science subjects are studied to a higher level—The Registrar, The University, Leeds 2 (September 18).

Head (well qualified in botany or zoology and with appropriate teaching, research and industrial experience) of the Department of Biology—The Principal, Brunel College of Technology, Woodlands Avenue, Acton, London, W.3 (September 18).

Research Student in Psychology—The Registrar, The University, Hull (September 18).

Histological Technician, Experimental Officer grade, to be in charge of a service to research workers involving a wide range of methods for research programmes—The Secretary, Institute of Animal Physiology, A.R.C., Babraham, Cambridge (September 23).

Research Assistant in the Department of Botany, Gatty Marine Laboratory, St. Andrews, to assist in cultural, cytological and taxonomic investigations of marine algæ—The Secretary of University Court, College Gate, St. Andrews (September 23).

Assistant Lecturers (2) in Organic, Inorganic or Physical Chemistry—The Registrar, The Manchester College of Science and Technology, Manchester 1 (September 25).

Lecturer (with an honours degree in electrical engineering or physics and experience in some branch of electrical or electronic engineering) in the Department of Electrical Engineering—The Registrar, The University, Leeds 2 (September 25).

Senior Lecturer or Lecturer in Applied Mathematics at the University of Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (September 25).

Demonstrator in Agriculture—The Assistant Bursar, The University, Reading (September 29).

Principal Lecturer in Polymer Chemistry and Technology in the Department of Chemistry, Metallurgy and Textiles, to teach in H.N.C., Grad. R.I.C. and Dip.Tech. standard courses—The Registrar, Lanchester College of Technology, Priory Street, Coventry (September 29).

Junior Lecturer (preferably interested in cytology, radiation effects, or other aspects of biology with an application to medicine) in the Department of Zoology—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (September 30).

Lecturer in Cytogenetics in the Department of Agronomy, Waite Agricultural Research Institute, University of Adelaide, Australia, to undertake cytogenetic studies as part of a cereal breeding and genetic research programme—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

Lecturer in Theoretical Physics; a Lecturer in Physics; and Assistant Lecturers in Physics—The Registrar, The University, Manchester 13 (September 30).

Plant Physiologists (2) (honours graduates with research experience in plant physiology) at the Tobacco Research Institute, Division of Plant Industry, C.S.I.R.O., Mareeba, to conduct research into the physiology of the tobacco leaf within one of the following fields: (*a*) morphogenesis, particularly leaf development; (*b*) water relations; or (*c*) photosynthesis and translocation—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 815/33 (October 2).

Lecturer in Biochemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 13).

Chair of Chemistry in the Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 15).

Lecturer in Mathematics at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 16).

Lecturer or Senior Lecturer in Mathematics at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 16).

Lecturer in Civil Engineering at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 20).

Lecturer/Senior Lecturer in Applied Mathematics at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 20).

Senior Lecturer in Physics in the School of General Studies, Australian National University, Canberra—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 21).

Fellow in the Department of Demography, Institute of Advanced Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 27).

Assistant Lecturer (Grade B) in Mechanical Engineering—Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

Chemist (male, with an honours degree in chemistry or an equivalent qualification, and not less than two years postgraduate experience or training) in the Department of Agriculture, Tanganyika, for research work on coffee, including soil and plant analysis connected with nutritional problems and soil survey work—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting BCD.63/8/020/T.

Fishery Research Officer (male, aged 22–35, with a good honours degree in natural science (zoology), some training in fish ecology, and preferably experience of handling nets and some acquaintance with hydrographic gear) in Nyasaland, for research into the biology and ecology of Lake Nyasa fish—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting BCD.152/4/01/T.

Instrument Makers or Toolmakers, for varied and interesting work in a small workshop engaged on scientific research—The Administrator, Medical Research Council, Radiobiological Research Unit, Harwell, Didcot, Berkshire.

Lecturer (with a good honours degree in physics and preferably a Ph.D. degree, experimental research experience in some aspects of plasma physics and an interest in high-current research work) in the Department of Natural Philosophy—The Secretary-Treasurer, Royal College of Science and Technology, George Street, Glasgow, C.1.

Physicists or Engineers in the Nuclear Physics Department, to assist in the bubble chamber development programme—Prof. D. H. Wilkinson, Clarendon Laboratory, The University, Oxford.

Research Assistant (with experience of numerical analysis and of high-speed computers) in the Mathematics Department, to be responsible for the day-to-day administration of a National-Elliott 803 digital computer, assist potential users, both from within the College and from outside, and to formulate and programme their problems—Chief Education Officer, Brunel College of Technology, Woodlands Avenue, Acton, London, W.3.

Research Assistants in (*a*) Metallurgy and (*b*) Chemistry—The Registrar, Bradford Institute of Technology, Bradford 7.

Research Associate and a Research Assistant, to join in an investigation of the synthesis and degradation of sulphate esters in mammalian tissues—Prof. Brian Spencer, Trinity College, Dublin, Republic of Ireland.

Research Fellow or Assistant (preferably with experience in programming for a digital computer) in the Department of Aeronautics and Astronautics, for work in the field of hypersonic gas dynamics—The Secretary and Registrar, The University, Southampton.

Scientists, Scientific Officers or Senior Scientific Officers (with a first- or second-class honours degree or equivalent, particularly in chemistry, physics, mathematics or engineering), for work in research and development establishments in the South of England—The Chief Scientist, The War Office, BN., London, S.W.1.

Senior Agricultural Officer (under 55, with a degree or diploma in horticulture or agriculture, a good knowledge of the production of tropical fruit and food crops and temperate vegetables, and preferably a knowledge of applied entomology and agricultural extension methods) in the Bahamas to encourage local production of subsistence crops and tropical fruits and advise on control measures of plant pests—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting RC.213/8/01/T.

Senior Lecturer in Solid Mechanics in the Department of Aircraft Design—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Senior Research Assistant (with a good honours degree in physics or chemical or mechanical engineering) in the Department of Fuel Technology and Chemical Engineering—The Registrar, The University, Sheffield.

Senior Technical Assistant (preferably with experience in the use of transistors, familiarity with nuclear instrumentation, and some knowledge of workshop practice) in the Physics Department, to help in the design and construction of electronic and other instruments to be used in rockets and artificial Earth satellites—The Secretary and Registrar, The University, Southampton.

Senior Technician in the Chemistry Department, to organize and develop the department stores, and to prepare for their expansion in a new building to be occupied in 1965—The Registrar (CSTS), Queen Mary College (University of London), Mile End Road, London, E.1.

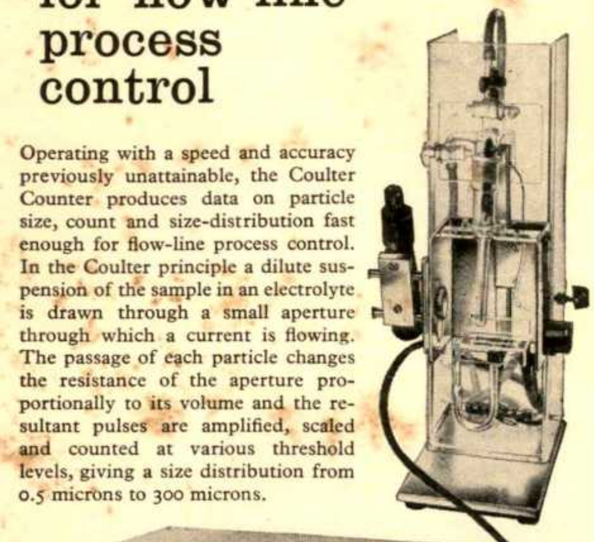
COULTER COUNTER

for accurate particle-size distribution data fast enough for flow-line process control

Operating with a speed and accuracy previously unattainable, the Coulter Counter produces data on particle size, count and size-distribution fast enough for flow-line process control. In the Coulter principle a dilute suspension of the sample in an electrolyte is drawn through a small aperture through which a current is flowing. The passage of each particle changes the resistance of the aperture proportionally to its volume and the resultant pulses are amplified, scaled and counted at various threshold levels, giving a size distribution from 0.5 microns to 300 microns.



Over 1,500 Coulter Counters are already in service in industry and medicine. Full details and technical literature will be sent on request.

In the Johnson Matthey laboratories techniques have been developed for the preparation of scandium, yttrium and the fourteen elements of the rare earth group as metals in a state of high purity.

All metals are available in ingot form and, with three exceptions at present, can be supplied as sheet or foil. Several metals can also be extruded into rod form and drawn to wire.

Further particulars will gladly be given on application

RE11/694

APPOINTMENTS VACANT

AIR MINISTRY

require in

SCIENTIFIC ADVISER'S DEPARTMENT

GRADUATES in PHYSICS, MATHEMATICS and ENGINEERING for appointment as SCIENTIFIC OFFICERS or SENIOR SCIENTIFIC OFFICERS. Successful applicants will be engaged on OPERATIONAL RESEARCH either at Air Ministry in Whitehall or at one of the R.A.F. Command H.Q. or Establishments.

OPERATIONAL RESEARCH at Air Ministry is mainly concerned with the assessment of future operational needs and problems connected with the weapons of the future, while at Commands the emphasis is on obtaining the maximum efficiency from existing weapons systems and the evaluation of their behaviour under operational conditions. In either sphere, scientists work in close co-operation with officers of the R.A.F. and have contacts with other Research Establishments and firms engaged on defence work. There are also opportunities for visits abroad.

CURRENT VACANCIES are for posts at:

(a) Air Ministry, Whitehall, where the need is mainly for Scientific Officers who will be concerned with studies of future R.A.F. offensive and defensive systems, of the interplay of offence and defence, of nuclear submarine detection, and of tactical aircraft and weapons systems.

(b) Bomber Command, High Wycombe, Bucks, working on the evaluation, use and operation of airborne and ground electronic equipment, the effectiveness of the Medium Bomber Force, and in computer organization and programming.

(c) Fighter Command, Stanmore, Middx, working on problems concerned with air defence and tactical operations of military aircraft in support of ground forces, requiring studies of aircraft performance, weapons systems, tactics and operating procedures.

(d) Transport Command, Upavon, Wilts, where a Scientific Officer will be concerned with broad studies of aircraft characteristics and aircraft utilization to meet the needs of the Military Air Transport Force, and studies with the specialist R.A.F. staffs on specific technical and navigational problems.

SUCCESSFUL CANDIDATES may expect to spend a reasonable time in their first appointments but will later have opportunities for broadening their experience in other branches of the Department.

PROSPECTS for able scientists are good. PROMOTION to higher grades depends basically on merit.

QUALIFICATIONS. Candidates should hold a First- or Second-class Honours Degree in Physics, Mathematics, or possibly Engineering. Senior Scientific Officer Candidates should be at least 26 and have had not less than three years appropriate postgraduate experience. SALARY SCALES are: S.S.O., £1,342 to £1,654; S.O., £738 to £1,222, but S.O.s with suitable experience may start above the minimum. Scales in London are somewhat higher. INTERVIEWS for appointment will be held in London. Forms from Ministry of Labour, Technical and Scientific Register (K), 28 King Street, London, S.W.1, quoting A.347/1A. Closing date October 24, 1961.

REPUBLIC OF THE SUDAN
MINISTRY OF EDUCATION

Applications are invited from those suitably qualified for the post of Vice-Principal of the Khartoum Technical Institute, Sudan. Candidates should hold a good university degree and preferably have higher qualifications and Associate Membership of one of the Engineering Institutions. A sound technical background and experience in a similar capacity is also desirable. The appointment would be on contract for a period up to five years, salary by arrangement according to qualification and experience. A cost of living allowance of approximately £S.187 per annum is also payable and an initial outfit allowance of £S.50 is paid on appointment. A house would be provided at an annual rent not exceeding 7¼ per cent of the official's salary. Leave would accrue at the rate of seven days per month. There is no income tax in the Sudan at the present time. (£S.1 equals £1 0s. 6d.)

Further information and application forms can be obtained from the Appointments Section, Sudan Embassy, 3 Cleveland Row, St. James's, London, S.W.1. Closing date September 30, 1961.

NATIONAL INSTITUTE for RESEARCH IN NUCLEAR SCIENCE

SENIOR MATHEMATICIAN

A senior mathematician is required to be the Head of a new mathematical laboratory which is to be built by the National Institute for Research in Nuclear Science at their Rutherford High Energy Laboratory, Harwell, to provide a service to the Atomic Energy Research Establishment, the Universities, the Rutherford Laboratory and Government Departments. The mathematical laboratory will have an "Atlas" computer and an estimated total staff between 30 and 40. Administrative services will be provided by the Rutherford Laboratory.

Under the direction of the Atlas Computer Committee of the National Institute for Research in Nuclear Science the duties of the successful applicant will be to plan and control:

(a) The setting up and running of the laboratory and the direction of the staff, including operational and programming staff and a small mathematics research section.

(b) The installation and operation of the Atlas computer and peripheral equipment.

(c) The arrangements for the use of the facilities by the Atomic Energy Research Establishment, the Universities, the Rutherford Laboratory and Government Departments, and for the sale of any spare time on commercial terms.

Candidates should have a good honours degree in mathematics, and must be capable of organizing a service to a wide variety of users on a fair and convenient basis. Extensive experience in the control of a mathematics laboratory and in the operation of fast computers is essential. A thorough familiarity with the major computational requirements of scientific research in the country would be a great advantage.

The post will carry a salary of not less than £3,350 per annum. There is a contributory superannuation scheme and assistance is given with housing.

Applicants quoting the names of two professional referees and giving brief details of career should be addressed to the Secretary, Rutherford High Energy Laboratory, Harwell, Didcot, Berks, from whom further details may be obtained.

MATHEMATICIAN

Team engaged in theoretical and applied petroleum research requires a Mathematician for further mathematical-model interpretation of engineering and geochemical problems involving extensive use of differential equations and numerical procedures. IBM-1620 and McBee LGP-30 computers available with access to larger machines when necessary. Participation in these projects with freedom to publish offers good opportunity for professional development.

Applications, with a résumé and an indication of salary required, should be addressed to: Research Council of Alberta, 87th Avenue and 114 Street, Edmonton, Alberta, Canada. Att: G. W. Hodgson, Petroleum Division.

WESTFIELD COLLEGE
(UNIVERSITY OF LONDON)
HAMPSTEAD, N.W.3
CHEMISTRY DEPARTMENT

Applications are invited for two appointments as Senior Research Assistant and Research Assistant to work on Optical Rotatory Dispersion. Salaries from £900 per annum (senior) and £600 per annum (junior) according to qualifications and experience.

Applications should be sent to Professor W. Klyne, Westfield College, Hampstead, N.W.3, from whom further particulars may be obtained.

A PHYSICAL CHEMIST REQUIRED BY Ministry of Aviation at the Rocket Propulsion Establishment, Westcott, Bucks, to lead small team investigating properties of materials at very high temperature with special emphasis on high temperature-resistant ceramics. Experience in the field of solid state physics advantageous. Appointment in grade of Senior Scientific Officer: minimum age 26. Qualifications: degree or Dip.Tech. with first- or second-class honours in chemistry or equivalent qualification, and at least three years' postgraduate research experience. Salary scale £1,342 to £1,654, with superannuation under F.S.S.U. Opportunity for candidates under 31 (normally) to compete for established (non-contributory pensionable) posts. Forms from Ministry of Labour, Technical and Scientific Register (K), 28 King Street, London, S.W.1, quoting F531/1A.

ST. BARTHOLOMEW'S HOSPITAL, London, E.C.1, requires Basic Grade Biochemist in October for work on steroids. This post is suitable for a graduate in biochemistry and will in the first instance involve routine chemical estimation of steroids. A suitable candidate will after a probationary period be able to assist in research and work for a higher degree. Salary £650 to £700 (plus London weighting) depending on qualifications.—Applications to the Clerk to the Governors, within fourteen days of the date of this advertisement.

INDUSTRIAL RELATIONS IN THE WELFARE STATE

IN his book, *Nationalized Industry and Public Ownership*, published last year, in dealing with labour relations, Prof. W. A. Robson wrote that those who emphasized the need to imbue the employees of public corporations with the spirit of public service were right from every point of view. Without it, nationalization cannot succeed, but we must not expect that nationalization by itself will transform the outlook or influence the motives of those who work in an industry. What we in Britain should seek is to awaken in the work-people a strong desire to serve the public as well as they possibly can, together with the desire to improve their own standard of living.

Prof. Robson recognized then quite frankly that for such aims to be realized the unions must be willing to abandon some of their most cherished prejudices and to change some of their obsolete practices; that they need to abandon their defensive negative, demanding attitude, conditioned largely by the capitalism which produced them, and display qualities of constructive leadership, understanding and co-operation with management. In this way they can respond to the challenge to co-operate in the administration of vast industries operated for the benefit of the community. Especially, he added, the unions need to improve the quality of their own officers. Even the largest and wealthiest unions are handicapped by a lack of skilled staff—economists, statisticians and research workers. They seem reluctant to appoint men who have had a university education, even when they are their own members who have won scholarships paid for by the union.

In the past year it has become more and more apparent that the unions, as Prof. Robson wrote, must consider the part they have to play in the sphere of nationalized industries, and recognize the need to revise their own organization, attitudes and practices so as to enable them to play it more effectively. Nor is this need confined to the nationalized industries. It is manifestly true of the shipping and shipbuilding industries, as was fully recognized in a debate on those industries in the House of Commons in July.

An admirable exposition of the function of labour and the trade unions in industry and commerce is contained in a paper by Mr. W. J. Carron, president of the Amalgamated Engineering Union, read before the Royal Society of Arts last December and now published (*J. Roy. Soc. Arts*, **109**, 248; 1961). Mr. Carron recognized the difficulty of apathy among union members, but here, as in the matter of restrictive practices, co-operation is necessary; and the better the understanding between the two sides of industry the more readily restrictive practices on either side, and perhaps also apathy, are likely to be removed. If there is one thing in fact that recent economic debates have emphasized, it is that trade unions, no less than other groups, whether scientists, technologists, teachers or others, are all part of the community and suffer with it when one section, luckier or less scrupulous than the rest, takes more than its fair share.

What is needed in fact is, as was admitted in the House of Commons, a climate of opinion which recognizes that higher wages or salaries must be earned and related to productivity; a system enlisting the co-operation of both trade unions and employers, making it in the interest of the unions to eliminate restrictive practices and the employers to show the maximum enterprise. To create such a climate of opinion or understanding is a major task, and might well be described as one objective of the industrial code which Lord Fleck advocated in his presidential address to the Industrial Co-partnership Association on July 9 and in a speech in the House of Lords on June 14. Studies such as that of Mr. D. F. Macdonald on *The State and the Trade Unions** are to be welcomed for the same reason, since they contribute to an impartial appreciation both of past mistakes and the action which now needs to be taken. Mr. Macdonald brings out particularly well the changed position of the unions in the social scene to-day, and the way in which the intimate concern to the community of their work and methods has stimulated such close scrutiny.

Mr. Macdonald does not intend to offer any constructive proposals. He shows that the trade unions cannot afford to ignore any attempts at a wage-policy and to condemn or belittle an independent body which studies and makes pronouncements on the wages question as part of a review of national economic considerations. The carping at the Council on Prices, Productivity and Income has probably done more harm to its trade union critics in the eyes of the public than to the prestige of the Council. Mr. Macdonald recognizes also that the principle of compulsory membership, or 'the closed shop', may call for safeguards to protect the individual as well as the public interest against group pressure; but he does not discuss the safeguards which from time to time have been suggested, and which might both safeguard the individual and offer a more effective redress of grievances that under present conditions are liable to result in unofficial strikes.

Some of these problems were considered in a debate on industrial relations in the House of Commons on March 17, when Mr. R. Marsh, in opening the debate, suggested that a rationalized trade union structure must precede the creation of a wages structure. He also maintained that most of the problems arose from a lack of joint consultation and of understanding on both sides. Sir Richard Glyn agreed that a more rational trade union movement is essential for a planned industry and a planned economy, but probably the keynote of this debate was the stress laid by both sides of the House on training for management. The right type of management—the right kind of men and the right kind of spirit—is an essential element. Although the limitations of management were equally recognized in this constructive debate, it was clear that given management of this type, there would be no failure to tackle the problem of re-training skilled men whose skills were made obsolete or redundant through technological advance.

---

* The State and the Trade Unions. By D. F. Macdonald. Pp. vii + 199. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1960.) 21*s*. net.

The recognition of the importance of sound industrial relations to the economic life of Britain and to the maintenance and improvement of the British standard of living obviously lies behind the idea of an industrial code which Lord Fleck proposed in the House of Lords debate on co-operation in industry. Earlier, in his Fawley Lecture, Lord Fleck had suggested that if at least ten universities, including colleges of advanced technology, were to develop departments specifically concerned to promote good industrial relations, it would be worth while attempting from such sources to draft a broad measure of industrial philosophy. Once again, in the debate in the House of Lords, there was a good deal of stress on education on both sides, Viscount Amory calling for positive and dynamic co-operation and team-work, for spontaneous respect and concern for efficiency, and for pride in the job, both individually and collectively; and Lord Citrine, who doubted whether there are really any new methods open to us in combating apathy, suspicion and hostility in this field, thought that the decisive factor is to re-establish the leadership of the Trades Union Congress.

This large measure of agreement on both sides as to the need for a fuller understanding of these problems, for a climate of opinion in which more effective co-operation could flourish and for inspired leadership was reflected in subsequent debates on the economic situation in both Houses of Parliament. Mr. Hugh Gaitskell, in a notable speech on July 18, appealed for an attack on the complacency of some managements and the appalling indifference of some workers, and the conditions which foster such situations. He recognized that this was much harder than the adoption of a greater measure of planning, the more positive attitude to particular industries, or the increased degree of professionalism in business and exporting on which he also insisted. To some extent the Government has already moved in this direction, but it cannot fairly be claimed that the Government has yet provided the leadership which is needed and which was even more powerfully adumbrated by Mr. Harold Wilson in speaking on the economic situation on July 26. The necessary climate of opinion is not to be created by appeals to materialism, selfish acquisitiveness, or social emulation. There must, he argued, be some planning, but we need also a sustained increase in production and greater determination to control rising costs; and he admitted frankly that we cannot afford, year by year, an increase in economic rewards—profits, salaries, rents or wages—greater than the increase in productivity which provides the means to all rewards.

This is, of course, an argument for giving much higher priority to increased productivity, and Mr. Wilson believes that it is well within the capacity of Britain to achieve an increase, year by year, of 4 or 5 per cent in productivity and of 4 or 5 per cent in wages. It was as part of a wide attack on the spirit of lethargy which pervades too much of British industry that he advocated the ending of restrictive practices wherever they occur which hold back the national inventiveness and skill, and it is in this context that the trade unions must be regarded to-day. Mr. Nigel Birch, in the same debate, made an equally forthright appeal for an attack on industrial inefficiency, wherever encountered, and for a policy of encouraging understanding by the fullest possible publicity. Mr. R. Carr also stressed this need for the consistent and clear exposition of policy and for a far-reaching attack on restrictive practices. He made, too, a number of constructive suggestions for dealing with the shortage of skilled labour and encouraging companies which are progressive and adventurous, and some of these suggestions were welcomed on the Opposition side of the House.

These suggestions, however, are scarcely relevant in the present context. What is relevant, however, is the measure of agreement between political parties as to objectives and as to the need for the Trades Union Congress to play its part and secure the shedding by the unions of outmoded practices and ideas. That is admittedly essentially a matter for the unions themselves, and whether Parliament can do anything to help, that can only be done with their co-operation. In his classic work on *The English Constitution*, Walter Bagehot wrote of the House of Commons that its teaching function was the one which was worse performed: "A great and open council of considerable men cannot be placed in the middle of a society without altering that society. It ought to alter it for the better. It ought to teach the nation what it does not know".

In some of its recent debates—on science and on economic affairs, for example—the House of Commons has shown the extent to which, even in the conditions of to-day, it can exercise that educative function. It can still do much to create public understanding. It could go far to create the climate of opinion which will accept the harsh measures that may be needed. When leadership is not forthcoming from the Government, it may well be able once again to stimulate it as well as elicit the response required to sustain the measures of policy that a situation demands. Further, the trade unions themselves may well provide a classic example of the way in which Parliament through its educative function may stimulate both the leadership needed and the support which will make the appropriate measures effective. At a time like this, the Parliamentary and Scientific Committee has something to contribute to this educative function of Parliament. It is partly a means of informing Parliament, and professional men should be careful to use it responsibly and imaginatively to the maximum extent; but it is also a means through which Parliament can exercise that function in a wider if specialized field.

BALLISTIC MISSILE AND SPACE TECHNOLOGY

Ballistic Missile and Space Technology

Proceedings of the Fifth Symposium held at Los Angeles, California, August 1960. Edited by Donald P. LeGalley. Vol. 1: Bioastronautics and Electronics, and Invited Addresses. Pp. xiii + 494. Vol. 2: Propulsion and Auxiliary Power Systems. Pp. x + 439. Vol. 3: Guidance, Navigation, Tracking, and Space Physics. Pp. x + 450. Vol. 4: Re-entry and Vehicle Design. Pp. x + 422. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 9 dollars per volume; 36 dollars per set.

A SERIES of symposia on ballistic missile technology was started in June 1946 by the Ramo-Wooldridge Corporation and the Ballistic Missile Division of the United States Air Force; the fifth symposium was held in August 1960 at the University of Southern California in Los Angeles. To those who know the extensive campus of this University and the enormous size of the United States missile industry it will be no surprise to learn that more than one thousand scientists and engineers from all parts of the United States attended this symposium, at which seventy-four unclassified and fifty-one classified papers were presented after selection from two hundred and fifty-five manuscripts submitted. It has become a feature of the United States' so-called 'aerospace' programme that huge gatherings of scientists come together at frequent intervals for the presentation of papers covering a field so vast that it is obvious that no single participant could appreciate more than a small fraction of the specialized subjects involved. Since most of the time at symposia is spent in discussion outside the formal sessions, this plethora of papers is perhaps of little importance. Another feature is, however, of more serious significance, and the four volumes which report in full the proceedings last year exhibit it only too clearly. The frequency and size of these gatherings are now so great that there are just not enough papers of good quality to go round; difficulties with military security no doubt also play a part. The result is a number of contributions of limited interest, which explore in detail some byway which only the author really wishes to tread.

Nevertheless, the present volumes of proceedings are, in total content, of considerable interest and value to workers in missile and satellite technology. This is especially so as the editor and publisher succeeded in producing them within a very few months of the actual conference, thus allowing us to gain an up-to-date view of the extremely varied topics which are the concern of the industrial, government and university research laboratories and development teams engaged in U.S. ballistic missile and space activities. The emphasis throughout is towards space topics; this is shown by the fact that only twenty-two out of the seventy-four papers deal with subjects which have any significant relevance to non-space missile applications. Few of the authors take a basic approach to their subject although here and there one finds interesting items such as the study reported in Vol. 1 of an experimental investigation of gyro spin-axis bearing lubrication; or the careful theoretical treatment of the equations of motion of a satellite in a gravitational field with particular reference to attitude stabilization and control system analysis in Vol. 3. Vol. 1 is devoted to bioastronautics and electronics and includes also the general addresses given to the symposium by such prominent speakers as Dr. T. Keith Glennan, John H. Rubel, General Bernard Schriever and Dr. Simon Ramo. A topical note is struck by Ramo, in a style familiar to all who have known him during the past fifteen years in the missile business, by his paper on "The Life and Times of the Crash Program". This diverts attention from missiles to the great and growing need for improvements in United States' educational methods, the shortage of teachers and the potential applications of electronic teaching devices for technical subjects; one awaits the howl of protest from protagonists of the humanities against this further indication of the narrowness of scientific educational methods. Vol. 2 covers propulsion and auxiliary power systems; Vol. 3 guidance, navigation and space physics. Re-entry and vehicle-design problems are dealt with in Vol. 4.

The text is reproduced by the photo-lithographic process; illustrations and diagrams are clear and graphs are particularly well reproduced with scales which allow accurate interpolation. W. H. STEPHENS

TECHNOLOGY OF CHEMICAL PROCESSING

Encyclopedia of Chemical Technology

Edited by Raymond E. Kirk and Donald F. Othmer. Second Supplement Volume edited by Anthony Standen. Pp. xi + 970. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 175s.

CHEMICAL technology preserves its position at the spearhead of advancing standards of living. Not only has man distinguished himself as a toolmaker, but also he is an enthusiastic converter of the materials in his environment. Chemical reaction, chemical plant and processing are all basic to this vast enterprise of our era.

The very range of chemical technology makes it extremely difficult for a worker to find readily information related directly or indirectly to his pursuit. Established work in physics, chemistry, applied mathematics and even biological science is of interest to him. Knowledge of these is likely to result in unexpected innovation. For example, the theory of turbulent diffusion has enabled those concerned with the dynamics of chemical reactors to refine the calculations for their designs. Often such refinements lead to simpler methods of operation, better yields and improved quality of products.

As a compendium of information for chemical technologists, the Kirk–Othmer encyclopædia is maintaining its traditional calibre, with the appearance of a second supplementary volume. The function of these supplements is to deal with recent developments. This is done in a comprehensive yet fairly readable manner. The range of material and level of appeal are extensive. Fundamental theory is presented; so too are various chemical processes, modern unit operations, techniques for analysing problems in processing, and there is also information which should be of interest to the technologist concerned with economics and planning. Since there are fifty-eight articles, a few selected more or less at random will help to illustrate the diversity.

The comparatively new field of irreversible thermodynamics is discussed by H. Balescu, very appropriately, since the Belgian school has been very active in promoting this work. He shows how the equations of change are used together with Gibbs's fundamental formula of classical thermodynamics in deriving a formulation for production of entropy. This expression, bilinear in the forces and the flows caused by them, is the central concept in irreversible thermodynamics. Onsager's phenomenological principle is described, followed by a section on application. We see that in cases where chemical kinetics becomes so complicated that it can no longer be used exactly, thermodynamics can be a valuable tool in providing a relationship between rate-constants.

A chemical process of great technological importance these days is the manufacture of halogenated butyl rubber. This confers properties such as resistance to degrading by oxidation, adherence and ability to co-vulcanize with other polymers. Yields and mechanisms of reaction are described for processes involving various halogenating agents; methods of curing with zinc oxide and amines are discussed.

Another commercial enterprise of note is the manufacture of polypropylene. Production of crystalline polymers on an industrial scale began toward the end of 1957. Chemical and physical properties are discussed; a very useful table shows a comparison of polypropylene and high-density polyethylene. In the section on Ziegler-type catalysts it is interesting to note that the question whether growth of polymer occurs on the transition metal or on aluminium is still obscure. Effects of processing variables on polymerization are discussed; so too are techniques of moulding and extruding the final products.

A unit operation which promises to become a standard technique in chemical technology is that of separation by diffusion. An article deals with separation, usually of helium or hydrogen, by diffusion through membranes composed of a substance in the glassy state. The theoretical treatment is particularly good.

The use of radioisotopes for analysing the operation of chemical processes is described. Apart from the determination of levels of liquids or fluidized solids in vessels, continuous chemical analyses can be carried out; they are also used to detect leaks in buried pipes or in heat exchangers. Another application is to investigate the extent of reverse flow in chemical reactors.

An example of information useful to the industrial economist is an article on synthesis gas. After a description of various processes, which includes typical data indicating performance of the gas, the investment needed to produce hydrogen is shown graphically as a function of rates of production.

This supplementary volume certainly has a wealth of information, and may be recommended to the chemical technologist, whatever his pursuit. It is a pity that 'technologese' is not avoided throughout the book; one flinches, for example, at reading the word 'recognization'.

R. H. VILLET

AMINO-ACIDS

Chemistry of the Amino Acids

By Jesse P. Greenstein and Milton Winitz. Vol. 1: Pp. xxi + 1–760*d*. Vol. 2: Pp. xi + 761–1816*b*. Vol. 3: Pp. xiii + 1817–2872. (New York and London: John Wiley and Sons, Inc., 1961.) £40 the three volumes.

A NEW comprehensive treatise of more than 2,800 pages on the chemistry of amino-acids is a major event in the chemical and biochemical literature. The first text-book in the English language specializing on amino-acids was *The Biochemistry of the Amino Acids*, by Mitchell and Hamilton, published in 1929. It was a book of 600 pages, and more than half of it was concerned with physiology and biochemistry. Nine years later its place was taken by *The Chemistry of Amino Acids and Proteins*, edited by C. L. A. Schmidt, a treatise of a little more than a thousand pages written by a team of eighteen authors. In 1951, D. M. Greenberg edited a similar multi-author text-book on amino-acids and proteins of about 900 pages which included the metabolic aspects. After an interval of ten years in which the literature has grown at an exceedingly rapid rate, the late Dr. Jesse P. Greenstein, in collaboration with Dr. Milton Winitz, has written a new monumental work, arranged in three volumes and fifty-two chapters. The approach is essentially that of the organic chemist, and unlike its predecessors it deliberately omits most aspects of metabolism as this field has been recently dealt with in Dr. Alton Meister's book published not long ago from Dr. Greenstein's laboratory.

The bulk of the work deals with the physiologically occurring amino-acids but a number of related substances are also discussed, and apart from the purely chemical features a few physiological aspects, for example renal clearance and active transport, are included. The first of the three volumes deals with the general and physical chemistry of amino-acids. There is a full discussion of nomenclature, classification and configuration. The physical chemistry covers *inter alia* the dipolar ion concept, thermodynamics and solubility. Other chemical features which are extensively described are the metal complexes in which amino-acids take part, salt formation, effects of radiation, the general principles of α-amino-acid synthesis and of the resolution of isomers. The second volume covers chemical procedures for the synthesis of peptides, the analytical procedures including manometry, titration methods, isotope dilution, chromatography, micro-biological assay and spectrophotometry. The sequential analysis of peptides is also extensively treated. One chapter deals with the enzymes involved in the determination, characterization and preparation of amino-acids. The third volume is mainly concerned with a description of the preparation of the individual amino-acids. Apart from the protein-bound amino-acids there is an exhaustive treatment of other amino-acids and their derivatives. These include the large number of new amino-acids which have been discovered in biological material in recent years, thanks largely due to the chromatographic techniques and to the isolation of numerous special peptides and proteins produced by micro-organisms (for example, antibiotics).

The senior author unfortunately did not live to see the publication of this book. He died suddenly in February 1959 as a result of a cerebral hæmorrhage when the book had been virtually completed. A brief biographical sketch by the junior author prefaces the book and imparts something of the unusual gifts of the mind and character of the senior author. The book bears throughout the mark of Dr. Greenstein's distinguished style, outstanding in its clarity, accuracy, liveliness, elegance and beauty. A sample of this, conveying also the intentions of the authors, is the following passage from the preface:

"Let it be admitted that we have been entranced by the spectacle of these many and diverse phenomena. In attempting to transfer these pleasurable emotions to paper, and to portray accurately the work of so many able investigators, we were well aware of the magnitude and difficulty of the task which we set for ourselves, and of the impossibility of perfection. With filial piety and in justice to those who have built this field, as well as to convey a sense of perspective, we have stressed where we could the historical development of each subject. The literature of science is generally curt and colorless, except when enlivened at times by the statement of controversial opinion; on occasion an expression of notable and graceful generosity or of far-seeing imagination finds its way into this literature, and such examples have been quoted where pertinent in the pages to follow. The topics covered in this work have generally been those wherein a certain stability has been attained and are thereby suitable for comprehensive treatment—not that progress has ceased in such topics, but rather that nothing has so far emerged to render any substantial portion of them obsolete or questionable."

The references to the historical developments and the quotations from earlier writers are a particular asset of the book. Those from foreign languages are given in the original, with a translation in an appendix of the book. They add to the enjoyment and interest of a standard work which for many years to come will be an invaluable source-book. H. A. Krebs

INORGANIC CHEMISTRY

Inorganic Chemistry

By Jacob Kleinberg, William J. Argersinger, Jr., and Ernest Griswold. Pp. viii+680. (Boston: D. C. Heath and Company; London: George G. Harrap and Co., Ltd., 1960.) 75*s*. net.

The past few years have witnessed radical changes in the teaching of inorganic chemistry to undergraduate classes. These may largely be attributed to a fruitful interaction, at the research level, between physical and theoretical chemistry on one hand, and descriptive inorganic chemistry on the other. It has thus been possible to stimulate the undergraduate by presenting inorganic chemistry as a subject which makes full demands on his powers of comprehension and reasoning.

A new single-volume text on inorganic chemistry is therefore to be welcomed at this time. Drs. Kleinberg, Argersinger and Griswold have attempted to tackle the subject so as to reflect these present-day changes in its teaching. To this end, the book is divided into three parts. Part 1 (211 pages) is devoted to a brief account of the development of atomic theory, to elementary quantum mechanics, then on to the problem of the electronic configuration of atoms and the consequence of this on chemical and physical properties, especially from the point of view of chemical periodicity, and finally a section on chemical binding and molecular structure. Part 2 (80 pages) is entitled "Some Aspects of Chemical Behaviour", and consists of two chapters, on co-ordination compounds and a particularly good one on acid-base relationships and reactions in non-aqueous systems. Part 3 is divided into three sections. The first deals with the representative elements (196 pages), the second (136 pages) with the transition elements (the descriptive chemistry is presented here with more detail than is usual), and the third (58 pages) with the lanthanides and actinides.

The authors have deliberately chosen to omit sections on nuclear chemistry, the inert gases, and organo-metallic compounds. The last of these topics was considered to be one which, in order to have covered it adequately, would have increased the scope and size of the text beyond limits that they had set themselves. I feel that this decision was unfortunate. The field of organo-metallic chemistry is one which has in many ways been in the forefront in the recently much talked of renaissance of inorganic chemistry, and its inclusion in this text need not have occupied more than 30 or 40 pages. I would also have wished to see sections on crystal chemistry, physical methods of structure-determination (for example, infra-red, visible, and ultra-violet spectra are rarely mentioned), and reaction mechanisms. Very few of the discoveries or developments of the past five years are included. The problem of bonding is dealt with almost wholly in terms of valence bonds and the treatment is obsolete in many instances. In addition, it would have been preferable to have introduced much more physical and theoretical chemistry into Part 3 and thus emphasize the essential unity of the subject.

The authors are to be congratulated on the general presentation of their book, which is well written. It can, with few reservations, be recommended for use at least up to Part 1 honours B.Sc. standard.

M. F. Lappert

A MUCH-STUDIED PROTOZOON

The Biology of Stentor

By Vance Tartar. (International Series of Monographs on Pure and Applied Biology. Division: Zoology, Vol. 5.) Pp. x+413. (London and New York: Pergamon Press, 1961.) 75*s*. net.

The ciliate protozoon *Stentor* is large enough to be operated on by hand (with skill) and is remarkably amenable to surgery. For these reasons it has been the object of numerous morphogenetic studies, culminating in Tartar's own outstanding contribution. As the author of this book, Tartar shows his over-riding interest in cell morphogenesis.

Fission, re-organization (the "physiological regeneration" of Schwartz) and regeneration are related, in that each involves the formation of new adoral membranellæ (which appear as a primordium) and mouth structures and the fusion and renodulation-of the macronucleus. Although the study of *Stentor* has contributed important information about the mechanism of cleavage, the events leading to fission have not been elucidated. More is known about re-organization and regeneration. Tartar rejects several theories and concludes with Schwartz that re-organization is induced by a certain departure from the normal macronucleo-cytoplasmic ratio and permits a re-adjustment. He does not reveal whether this re-adjustment is merely one of area, or how it affects the quantities of deoxyribonucleic acid and other macronuclear constituents. Regeneration is induced by damage to the feeding organelles or when these are defective. Tartar interprets grafting experiments in terms of two cytoplasmic states: activation, which favours the formation of a primordium, and inhibition, which blocks this process. The fusion and renodulation of the macronucleus and mitosis of the micronuclei are considered by Tartar to be set in motion by the onset of cytoplasmic activation, for which the presence of the macronucleus is itself necessary. There is some evidence to suggest that the differentiation of mouth parts at the posterior end of the primordium is induced by the surrounding protoplasm, probably in relation to a gradient.

Perhaps Tartar's greatest achievement concerns the induction of the primordium itself. The precise localization of the primordium in relation to the pattern of stripes in the ectoplasm had already been noted by earlier workers, but Tartar has postulated that a primordium is formed in a region of contrast in stripe width, and has adduced effective experimental evidence in support of this hypothesis. This brings us back to gradients within the cell cortex, and so to the kinetosomes, linearly ordered, prolonged outwards as cilia, presumably themselves the site of important aspects of ciliary activity, and thus perhaps the dominant feature in cell gradients and 'molecular ecology'. All these and other aspects of morphogenesis are treated very fully; Tartar's book is of the nature of a detailed, lucid, and comprehensive review of these topics.

What then of other aspects of the biology of *Stentor*? These are in general summarized very competently and usefully from the literature, though with something slightly less than the critical approach of the cytophysiologist. Even the arrangement is peculiar. Behaviour is treated rather well near the beginning, followed by fine structure, including contractility; but ciliary co-ordination is exiled to a hotch-potch chapter far removed. Some important aspects of fine structure are summarized in a single stereogram; but it is doubtful whether the reader can appreciate or assess the evidence without electron micrographs such as those by Randall and Jackson. Sleigh's work on membranellar beat is faithfully retailed, but the co-ordination of body cilia is quite inadequately discussed, with no mention of the possibility of surface depolarization and no reference to pertinent work on other Protozoa.

Considerable space is given to the function of the macronucleus and to interspecific grafts, and useful comparisons are drawn with experiments on amoebae. The species of *Stentor* are briefly but usefully described and are illustrated in colour. In the penultimate chapter the simple secrets of microsurgery are very helpfully revealed.

This book is well produced apart from a number of obvious misprints. Tartar writes concisely and has given us excellent measure. *The Biology of Stentor*, though a book for the specialist, is indispensable to every zoological, cytological and embryological library, and many professional cytologists and protozoologists will want to own it. J. A. KITCHING

BASIC APPROACHES TO STRUCTURAL ANALYSIS

Energy Principles in Applied Statics

By T. M. Charlton. Pp. vi + 112. (London: Blackie and Son, Ltd., 1959.) 25*s*. net.

IN many institutions a student learns to determine the deflexion of nodal points in a pin-jointed framework and the forces in members of a statically indeterminate framework by use of Castigliano's theorems. There is no doubt that many students (and engineers) never realize that the solution is valid only when the load-deflexion relationship for the particular structure is linear. For most of the materials and proportions encountered in traditional practice, this assumption can be made with confidence and, frequently, the various design codes which an engineer must follow have implicitly made the initial step. With the development of new materials, and with the increasing awareness by the structural designer of the importance of ranges of mechanical behaviour outside those previously considered, it is desirable that the teaching schools, and the practising engineers, should look more closely at the fundamentals of the methods of analysis used.

During the past ten years, Mr. Charlton has been the author of a number of articles in the technical Press, in which he has treated several of these fundamental theorems of classical analysis. His recent book brings together much of that early work, and, by concentrating on the simplest plane pin-jointed systems, emphasizes the concepts involved in the basic equations of structural equilibrium and compatibility, and directs attention to the general applicability of approaches to analysis using complementary energy and the method of virtual work.

The differences between the various approaches may not be apparent in some cases to a superficial reader, and five of the seven chapters conclude with brief paragraphs which place each section in its proper position within the framework of the whole text. Many readers would prefer that these signposts occurred at the beginning rather than the end of the course, and at both, rather than either; but since the halting places are so well chosen the point becomes one of minor significance only.

Throughout the text the author speaks in terms of stiffness and flexibility coefficients and the final chapter is devoted mainly to the properties of these coefficients for linear systems. These concepts are becoming increasingly valuable with the introduction of the electronic computer in structural analysis, since the necessary equations may be set up in a systematized manner and lend themselves to solution by matrix methods on the machine.

The book is no vade-mecum for practising structural designers and does not purport to be. It would be, however, of great benefit to the good student and, one suspects, to most teachers of the theory of structures for, with both, fundamental principles are frequently obscured by an undue concentration on the techniques of analysis.

R. C. COATES

Pulp and Paper

Chemistry and Chemical Technology. By James P. Casey. Vol. 2: Papermaking. Second edition, revised and enlarged. Pp. xxiii + 581–1249 + 147. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 188*s*.

THE scope of the second volume of this work is indicated in the review of Volume 1 (*Nature*, **190**, 380; 1961). Much the same general comments apply to Volume 2. Thus, British readers will be surprised at the absence from the chapter on fibre bonding of any reference to the important 1957 Cambridge symposium on that subject.

However, this should not be allowed to detract from a recognition of the general excellence and high standard of this work as a whole. It contains a tremendous amount of information of a fundamental nature covering paper-making operations from stock preparation to supercalendering, and taking in water usage and disposal, microbiological considerations and beater and wet-end additives.

Incidentally, it is completely self-contained in its subject-matter, so that there is no necessity to possess Volume 1 in order to derive the fullest benefit from Volume 2. This fact may appeal to many in Britain who are more interested in paper making than in pulping and to whom the cost of these books must appear very high.

JULIUS GRANT

Gas Chromatography Abstracts, 1958

Pp. vii + 262. 42*s*.

Gas Chromatography Abstracts, 1959

Pp. ix + 164. 42*s*.

Edited by C. E. H. Knapman, assisted by C. G. Scott. Sponsored by the Gas Chromatography Discussion Group associated with the Hydrocarbon Research Group of the Institute of Petroleum. (London: Butterworths Scientific Publications, 1960.)

THE two volumes of gas chromatography abstracts have been sponsored and prepared for publication by the Gas Chromatography Abstract Editorial Committee of the Gas Chromatography Discussion Group. The first is a combination of bibliographies compiled independently by three members of the Committee and covers the literature until the end of 1958. The 1,468 abstracts are listed alphabetically according to the first author. Considering the somewhat limited resources, reliance has had to be placed on abstracting journals particularly in connexion with foreign publications. This cannot be said of the second volume, which is compiled from abstracts obtained from 28 abstractors who between them have covered more than 110 journals. Although no precise date is given, the 717 abstracts in this volume appear to cover the literature until the end of 1959.

The abstracts in both volumes, although short (averaging 30–50 words), are very concise and to the point. Easy reference is made possible by author and subject indexes, the latter in particular being most comprehensive, enabling a complete survey of the literature on any topic to be carried out with great rapidity. Although the difficulties of compiling works of this type must be very great, few errors appear to have crept in. One criticism, however, is the frequent omission of any indication of the language of the article abstracted.

These volumes were compiled by the voluntary efforts of gas chromatographers, who, seeing a need for an efficient abstracting system, pooled their resources and produced their own. Their achievement deserves the highest praise and will certainly be welcomed by many wishing to keep abreast of this rapidly expanding field.

A. GOLDUP

South African Animal Life

Results of the Lund University Expedition in 1950–1951, Vol. 7. Edited by Bertil Hanstrom, Per Brinck, and Gustaf Rudebeck. Pp. 488. (Stockholm: Almqvist and Wiksell, 1960.) 75 Sw.kr.

VOLUME 7 of *South African Animal Life*, in which results of the Lund University Expedition (1950–51) are reported, maintains the high standards of the previous volumes in this series. Groups dealt with are preponderantly from among the Coleoptera, Diptera, Hymenoptera and Hemiptera. There are also chapters on the Oligochaeta, Decapoda, Crustacea and on the Isoptera. The authors are again recruited from many countries and seats of learning, and of the twenty-seven articles three are written in French, eight in German and sixteen in English.

O. LOWENSTEIN

A Collection of Tables and Nomograms for the Processing of Observations made on Artificial Earth Satellites

By I. D. Zhongolovich and V. M. Amelin. (Mathematical Tables, Vol. 12.) Issued by the Institute of Theoretical Astronomy, Academy of Sciences of the U.S.S.R. Pp. iv + 188. (London and New York: Pergamon Press, 1961.) 100*s*. net.

THIS volume is a welcome addition to the very few existing mathematical tables which are designed to help in the calculation of artificial satellite orbits. The main table gives the true anomaly and the ratio of radial distance to semi-major axis, for a complete range of values of both mean anomaly (at 1° intervals) and eccentricity (from 0 to 0·76 at intervals of 0·01). Other tables give period and semi-major axis in terms of the mean angular motion, solutions of the equations used in calculating geocentric latitude and longitude, and the main secular perturbations of orbits. Finally, there are nomograms to determine the angle of elevation of a satellite. The intervals of tabulation and the number of figures in the tabulated quantities have been well chosen, and the layout of the tables is pleasing.

The tables themselves have been reproduced from the Russian original by a photographic process, and only the 10 introductory pages needed translating. Despite its minimal contribution to the subject-matter, the Pergamon Press has chosen to charge £5 for the volume, although it was advertised at 70*s*. This high price would be more justifiable if the 10 introductory pages were perfect, but they are not. There are irritating errors, such as the inconsistency of printing the symbol v as a Greek ν in the introduction but not in the tables. Also, the translation is at times sadly deficient. For example, the key sentence defining the units—"n is expressed in degrees per mean solar day and is given to 0·01 min. . ."—is nonsensical because of the omission (after 'day') of some 15 words, which give the tabulation interval for n and state that the orbital period is in minutes. These shortcomings do not, however, seriously mar the value of the volume to the specialist.

D. G. KING-HELE

STRUCTURE OF THE NORTHERN APENNINES

By Sir EDWARD BAILEY, F.R.S.
Formerly Director of H.M. Geological Survey
AND
Prof. W. J. McCALLIEN
University College of Ghana

IN 1957 we spent a full month in Florence, Spezia and Levanto, and have paid a few shorter visits since. In addition we have made an intensive study of publications, especially sheets of the Italian Geological Survey 1 : 100,000 map. We also have had the advantage of discussions with Prof. G. Merla and Dr. A. Valduga at the University of Florence; and we are specially grateful to the latter for conducting us over the exposures of the famous Carrara window. As a result of our inquiry we have come to conclusions that are in some respects novel. We consider that the rocks of the Northern Apennines, in large part Ligurian, can be conveniently assigned to four structural units as follows:

(1) The lowest unit is only seen in the Carrara window. Its rocks, as exposed, reach from Palæozoic, through Mesozoic to Tertiary, with a Miocene greywacke, termed Macigno, as their top member. The window interpretation advanced by S. Lencewicz[1] is now accepted by everyone.

(2) The next unit frames the window, and is widely, though intermittently, exposed in all directions therefrom. Its rocks, like those of unit 1, reach from Palæozoic through Mesozoic to Tertiary, with Miocene Macigno as top member.

(3) Above comes the Ligurian nappe, an old name, but used by us here in a somewhat extended sense. Its main rocks are a Jurassic submarine volcanic group, a Cretaceous shale group and an Eocene limestone, called Alberesi; and there is locally a further repetition of Macigno. The volcanic group, in addition to gabbro and ash, abounds in serpentinite, pillow-lavas and radiolarian chert, an assemblage which, here and elsewhere, has been called the Steinmann trinity. Detached masses of these rocks, sometimes of mountainous proportions, sometimes mere boulders, are distributed over an area measuring 200 km. by 100 km.; and everywhere they manifestly overlie Tertiary sediments, the Macigno of unit 2. They were for many years supposed to be themselves Tertiary, until Steinmann[2] demonstrated their Jurassic age. Ever since, they have ranked as particularly clear examples of older rocks transported for an amazing distance over younger rocks. Steinmann, coming from the complicated Pre-Alp nappe of Simmenthal in Switzerland, regarded the transport as a subterranean tectonic operation, a view with which we agree.

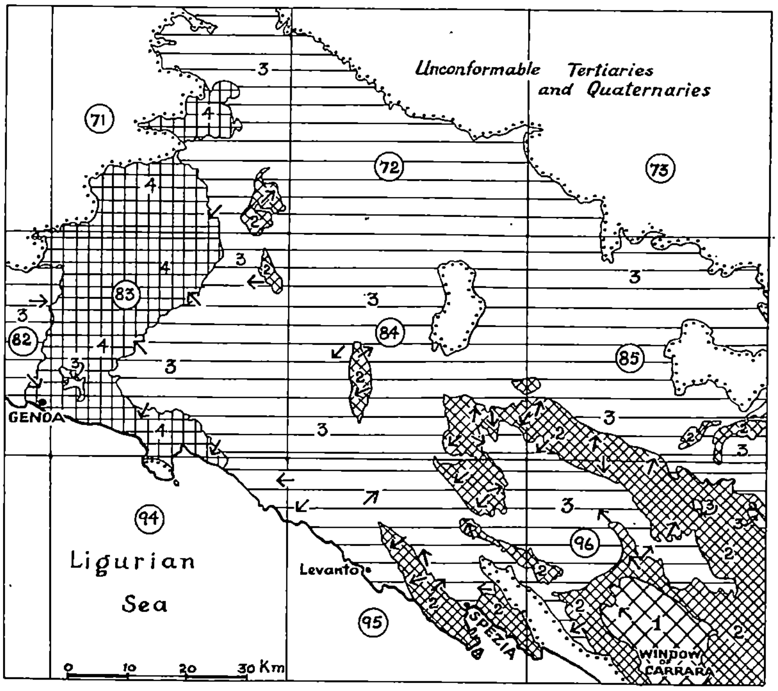

Fig. 1. Geological map showing four structural units in the Northern Apennines. Numbers in circles refer to map sheets of Italian Geological Survey 1 : 100,000. The other numbers are those of the structural units

A difficulty concerns the remarkable discontinuity of the igneous outcrops. L. W. Collet[3], a specialist in nappe structures, attributed their separation in large measure to erosion, and has called them klippes, in the sense of the klippe outliers of the Lucerne district of the Alps. This is clearly a mistake, for the masses, large and small, lie already separate in a matrix furnished by the Cretaceous shale, itself broken to pieces. The whole constitutes a *mélange* in the sense E. Greenly has applied the term to the Gwna *Mélange* of Anglesey. C. I. Migliorini[4], followed by Merla and others, has gone on to interpret the Ligurian *Mélange* as a product of superficial stage-by-stage landslipping, supposed to have taken place from a series of anticlines, uplifted successfully farther and farther to the north-east.

A strong objection to this interpretation is, in our opinion, furnished by the restriction of the igneous enclosures to the shale outcrops, where they occur by the thousand. They are very seldom, if ever, found in the associated, far-travelled, and supposedly land-slipped Alberesi. Our view is that the *Mélange* is due to underground flow of the mobile shale material during nappe formation. Another argument against the superficial landslip interpretation follows from unit 3 showing a layered structure within itself, which can be traced through a succession of folds, persisting for many kilometres. Thus in the frame of the Carrara window the structural succession in unit 3 is Ligurian *Mélange*, on Alberesi, on Ligurian *Mélange*, on Macigno of unit 2; while on the two sides of the Spezia anticline (see Sheet 95 of the Italian map) Alberesi is poorly represented, and the structural sequence is, broadly speaking, Macigno, on Ligurian *Mélange*, on Macigno of unit 2.

(4) The top unit may be called the Genoa nappe, and consists of a great sheet of Alberesi, strikingly discordant to the contents of unit 3.

We hope shortly to furnish detail sufficient to establish the truth of the above outline sketch. Meanwhile, like P. Fallot, we may direct attention to a recent account by T. Rocco[5] of boring and geophysical exploration in the Po Valley in pursuit of oil. The Po Quaternary sometimes exceeds 2,000 m. in thickness, and the late-Tertiaries below it furnish another 8,000 m. These sediments are gently folded and are supposed to occupy the foredeep of the Apennines. If so, we suggest that the Po Valley is homologous to the Swiss Plain, and that the articulation of the Alps with the Apennines is homologous with the articulation of the Juras with the Alps.

ORGANIC CONSTITUENTS OF METEORITES

By MICHAEL H. BRIGGS

Department of Chemistry, Victoria University of Wellington, New Zealand

PROF. J. D. BERNAL has recently commented[1] on the significance of carbonaceous meteorites in theories on the origins of terrestrial life. He points out that the reported[2] organic constituents of these meteorites may have played a part in the formation of life on Earth, or may be derived from some extra-terrestrial life-form. Alternatively, the meteorites could be fragments of Earth that broke away before the development of life, but after the abiotic formation of the complex compounds that are widely assumed to have given rise to the first terrestrial life-forms by a process of chemical evolution.

In this article I wish to discuss my own analytical results on a carbonaceous meteorite, and then to attempt to assess the available evidence concerning the origin and importance of meteorite organic matter.

Investigations of the organic constituents of meteorites have so far revealed materials of little biochemical interest. This could be due to the methods of extraction. Mueller, for example, removed compounds from the Cold Bokkeveldt meteorite with a variety of organic solvents, while Nagy *et al.* resorted to high-temperature distillation. Yet biochemicals are characteristically very soluble in water, and Calvin *et al.* have shown that some of the carbon in both the Orgueil and Murray meteorites is removable with water. With this in mind I have prepared hot-water extracts of a carbonaceous meteorite that fell at Mokoia, near Wanganui, New Zealand, in 1908.

The Mokoia meteorite consists mainly of two pieces (Fig. 1), with a total weight of approximately 10 lb. These two stones were found two days after impact. Consequently there is no chance that they picked up organic matter by prolonged contact with the soil. Since discovery the meteorite has been in the Wanganui Museum. The circumstances of discovery[3], together with the chondritic structure (Fig. 2), render the meteoritic nature of the stones unquestionable. Additional evidence is provided by the chemical composition (Table 1) and the X-ray diffraction analysis (Fig. 3).

Small samples of the meteorite have been supplied by the New Zealand Geological Survey. These fragments have been extracted by the following method:

The sample was first washed with distilled water and the upper 2 or 3 mm. removed from all over the surface by abrasion. In this manner the chances of extracting any surface organic compounds picked up by the stones from perspiration were minimized. The remainder of the sample was crushed to a fine powder by pestle and mortar, and the powder extracted with distilled water in a Soxhlet apparatus for two days. After filtration and evaporation of the solution so obtained, a pale brown residue was secured. This residue represented approximately 2 per cent by weight of the original meteorite fragment. The elemental composition of this residue varied quite appreciably from one meteorite fragment to the next. One residue contained approximately 6 per cent carbon, 1·3 per cent hydrogen, with traces of nitrogen. Spot tests carried out to detect inorganic constituents gave negative results for carbonate,

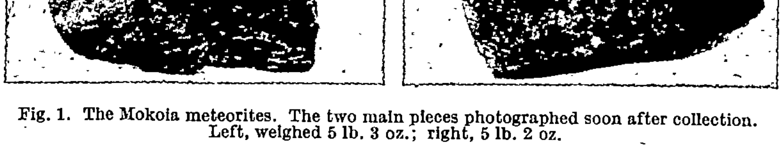

Fig. 1. The Mokoia meteorites. The two main pieces photographed soon after collection. Left, weighed 5 lb. 3 oz.; right, 5 lb. 2 oz.

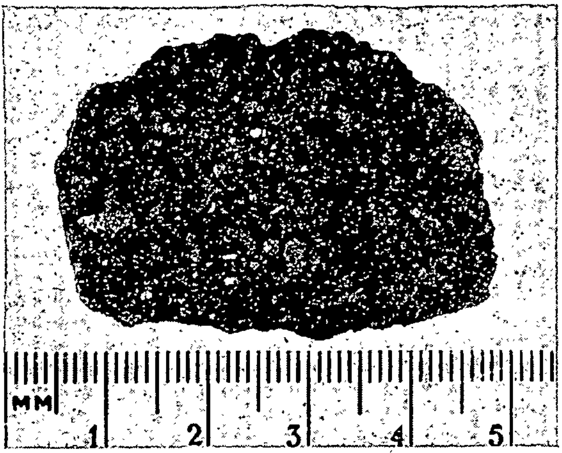

Fig. 2. Section of the Mokoia meteorite. Close-up of a small fraction (c. 40 mm. across) of the meteorite

Table 1. Composition of a Fragment of the Mokoia Meteorite

	Per cent
Fe_3O_4	36·95
FeS	5·64
NiO	2·20
MnO	trace
SiO_2	37·55

CaO	3·50
MgO	6·30
P_2O_5	0·64
Na_2O	2·86
CoO	trace
C	1·25
Total	99·51

This analysis is by B. C. Aston and is reported by Marriner in ref. 3. Analyses on fragments used in the present work gave carbon values of 1·36 per cent.

bicarbonate, nitrate, nitrite and ammonium. It was therefore concluded that the residue contained water-soluble organic compounds, with some organic nitrogenous substance present in trace amounts.

Inorganic constituents actually detected by spot tests were the following: magnesium, sodium, potassium, sulphate, phosphate, arsenate and chromate. Negative results were obtained in tests for all other common inorganic anions and cations.

To identify the organic compounds present has so far proved an impossible task, due mainly to the very small quantities available for investigation. However, by the use of ultra-violet and infra-red spectroscopy, and of paper chromatography, some tentative conclusions have been drawn.

Small amounts of the residue have been submitted to paper chromatography in a variety of solvents. By the use of sprayed reagents several spots have been developed and their R_F values calculated. Of the many compounds detected in this manner, four of the most interesting will be described.

Compound I is strongly fluorescent in the short ultra-violet (below about 320 mμ) and may be detected on paper by this property. From the shape of the spots in several solvents it is possible that this is more than one substance. The descending R_F value at room temperature on Whatman No. 1 paper in water-saturated phenol is about 0·9. The compound also reacts very slowly on paper with picric acid to give a yellow-orange colour.

Compound II is also strongly fluorescent in short ultra-violet, but unlike compound I has a very low R_F in water-saturated phenol (less than 0·1). Nor does this spot react with picric acid.

The fluorescence of both these compounds is unaffected by *p*H. Both dissolve readily in ammonia, but not in hydrochloric acid.

Compound III may be detected on paper by the two tests normally used in the detection of purines on chromatograms. When sprayed with silver nitrate solution, then bromophenol blue, then washed with water, a very pale blue spot remains. When sprayed with silver nitrate, then potassium chromate solution, then washed in dilute nitric acid, a pale red spot remains that slowly fades. These two tests give a spot with the same R_F value in all solvents so far used. The spot cannot be detected on paper by examination in short ultra-violet, but if the chromatogram is first sprayed with a very dilute solution of fluorescein, the spot can be detected by its weak absorbance of ultra-violet. The R_F values of this compound on Whatman No. 1 paper at room temperature are: 0·1 *N* ammonium hydroxide (ascending) 0·87; 86 per cent *n*-butanol (descending) 0·23; *n*-butanol–water–acetic acid (descending) 0·13.

Compound IV was detected in only one meteorite fragment and not in two others. It was observed on paper chromatograms which had been allowed to run overnight so that the solvent (86 per cent *n*-butanol with 5 per cent by volume conc. ammonia solution) had run off the end of the paper. The compound consequently has a very low R_F in this solvent. The wet paper chromatograms showed no markings, but on allowing the papers to dry at room temperature a dark red spot appeared with a 'tailed' appearance. This experiment was successfully repeated several times on the residue from one fragment. The spot could be drawn down from the origin only by allowing the solvent to run for many hours. Acid solvents were without effect; only ammoniacal solvents were successful. On this basis it is possible that the red colour is produced by a reaction of some organic constituent of the meteorite residue reacting with magnesium hydroxide formed *in situ* by the basic solvent. Quite a variety of organic compounds will form red complexes with magnesium.

While it is impossible to identify any of these compounds from this information, tentative hypothe-

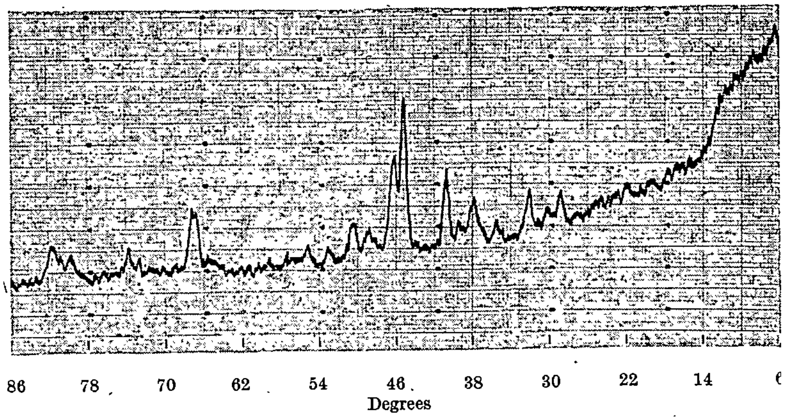

Fig. 3. X-ray diffraction analysis of the Mokoia meteorite. Determined on the powdered meteorite; wide slit, iron tube

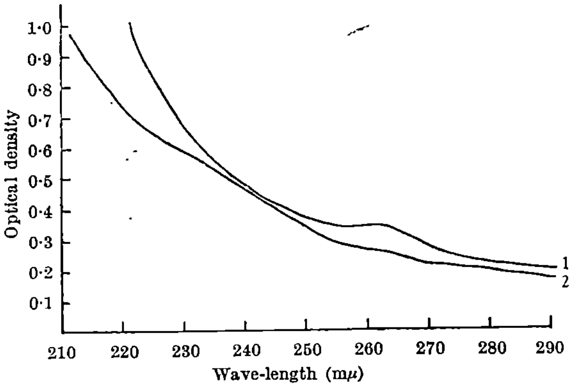

Fig. 4. Ultra-violet spectrum of meteorite extract. Curve 1 at pH 7; curve 2 at pH 2

ses concerning their constitution can be postulated. Thus from its reactions compound III must be able to form a silver compound capable of reacting with bromophenol blue or chromate to give a coloured complex. This immediately suggests a purine or related imidazole compound. Similarly, the fluorescent properties of compounds I and II suggest some conjugated ring system; while the water-solubility of all indicate the presence of polar groupings, such as carboxyl, hydroxide and amine. The low quantity of nitrogen in the residue indicates that amines can be present only in trace amounts.

Further information concerning the organic constituents of the residue is provided by ultra-violet and infra-red absorption spectra. In the ultra-violet the most characteristic property of the spectrum (Fig. 4) is a high end-absorption. However, the absorption curve varies somewhat with the pH of the solution. In neutral solutions there is a significant increase in absorption around 260 mμ as compared with the spectrum of acid solutions; suggesting an acidic chromophore.

Little information is given by the infra-red absorption spectrum of the intact residue; beyond a weak C—H absorption around 2,900 cm.$^{-1}$, a weak C=O absorption around 1,725 cm.$^{-1}$, and a strong double absorption at 860 and 880 cm.$^{-1}$. Most of the spectrum consists of strong, broad absorptions due to sulphate and water (even in carefully dried samples). One residue sample gave a sharp absorption at 1,395 cm.$^{-1}$; but this was not detected in other samples from different meteorite fragments. It is possibly significant that the residues giving this absorption also contained compound IV.

In an attempt to secure more information the residues were fractionated with different solvents. Cold water was found to dissolve only a part of the residue. After evaporation this cold-water-soluble portion was extracted first with chloroform, then with ethanol. All solvents used were carefully re-distilled analytical reagents that gave no residues on evaporation. The original hot-water-soluble extract of the meteorite was thus separated into four parts: cold-water-insoluble (residue *A*), chloroform-soluble (residue *B*), ethanol-soluble and chloroform-insoluble (residue *C*), and cold-water-soluble, ethanol-insoluble, and chloroform-insoluble (residue *D*). The infra-red absorption spectrum of each of these residues was determined, and the results are shown in Fig. 5.

Residue *A* shows few organic absorptions. There are a weak C=O and C—H absorptions, and absorption maxima at 2,500, 2,350, 880 and 800 that could be due to organic compounds. Residues *B* and *C* show the spectra with the greatest detail. Again C—H and C=O absorptions are present as well as a large variety of other peaks due to organic compounds. Residue *B* was not fluorescent. Residue *C* was strongly fluorescent and contained compounds I, II and III. After extraction with the two

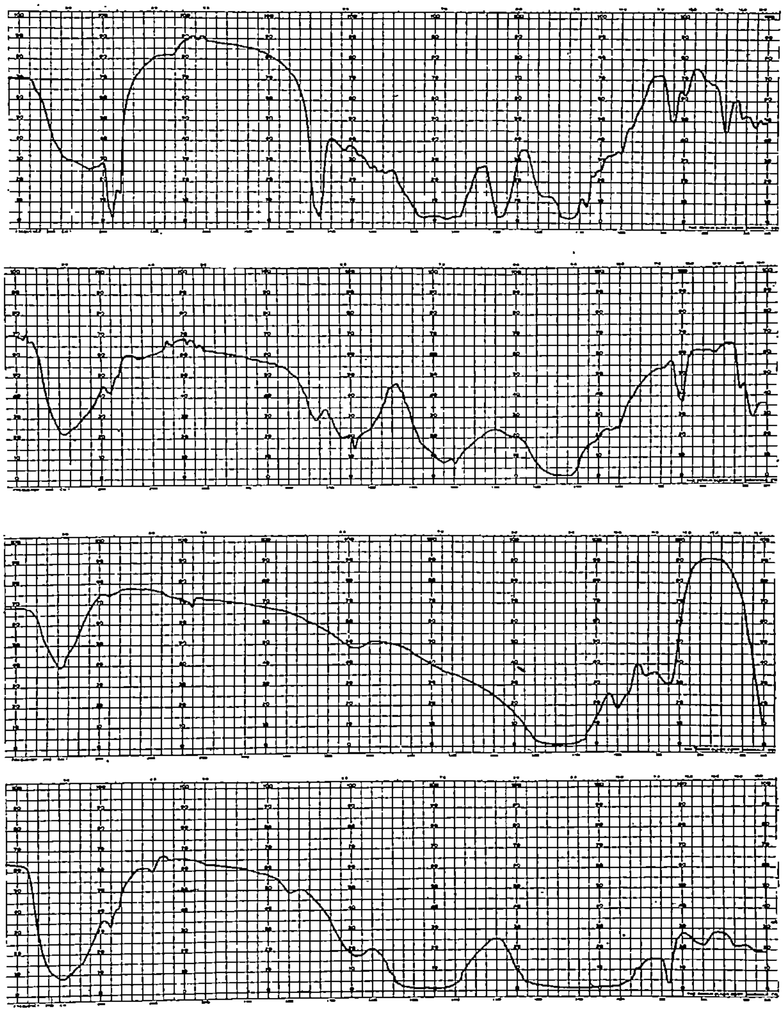

Fig. 5. Infra-red spectra of various fractions of the Mokoia meteorite extract. Spectra in descending order: chloroform-soluble fraction; ethanol-soluble, chloroform-insoluble; residue after chloroform and ethanol extraction; hot-water soluble, cold-water insoluble

organic solvents, residue *D* obviously contains little organic material, though a very weak C—H is present.

Residue *A*, which did not contain either compound I or II, was weakly fluorescent; indicating the presence of a third fluorescent compound.

Considering the evidence given here as a whole, it is apparent that the Mokoia meteorite contains a variety of quite complex organic compounds. Preliminary attempts to extract the carbon from the ground meteorite residues after water extraction with organic solvents have proved successful, and indicate the presence of water-insoluble organic material.

The problem raised by this, and other, work on meteorites is to provide a satisfactory explanation of the origin of these organic compounds. It is quite clear that, at least in the Mokoia case, the compounds are actual constituents of the meteorite and not terrestrial contaminants. The circumstances of discovery, preservation and the lack of such common soil compounds as amino-acids all render a contamination hypothesis untenable.

There would seem only two main possibilities for the origin of the meteorite compounds. Either they are the decomposition products of an extra-terrestrial life-form, or they are abiotic compounds formed early in the development of the solar system.

It has recently been demonstrated[4] that the cosmic-ray exposure ages of stony meteorites are all less than about 2×10^9 years, while the solidification ages are around $4{\cdot}5 \times 10^9$ years. This can be interpreted as evidence that the meteorites are fragments of a larger body that has disintegrated. While the cosmic-ray exposure ages of carbonaceous meteorites have not been determined, their overall similarity to non-carbonaceous chondrites makes the hypothesis that the two groups have cosmic-ray ages that are approximately the same at least plausible. Now the Earth has borne life for more than 2×10^9 years[5], hence, if carbonaceous meteorites have a cosmic-ray age less than this, it is unlikely that the organic compounds carried by these meteorites played any part in terrestrial biopoiesis.

However, several workers[6] have cast doubt on the interpretation of cosmic-ray ages, and propose that the meteorites and asteroids are not fragments of a larger body but have always been small objects. Several authors[7] also have suggested that the major features of Earth and Moon were produced by meteorite collisions. If this is true, it is evidence of the existence in the past of meteorites before the beginnings of terrestrial life.

The problem of the origin of the meteorite compounds is closely bound up with the larger problem of the origin of meteorites. If these bodies are fragments of a larger mass that no longer exists, then the compounds could be the remains of some exotic life-form. However, if the meteorites are not fragments of this nature, the compounds can only be the products of reactions of substances adsorbed on to surfaces. The numerous recent demonstrations[8] that highly complex compounds can be formed from simple materials by discharges and radiation suggest that organic syntheses could occur within a large cloud of meteorites in space.

Prof. J. Oro has recently suggested[9] that biochemical compounds would be formed at the point of impact of a comet with a planet. The asteroids, which obviously present a much larger target for comets, must have been in such collisions many times. Consequently the meteorite organic compounds could be the results of such collisions.

It is apparent that two major advancements remain to be made in this field. First, the chemical nature of the meteorite compounds must be established and mechanisms for their synthesis devised. Secondly, the cosmic-ray exposure ages of the carbonaceous chondrites must be measured to allow an estimate of the significance of these compounds in the early history of the solar system to be made.

I wish to thank Dr. W. A. Watters of the New Zealand Geological Survey for supplying samples of the Mokoia meteorite and for helpful advice; Dr. B. Cleverly and Dr. P. Grant of the Dominion Laboratory for the infra-red spectroscopy; Dr. N. F. Curtis and Mr. D. A. House for assistance with the inorganic spot tests; Dr. A. T. Wilson for assistance with the X-ray diffraction determination and for numerous helpful discussions; and Mr. D. Ward for helpful discussions on the infra-red analyses.

THE WORLD UNIVERSITY SERVICE

By HILDA M. BROWNE

General Secretary

FOR three generations since 1920, the promotion of international co-operation and mutual service between and within universities and centres of higher learning throughout the World has been a task carried out by the organization known first as European Student Relief, then as International Student Service, and finally, since 1951, as World University Service. Its material aid programme has been complemented by the facilities it offers for the exchange of knowledge and experience gained in solving basic problems within its sphere. Non-partisan in its attitude, it makes no discrimination as to race, colour, religious belief or political creed.

The officers of the Co-operating Committee for Great Britain and Northern Ireland are: *president*, Sir Walter Moberly; *chairman*, Prof. W. R. Niblett; *hon. treasurer*, Sir Robert Mayer; *general secretary*, Miss Hilda M. Browne, World University Service, 59 Gloucester Place, London, W.1. The address of the International Headquarters is 13 Rue Calvin, Geneva.

Appearing in September

Aircraft Stability and Control

A. W. BABISTER, *James Watt Engineering Laboratory, Glasgow University*

A comprehensive treatment of the whole subject of aircraft stability and control. The theory of longitudinal stability and control and lateral stability and control is developed from first principles, and then it is applied to problems of practical interest and importance. A numerical example is given, and the problems of stability and control discussed. 700 *pages* £7 7*s. net* ($21.00)

Experimental Methods in Combustion Research

A Manual Edited by **J. SURUGUE**

This loose-leaf AGARD Manual presents current and comprehensive data on experimental methods used and recommended by experts in solving combustion problems. Included is Experimental determination of local concentration in flames—R. M. Fristom; The energy balance in the combustion process—A. S. Leah; and Modern methods in high speed photography—J. S. Courtney-Pratt.
300 *pages.* £5 5*s. net* ($15.00)

The Chromatography of Steroids

I. E. BUSH, *Professor of Physiology, University of Birmingham*

This book reviews the available methods for the chromatography of steroids, giving particular attention to the application of the theory of partition chromatography to the behaviour of steroids in chromatographic systems.
448 *pages.* 80*s. net* ($12.50)

Absorption Spectra and Chemical Bonding in Complexes

C. K. JØRGENSEN

In this book the molecular orbital theory is shown to be the appropriate description of complexes, while the ligand field theory (in its electrostatic model) and the valency-bond model (especially Pauling's hybridisation hypothesis) are shown to be inadequate for the description of the energy levels and for the chemical bonding. Chapters on atomic spectroscopy and complex chemistry are included and a large number of references are given. This book will interest inorganic chemists and non-nuclear physicists at a fairly advanced level in addition to theorists of chemical physics.
350 *pages* 70*s. net* ($10.00)

Genetical Variation in Human Populations

Edited by G. A. HARRISON, *Department of Anatomy, University of Liverpool*

Contains the papers presented at the latest Symposium of the Society for the Study of Human Biology, including Blood Groups, Abnormal Haemoglobins and Erythrocyte Enzyme Deficiency Traits, Haptoglobins and Transferrins, Urinary Amino-Acids, and Determatoglyphic Patterns and Pigmentation.
121 *pages* 35*s. net* ($6.00)

The Relation between the Photo-Production and the Scattering of π-Mesons

N. F. NELIPA

A full multipole analysis of the transition amplitude for photoproduction of mesons, describing in particular the relationship of this process to that of meson nucleon scattering. This book is a valuable complement to that by Baldin, Goldanskii and Rozenthal—*Kinematics of Nuclear Reactions*—(Pergamon Press 1960).

HENDREY
Mercury Vapour Concentration Meter
Type E.3472

Measures concentration of mercury vapour present in air. Essential where quantities of mercury are regularly used or where danger exists of leakage of mercury vapour from apparatus.

Two sensitivities are available at the touch of a switch, giving either full-scale meter reading at a concentration of 770 microgrammes per cubic metre of air or full-scale meter reading at a concentration of 200 microgrammes. Terminations provided at rear for operation of a recorder to give continuous readings of concentration present.

The World University Service programme of aid, material and intellectual, is planned by mutual agreement among peers; need does not create inequality within the Service. The problems of a community, as they are seen by those who experience them, are presented for solution to the International Assembly, which consists of representatives, senior and student, drawn from the forty-two countries in which there are national World University Service committees. By accepting a project for inclusion in its programme, the Service can publicize the need and draw to it government and public interest and help.

In this way, health services have been established in countries where ill-health saps the student potential; hostels and student centres have been set up to improve living conditions; educational equipment and scholarships have been provided and funds created for the benefit of refugees, both student and teacher, in flight from man-made and natural disaster.

In Africa this year, the World University Service will assist community development projects on literacy, hygiene and construction which will bring together manual workers and members of the university community in a common effort and so restore the relationship with their own people of the small *élite* in the European-type university colleges. A five-year plan is being developed for the establishment of health services at university colleges in Basutoland, the Congo, Ethiopia, Kenya, Rhodesia and the Sudan, where the increasing influx of students will make medical examination even more essential in the future than it is now. Pius XII College, Basutoland, the only non-segregated college in South Africa, is being besieged by applicants who must be rejected for lack of space. The World University Service is to help with a vast project to raise sufficient funds for building a new Department of Education for which the organization will provide furniture and equipment, and aid will be given to a co-operatively run bookstore supplying text-books and materials not easily obtainable from the usual commercial sources. University College, Ibadan, Nigeria, is to open a co-operative hostel, to relieve the shortage of accommodation which is limiting acceptances. Medical equipment will be supplied for the student health service at the University of Khartoum, and financial help given towards a co-operative book-store there also. For many years the Service has given aid to the African Medical Scholarships Trust Fund, which enabled non-European students to study medicine at the University of the Witwatersrand, and latterly to the Non-European Students Fund which helps students at the University of Cape Town. The passage of the Extension of University Act, limiting the African Medical Scholarships Trust Fund and the Non-European Students Fund to continued support of students already enrolled at the two Universities, was followed by the establishment of the South African Committee for Higher Education, the funds of which are enabling non-Europeans to work externally for university degrees. The World University Service International South African Student Fund is supporting the South African Committee for Higher Education, making supplementary awards to students at Cape Town and providing emergency assistance to university personnel suffering through apartheid.

Direct health projects in Asia, where so much has already been done as the consequence of a student health conference held in 1951, include the establishment of the first health centre at the Chinese Language Colleges in Hong Kong, of student wards at the Banares Hindu University and the University of Bombay, of a comprehensive health service at the latter University, of out-patient care for tubercular students in Japan, where the Service already has two sanatoria, and of a clinic at Seoul, Korea. In addition, medical equipment and supplies, and X-ray apparatus, will be sent to Pakistan and Vietnam, and financial support given for the expansion of the student tuberculosis ward at Masan, Korea, and for further development of the anti-tuberculosis campaign in Thailand.

Outside the field of medicine, other preventive measures must be taken in Asia to combat the danger of ill-health arising out of poverty and malnutrition. Co-operative projects, which provide living accommodation, food, books, stationery, etc., at prices well below the commercial level, can do much to lessen the cost of living for the student. Following a conference on co-operative techniques organized in January 1959 in Madras at which experts addressed the representatives of ten south-east Asian countries, co-operative cafeteria, hostels, student centres, libraries, book-stores, book banks and employment bureaux have been set up by World University Service committees in Burma, India, Indonesia, Japan, Nepal and Pakistan.

Since the end of the Second World War, one of the main duties of European World University Service committees, including that of Great Britain, has been the care of refugee students and staff members in their countries. The two major crises in the past few years have been primarily the Hungarian uprising, when more than 7,000 staff members and students fled to Austria and Yugoslavia, and the flight of Algerian students from France and their native country into Europe, Tunisia and Morocco. Both called for strenuous efforts by the Service to raise funds on the local level and from trusts and foundations in order that staff members might gain the necessary qualifications for continuation of their work in the country of their adoption and that students might have the opportunity of completing their interrupted studies. In Great Britain, the Hungarian refugee settlement programme has provided free scholarships for university study for 119 students, and supplementary grants for those studying at technical and other colleges of higher education. More than £36,000 has been spent by the Service on scholarships and material for Algerian refugee students, many of whom are still in dire need.

Gradually, from the narrow front of Vienna in 1920, the field of activity has spread and moved, as the need for the World University Service help has declined in one area and grown in another. The demand for help always exceeds the supply of funds, which, apart from those drawn from major foundations and non-government agencies for very large-scale special projects, are derived from the community most concerned with higher education.

In Great Britain it is agreed that education should be given according to the capacity of the individual: we must also face our responsibility for the practice of this creed in the emerging and less-prosperous lands, particularly those having direct links with our own. Until they approach our level of economy, World University Service can do much to remove the barriers to teaching and learning set up by poverty, ill-health and lack of equipment.

OBITUARY

Dr. G. C. J. Dalton

It was with deep regret that atomic energy scientists throughout the world learnt of the death of Dr. G. C. J. Dalton on July 17.

Dr. Dalton was born in Te Awamatu in the centre of the North Island of New Zealand just a little more than forty-five years ago. After a distinguished university career at Auckland and Canterbury University Colleges, Dalton was awarded a Rhodes Scholarship in 1936. At about this time he characteristically played in a major rugby football match while suffering from influenza; in his subsequent weakened condition he contracted poliomyelitis which resulted, after a year's illness, in the loss of the use of one of his legs. This did not deter him, and his strong traits of courage, fortitude and determination enabled him to overcome this physical disability. It did not prevent him from breaking his studies at Oxford to take an active part with the Royal Air Force in the radar defence of Britain, to enjoy rowing at Oxford, tennis at Harwell and swimming in Sydney. These brave and unselfish characteristics again revealed themselves during his fatal illness when he continued his work long beyond the time when he could humanly or medically be expected to do so.

Dalton claimed that as the engineer had to design equipment to operate, "he had to know his physics better than the physicist". Dalton himself certainly showed a penetrating and critical approach to the basic scientific problems, and his mastery of these, coupled with his considerable mathematical ability, enabled him to make major contributions to both research and teaching in the newer engineering developments, such as atomic energy.

These broad scientific interests coupled with a critical and imaginative mind showed themselves to full advantage in his initiation of the fast reactor programme at Harwell, in academic life as dean of the Faculty of Engineering in the University of Auckland, in the formulation of the Australian high-temperature gas-cooled reactor programme; and from 1960 as director of the Australian Atomic Energy Research Establishment.

To quote Sir Mark Oliphant: "Dr. Dalton was a warm friend of all who thought about the new ideas in engineering, helpful and generous of his time and effort, inspiring to young and old, and completely devoted to his work, his family and his ideals".

His loss is indeed a grievous one to Australia, to atomic energy and to his many friends and colleagues scattered throughout the Western world.

C. N. Watson-Munro

NEWS and VIEWS

New Appointments at Associated Electrical Industries, Ltd.: Mr. L. J. Davies, C.B.E.

Mr. L. J. Davies has recently been made responsible for the direct supervision of the four Research Establishments of Associated Electrical Industries, Ltd., at Aldermaston, Harlow, Manchester and Rugby. Mr. Davies was educated at Oxford, going there with an open exhibition in natural science, taking his first degree and carrying out postgraduate work, joining British Thomson-Houston Co., Ltd., in 1924. For the past sixteen years he has been director of research at Associated Electrical Industries (Rugby), Ltd. During this period, under his guidance, many changes have been made in the scope and nature of the work and in the laboratory buildings, culminating in the setting up and occupation last year of completely new buildings on an eight-acre site reserved for research. For a period his interests were concerned with lamps and lighting. He was closely connected with the introduction into Britain of the fluorescent lamp and in a form that made it suitable for production for factory lighting during the Second World War. He was awarded in 1942 (with co-authors) the Crompton Premium of the Institution of Electrical Engineers for a paper on this subject. He is a past president of the Illuminating Engineering Society, a member of Council of the British Electrical and Allied Industries Research Association, and chairman of the Board of Governors of Rugby College of Engineering Technology. He was twice Faraday lecturer of the Institution of Electrical Engineers, and was made C.B.E. in 1960.

Dr. J. E. Stanworth

Dr. J. E. Stanworth has been appointed as director of research of Associated Electrical Industries, Ltd., in succession to Mr. L. J. Davies. Dr. Stanworth is a native of Lancashire, and was initially educated at Nelson Secondary School, from which he went to the University of Sheffield to gain a B.Sc. (Tech.) degree with honours in 1935 and his M.Sc. (Tech.) degree in 1937. He joined the British Thomson-Houston Co. as glass technologist in 1937. He spent his first years at Rugby in research on glasses and on glass structure, eventually leading a team on this subject partly in the research laboratory and partly in the glass works of the Company. He then took over wider duties involving the supervision of the research of a large number of groups engaged in investigating new materials and their applications, particularly in the fields of semiconductors, materials for nuclear power reactors, lamps, high-temperature materials and hard materials. Dr. Stanworth was awarded the degree of D.Sc.(Tech.) by Sheffield in 1958. He is a Fellow of the Royal Institute of Chemistry, the Institute of Physics and the Physical Society, and the Society of Glass Technology.

Medical Research Council: New Members

Prof. M. L. Rosenheim (professor of medicine in the University of London at University College Hospital Medical School) and Prof. Wilson Smith (lately professor of bacteriology in the University of London at University College Hospital Medical School) have been appointed members of the Medical Research Council from October 1, 1961.

New Research Group

The Medical Research Council has recently agreed to establish a Research Group at the University of Durham on demyelinating diseases. The Group, to be situated in the William Leech Research Laboratories, Royal Victoria Infirmary, Newcastle upon Tyne, will be under the direction of Dr. E. J. Field, senior lecturer in neuropathology, King's College Medical School, and consultant neuropathologist at the Infirmary; Dr. H. G. Miller, physician in neurology to the Infirmary, will act in an advisory capacity on the clinical side.

Feldberg Foundation for Experimental Medical Research

A foundation to endow an Anglo-German lectureship has recently been established by Prof. W. Feldberg, a senior member of the Medical Research Council's scientific staff at the National Institute for Medical Research. Prof. Feldberg has set up this Foundation out of funds awarded to him by the Federal German authorities as compensation for professional damages. It will be known as the Feldberg Foundation for German–English Scientific Exchange for Experimental Medical Research and will be administered by a Board of Directors consisting of three German and three British scientists. Each year the Board will award a prize to one German and one British research worker of distinction, and in recognition of this gift the German recipient will give a lecture in Britain and the British recipient a lecture in Germany. The prizewinners for 1961 are Sir Lindor Brown, Waynflete professor of physiology in the University of Oxford, and Prof. Herbert Hensel, director of the Physiological Institute of the University of Marburg. In November of this year, Prof. Hensel will lecture at University College, London, on "The Electrophysiology of Thermoreceptors", and Sir Lindor Brown will lecture at Heidelberg on "The Adrenergic Neurone". The German Federal Republic recently conferred a decoration, the 'Grosses Verdienstkreuz', on Prof. Feldberg in recognition of this generous endowment.

Change of Address

The Medical Research Council's headquarters office will shortly be moving to new accommodation, and from September 18 its address will be: 20 Park Crescent, Regent's Park, London, W.1. Telephone: MUSeum 5422.

The International Atomic Energy Agency

The International Atomic Energy Agency, Vienna, has issued a short pamphlet explaining the purpose which the Agency serves and describing its origin, structure and growth and what it has achieved since it came into being in October 1957. By April 1961 more than 600 senior workers from 50 countries had completed their training or were receiving it in 26 countries under the Agency's programme of nuclear science fellowships. The exchange and diffusion of information is another major programme under which four large conferences were held in 1959 and 1960, while under its technical assistance schemes, early in 1961, 30 Agency experts were serving in 16 countries and 7 composite teams had visited 31 countries. Another statutory function is to arrange for supplies of nuclear fuel at the request of member States, and the Agency has also formulated standards and measures of safety for various types of nuclear operations and has worked to establish internationally agreed legal obligations to compensate for damage caused by nuclear accidents. Besides research in its own laboratories on the preparation of standards of radioactive sources, calibration of nuclear equipment and analysis and handling of nuclear materials, the Agency sponsors research projects in member States.

Nuclear Energy Training Courses

As part of its expanding training programme, the International Atomic Energy Agency is organizing, in co-operation with some Member States and specialized agencies of the United Nations, four courses on various practical applications of nuclear energy during September 1961–February 1962. The first such course, on the "Use of Radioisotope Techniques in Soil–Plant Aspects of Agricultural and Forestry Research", held by the Agency jointly with the Food and Agriculture Organization and in co-operation with the Government of the Netherlands, at Wageningen, began on September 4 and will last until October 27. The course is under the direction of Prof. A. C. Schuffelen, head of the Laboratory of Soils and Fertilizers, Agricultural University, Wageningen, Netherlands, and Dr. C. H. Fuller, Brookhaven National Laboratories. A four-month advanced international training course on "Biological Effects of Radiation", commencing October 24, will be conducted by the Agency and the Government of Israel at the Radioisotope Training Centre near Rehovoth. Dr. Peter Alexander, of the Royal Cancer Hospital, London, United Kingdom, will be scientific adviser for this course. A four-week international training course on "Radiation Health and Safety", organized by the Agency and the World Health Organization in co-operation with the Government of Japan, will be held in Chiba City, Japan, during October 24–November 21. This course will be directed by Dr. J. N. Stannard, University of Rochester. A regional training course in the "Medical Applications of Radioisotopes" will be held by the Agency in co-operation with the Government of the United Arab Republic during November 4–December 28 in Cairo. Dr. William J. MacIntyre, University Hospitals of Cleveland, will be general adviser to the course. The courses in Israel and the United Arab Republic are financed from funds provided under the United Nations expanded programme of technical assistance. The sponsoring organizations will provide fellowships and some scientific equipment for the four courses. Further information can be obtained from the headquarters of the International Atomic Energy Agency, Vienna.

Glass in the Electronics Industry

In many ways the lamp and vacuum tube industry is peculiarly dependent on glass as a raw material. Until the advent of semiconductors it was probably true to say that every lamp and electronic device contained several glass-to-metal seals, and the new vapour lamps, particularly the sodium and mercury vapour lamps, only became possible after the development of suitable new glasses to contain the metal vapours. It is appropriate, therefore, that the Philips organization should have devoted a double number of the *Philips Technical Review* to the material glass (22, Nos. 9 and 10, 281; 1960–61). There is a most interesting introductory paper on the history of glass, which is beautifully illustrated with colour reproductions of ancient pictures showing the use of glass and monochrome illustrations of ancient pieces of glass, including one of a Roman cage cup which consists of a series of circles of glass joined together but which has been carved out of the solid. Of particular note are two carefully written articles, one describing the development of automatic bulb-blowing machinery and the other dealing with the automatic control of modern glass-melting tank furnaces. There is a brief reference to the Glass Development Centre opened at Eindhoven in 1957; this is a well-designed laboratory which has its own pilot plant capable of taking to the manufacturing stage any new glasses and articles made therefrom. The more fundamental investigations of glass which are carried out in the central research laboratories are represented by a characteristic article on the structure of glass from J. M. Stevels.

Ferro-Alloy Industry in India

SINCE the turn of the last century, technological developments in the production of ferro-alloys have been remarkable both in range and quality. The National Metallurgical Laboratory, Council of Scientific and Industrial Research, India, has embarked on some major research and development projects to investigate the suitability of Indian raw materials for production of a range of ferro-alloys to exacting specifications and to study the economical application of the latest metallurgical techniques.

A symposium on the ferro-alloy industry in India will be held at the National Metallurgical Laboratory, Jamshedpur, during February 1962. The symposium will cover the following: (1) survey of raw materials in regard to quality and quantity for production of different types and grades of ferro-alloys in India, including auxiliary requirements such as fluxes, fuels, electric power, transport, etc.; (2) beneficiation of raw materials for indigenous ferro-alloy industry based on physical, chemical and thermal beneficiation techniques and ore-dressing cycles, formulation of optimum flow-sheets and assessment of recovery yields and economics; (3) evaluation of electro-thermal, pyrometallurgical techniques and other specific processes and developments in the production of different types and grades of ferro-alloys in relation to possibilities for application in India in the context of indigenous resources; (4) study of the basic physico-chemical and thermodynamic principles involved in the production of ferro-alloys, including theoretical investigations on slag and metal equilibria and related fundamental hypotheses; (5) latest advances in technology of production of ferro-alloys considered in relation to the laboratory-scale, pilot-plant and industrial prototype production trials; (6) utilization of by-products obtained in ferro-alloy industries and overall economics of integrated production cycles; (7) standard specifications for different grades of indigenous ferro-alloys based on corresponding specification of the raw materials needed; (8) present status of ferro-alloy industry in India and future expansion plans to be projected during India's successive Five Year Plans in the general background of trends in world production. Invitations are being extended to technologists, metallurgists and research scientists in India and abroad to attend the symposium and contribute technical papers for discussion. The symposium will provide an international forum for establishing personal contacts and facilitating exchange of ideas on the development of ferro-alloy industry in general and that of India in particular.

Sub-bituminous Coals as Oil-well Drilling Mud-thinners

MODERN procedure in drilling oil-wells, especially the rotary system, is to employ a heavy 'mud' fluid, for example, bentonite, to counteract hole-pressure, act as drilling-bit lubricant, assist in removal of rock-cuttings, and to seal borehole walls. It is customary to introduce additives or thinners to control the rheological properties of drilling mud, which normally tends to a progressive contamination, hence thickening, by rock-powder derived from cuttings. Such additives may be of chemical origin, but also natural humic acid types are employed (in the United States under the common but perhaps somewhat misleading name of 'lignite'). The active components of this type occur in naturally weathered or artificially oxidized coals, from which they can be extracted with aqueous solution. Several Alberta coals are rich in humic acids, and in a recent publication of the Research Council of Alberta, *Alberta Subbituminous Coals as Drilling Fluid Thinners*, by E. J. Jensen (Information Series No. 33. Pp. 25. Edmonton: Research Council of Alberta, 1961), it is concluded that deposits of suitable coals requiring no treatment but pulverization occur abundantly in this Province; that they possess good thinning qualities and are characterized by high cation-exchange capacity and fixed carbon : volatile matter ratio of less than unity. The amount of coal required for maximum thinning is 2–4 per cent by weight of the drilling mud. Further investigation by the Research Council into this interesting development is foreshadowed in this publication, which also includes relevant analytical and experimental data on these Alberta coals as potential sources of drilling mud thinners.

The Le Play Society

SIR JOHN RUSSELL's presidential address to the concluding conference of the Le Play Society at Wadham College, Oxford (April 9–13), has now been published by the trustees of the Frederick Soddy Trust (Pp. 22. Hove, Sussex: The Frederick Soddy Trust, 9 The Drive, 1961). After reviewing briefly P. G. F. Le Play's methods of studying a country and its people and the developments due to Patrick Geddes, Sir John describes the characteristic activities of the Society, including its summer journeys abroad, its classes on the technique of surveying and field surveys by groups of students and the annual conferences. The changed conditions after 1945 limited considerably the character of its post-war visits, quite apart from the great increase in costs, and Sir John also discusses in some detail the drastic changes in environment that modern technology has made possible, for example, in the Zuider Zee and elsewhere in Holland, and in Jutland and the Channel Isles. While the Society can look back with satisfaction on the part it has played in fostering and stimulating interest in survey work, especially the interactions of place, work, and folk, the work has grown beyond its powers, although both name and work will live through the Frederick Soddy Trust. Sir John concludes with a warm tribute to the work of Miss Margaret and Miss Alice Tatton.

Research into Problems of Ageing

THE second compilation of reviews of selected papers reporting research in ageing, supported by grants from the United States National Institutes of Health or conducted in the Institutes' laboratories, has been made from reviews of more than 500 papers published during the year 1960. These articles range from fundamental work on the biology of ageing to studies concerned with the physical, psychological, and social problems of ageing people. The number of grants made to medical schools, research hospitals, and other research institutions for investigations on problems of ageing has been mounting steadily. To-day, 16 million dollars of support is being provided by the National Institutes of Health for more than 700 projects in ageing. The compilation, entitled *Research Highlights in Ageing*, can be obtained from the Superintendent of Documents, U.S. Government Printing Office, Washington, 75, D.C., price 25 cents. (United States Department of Health, Education, and Welfare: Public Health Service Publication No. 854. Pp. vii+50. 1961.)

The Plastics Institute

MR. L. M. READ, administration and services manager, Research and Development Laboratories, DCL Plastics Group, has recently been appointed chairman of the Council of the Plastics Institute. Mr. Maldwyn Jones, development director of the Plastics Division of Imperial Chemical Industries, Ltd., has been appointed vice-chairman. A Building Sub-Committee to deal with all matters consistent with the objects of the Institute relating to the development of the use of plastics in building has been set up. The following are members: H. D. Atkin (Allied Structural Plastics, Ltd.), G. A. Britton (John Laing Research and Development, Ltd.), Dr. W. B. Brown (Monsanto Chemicals, Ltd.), Dr. W. Dawson (Imperial Chemical Industries, Ltd., Plastics Division), D. Gonda (EPS (Research and Development), Ltd.), D. B. Honeyborne (Building Research Station), D. S. Mahon (Bakelite, Ltd.), Dr. Z. S. Makowski (Imperial College of Science and Technology), H. Stanley Smith (Richard Costain, Ltd.), K. Turner (chartered architect), V. H. Wentworth (Monsanto Chemicals, Ltd.).

The Night Sky in October

NEW moon occurs on Oct. 9d. 18h. 53m. U.T. and full moon on Oct. 23d. 21h. 31m. The following conjunctions with the Moon take place: Oct. 5d. 21h., Regulus 0·2° N.; Oct. 7d. 08h., Venus 0·5° S.; Oct. 17d. 05h., Saturn 3° S.; Oct. 17d. 14h., Jupiter 3° S.; Oct. 26d. 17h., Aldebaran 0·6° S. In addition to these conjunctions with the Moon, Mercury is in conjunction with Mars on Oct. 11d. 20h., Mercury being 4° S. Mercury is too close to the Sun for observation. Venus is a morning star, rising at 3h. 15m., 3h. 55m. and 4h. 45m. on October 1, 15 and 31, respectively. Its stellar magnitude on October 15 is − 3·4, the visible portion of the apparent disk increases during the month from 0·870 to 0·934, and its distance from the Earth increases from 131 to 144 million miles. Mars is too close to the Sun for observation. Jupiter is an evening star, setting at 23h. 25m., 22h. 35m. and 21h. 40m. on October 1, 15 and 31, respectively. It is near the border of Sagittarius and Capricornus; its stellar magnitude is − 2·0 on October 15 and its distance from the Earth is 450 million miles. Saturn is an evening star, setting at 23h. 05m., 22h. 10m. and 21h. 10m. at the beginning, middle and end of the month, respectively. It is in Sagittarius; its stellar magnitude is + 0·7 on October 15 and its distance from the Earth is 920 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Oct. 20d. 21h. 55·5m., χ Aqr. (*D*); Oct. 27d. 2h. 40·1m., 318*B*. Tau. (*R*). There is also an occultation of Venus: Oct. 7d. 6h. 31·0m., (*D*); Oct. 7d. 7h. 56·1m., (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Orionid meteors are active during October 15–25, maximum activity being on October 20. The radiant is at R.A. 6h. 24m., Dec. + 15°, and conditions for observation are moderately favourable.

Announcements

DR. G. G. MACFARLANE, at present deputy director of the National Physical Laboratory (see *Nature*, 184, 1844; 1959), has been appointed director of the Royal Radar Establishment at Malvern, in succession to Mr. W. J. Richards.

As from August 30, the address of the headquarters of the Department of Scientific and Industrial Research became State House, High Holborn, London, W.C.1. Telephone: Chancery 1262.

A CONFERENCE of professors of mathematics from the universities of Great Britain is being convened by the Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom at the end of September to consider the teaching of mathematics. The proceedings will be private.

THE Royal Entomological Society of London is organizing a symposium on "Insect Polymorphism", to be held at the Imperial College of Science and Technology, South Kensington, during September 21–22. Further information can be obtained from the Registrar, Royal Entomological Society of London, 41 Queen's Gate, London, S.W.7.

THE second summer research institute of the Australian Mathematical Society will be held at the Australian National University, Canberra, during January 3–February 1, 1962. Analysis and number theory will be the main fields of research, and Prof. A. Erdelyi (California) will be the guest lecturer. Further information can be obtained from the director of the Institute, Prof. E. S. Barnes, Department of Mathematics, University of Adelaide, Adelaide, South Australia.

A SYMPOSIUM on "Optical Character Recognition" will be held during January 15–17, 1962. It will be jointly sponsored by the Information Systems Branch of the Office of Naval Research Information Centre of the National Bureau of Standards, and will be held in the Department of the Interior Auditorium on C Street, between 18th and 19th Street, N.W., Washington, D.C. Further information can be obtained from Miss Josephine Leno, Code 430A, Office of Naval Research, Washington 25, D.C.

ERRATUM. The article entitled "Reactions of Salt Solutions in Calcium Chloride on Mortar and Concrete", appearing on p. 125 of the July 8 issue of *Nature*, refers to two original articles appearing in the *Australian Journal of Applied Science* (11, No. 4, December 1960).

FROM RADAR TO SPECTROSCOPY: NEW REGIONS OF THE SPECTRUM*

By PROF. D. J. E. INGRAM

Department of Physics, University College of North Staffordshire, Keele

THE applied research that was concentrated on radar and microwave electronics during the War has now produced a new branch of research in pure science; it has opened what we might call a new 'window' in the spectrum of the electromagnetic radiations which stretch from the very energetic γ-rays at one end to the long wave-length radio waves at the other. This is one of the most striking examples of how development in applied physics can sometimes initiate a major advance in fundamental research and thus reverse the normal trend in scientific development.

The study of the emission and absorption of various types of radiation in the different regions of the electromagnetic spectrum may be taken as a reflexion of the progress of the whole history of physics, from its initiation with the classic experiment of Newton in which he split white light into its component colours. The detailed measurements on the spectral lines of different atoms in the visible region, followed by the beautifully simple explanation of all these complex frequencies by Niels Bohr in terms of quantitized orbiting electrons, are other major steps along this pathway. Somewhat earlier, too, the work of Madame Curie and others had shown that the nucleus itself would give off radiations of very short wave-length, and a study of these γ-rays has proceeded ever since to obtain as much information as possible about the nuclear forces themselves.

The electromagnetic spectrum can still be taken as the background to the advances in physics of recent years, and it can be said in all fairness that the two fields in which physics has made its greatest advances since the War have been, first, that of high-energy nuclear physics, with its study of radiations of very high energy produced by large accelerating machines; and secondly, radiophysics—or the study of the discrete radiations absorbed and emitted in the long wave-length region of the spectrum.

Radio astronomers have made particular use of this latter region of the spectrum; they have followed one discrete emission line in their investigations, as well as pursuing their general study of the radio noise, spread evenly across the spectrum, which can be detected from the remoter galaxies near the edge of the observable universe. This discrete spectral line of 21-cm. wave-length comes from the atomic hydrogen present in the arms of our own and other galaxies; and it is used by the radio astronomers to map the features of our own galactic system, and also to measure its speed of rotation from the slight changes that occur in the wave-length.

The terrestrial physicist is also very interested in this spectral line, although he uses it for exactly the opposite purpose: instead of following it out into the nearly infinite depths of space like the radio astronomer, he can pursue its origin back into the very heart of the atom, and deduce the nature and magnitude of the forces that are interacting there. It is possible to do this because the frequency, or wave-length, of the radiation emitted by an atom is related directly to the changes of energy which take place in it when the radiation is emitted. It follows that a careful study of the wave-lengths of these different radiations will therefore give very precise information on the energy-states existing within the molecules and atoms themselves, and, from this, on the nature of the actual forces which hold the atoms together.

The great advantage of carrying out spectroscopy in the radar or micro-wave regions is that very well-defined and highly stabilized wave-lengths are available, and these can be measured to accuracies of better than one part in a thousand million. An immense wealth of information is therefore available from the fine and hyperfine patterns that arise on these spectra, and which are produced by interactions with the nuclei of the different atoms. This was discovered very soon after the end of the War, when Bleaney and his co-workers in Britain, and Good in the United States, first applied the war-time radar techniques to a study of ammonia and other molecules.

Another branch of microwave spectroscopy, which was somewhat slower in starting than the work on gases, but which has now outstripped it, and developed widely in a variety of different directions, is that of electron resonance. In this type of experiment a magnetic field is applied across the specimen at the same time as it is bathed with the microwave radiation, and the energy jumps of the unpaired electrons can then be followed very precisely.

Some of the more practically minded might well ask at this point what relevance such investigations have to everyday life. One can usually justify most scientific investigations on two grounds: first, from an innate sense of curiosity, the desire to find out and unravel the truth so far as we can go; and secondly, from the fact that very useful and practical applications usually derive from this 'pursuit of truth' on the way. So it is with microwave spectroscopy. The war-time developments in radar opened up a vast unexplored region of the electromagnetic spectrum, and we have been eagerly and enthusiastically exploring all its features. This has afforded some new ideas and results which have proved to be of immense practical value.

First, the measurement of frequency and time—we find that the vibrations of the atoms are more regular and reliable than the rotation of the Earth and movement of the stars, and our standard time signals are now, in fact, controlled by microwave frequencies linked to the oscillations of cæsium atoms. A second application of increasing importance is the use of electron resonance as a probe for unpaired electrons in all kinds of systems—those formed by transient chemical reactions, those produced by irradiation damage, and, more recently, in biological systems involving cancerous growth or other abnormal metabolic activity.

---

* Substance of the Kelvin Lecture delivered on August 31 at the Norwich meeting of the British Association.

One final example will serve to turn the wheel full circle and show how the latest results of the pure physicists in this field have now produced a new device which promises to be of immense help to the microwave engineer. This is the maser, which uses the atoms themselves to produce microwave amplification and oscillation, rather than any radio circuits or electron beams. Thus the debt to the applied scientist has been repaid, and this new line of research continues to develop and flourish as the different sides go on together.

BRITISH WELDING RESEARCH ASSOCIATION: NEW LABORATORY

THE official opening by Lord Mills of a new laboratory block of the British Welding Research Association at Abington Hall, Cambridge, on July 12, marked an important stage in the development of the Association's Research Station. Since 1946, when Abington Hall was first taken over by the Association, much of the research work has had to be carried on in some of the original outbuildings of the estate and in wooden huts remaining from war-time military occupation. The first new laboratory was built during 1951–52, to accommodate large-scale equipment for fatigue researches, and this was followed in later years by the construction of a second research block which permitted the integration at Abington of the metallurgical work previously housed in London. The present scheme represents the completion of a further stage that was put in hand three years ago with the building of a welding construction shop that now forms part of the new laboratory opened by Lord Mills.

The new block is a two-storey building, the steel frame of which, in common with the earlier laboratories of the Association, is of welded construction and designed by the plastic theory. The ground-floor, of 15,000-sq. ft. area, accommodates research sections working on the design of pressure vessels and pipe-lines, the brittle fracture behaviour of steel, and the development and application of resistance welding methods. It also contains a machine shop. Office and conference rooms are provided on an upper floor of 8,200 sq. ft. area. The laboratory was designed by Messrs. H. C. Hughes and P. Bicknell, of Cambridge, and erected by Messrs. Rattee and Kett, Ltd., also of Cambridge.

It is appropriate to recall that the pressure, brittle fracture and resistance welding investigations were among the first projects to be inaugurated at Abington. Each, therefore, has a fairly extensive background of development and, clearly, each is seen to retain an important future in the welding research programme as a whole.

The subject of the design of welded pressure vessels was recently discussed at a symposium organized by the Institution of Mechanical Engineers in collaboration with the Association. With a theme of research towards better design, an excellent forum was provided for the presentation and consideration of the Association's particular contribution in this field, which has always been strongly directed towards defining the means of achieving more economical design. This has involved a lengthy and painstaking programme of stress analysis, for example, of the stress distributions set up by typical nozzle attachments, in which the deliberate choice of the examination of large-scale specimen vessels was made and to a large extent made possible by the co-operation of manufacturers of pressure vessels. If, to-day, the experimental approach in this field can be more elegant, it would be difficult to say that this possibility does not arise from the knowledge and confidence won from the large-scale testing work. The answers from such work appear, in any event, to have arrived at a time when, to judge from the mood at the symposium of the Institution of Mechanical Engineers, arguments for advancing code-of-practice design methods in the United Kingdom are likely to be sustained, particularly since much has been done by the Association to translate its accumulated research results into a simple design process.

Equipment for the static and pulsating pressure-testing of large vessels has been moved into the new laboratory, where work will continue on the current phase of the programme, in which attention is being given to some further aspects of the concentration of nozzle-stress factors and also to the important problem of the comparative merits of low-alloy steels in pressure-vessel service. A development foreshadowed in the exhibits displayed by this section on the Association's open day is the study of the behaviour under repeated pressure of vessels at high temperature.

The adjacent section of the new laboratory is concerned with the brittle fracture of welded steel structures and accommodates testing rigs for carrying out the Wells's wide-plate test. Basically, this is a tensile test, giving a stress–strain record to fracture, but the rig is designed specifically to accommodate wide (typically 36 in.), thick plates with the facility for cooling to sub-zero temperatures. The specimen plates contain a longitudinal butt weld, and an artificial notch is placed in the zone of the weld, where it is subjected to the heating cycle and the high, local, residual stresses induced by welding. As a means of studying the influence of important technological factors, for example, quality of steel, type of electrode, stress-relieving treatment, etc., the test has already given results of considerable significance to present practice in heavy engineering in which the brittle fracture problem can in certain circumstances be critical. This work has been done with rigs of 700 and 2,000 tons capacity, counterparts of which now exist in other countries, and the satisfactory performance of these has permitted the Association to advance the design to a new rig, exhibited in model form, that will be used for the study of low-alloy steels and which will have a capacity of 4,000 tons tensile load.

Fundamental aspects of brittle fracture in steel, with particular reference to fracture initiation and propagation, are also being investigated. The determination of a generalized resistance of the material embodied in the measurable quantity fracture toughness, has proved a difficult experimental problem in relation to propagation of fracture. Recent work on measurements of transient force against time in the Charpy (impact) test has indicated, however, that this test might well be capable of modification for the particular purpose. The examination of fracture surfaces for the detection of slip patterns, using suitable materials and etching and microscope techniques, has proved extremely fruitful in the study of fracture initiation. By causing the arrest of fracture in a Charpy test at an extremely early stage, a trigger mechanism has been revealed that appears in accord with Cottrell's hypothesis (*Trans. Amer. Inst. Met. Eng.*, **212**, 192; 1958) of a crack resulting from the intersection of two mutually perpendicular slip bands (see *Nature*, **190**, 432; 1961).

The third research section of the new laboratory of the Association is devoted to work on the resistance group of welding processes, namely, spot, projection, seam welding, etc. These methods are normally used in the quantity production of sheet metal components, in which field the problem of maintaining consistency of quality under rapid fabrication conditions often demands a critical examination of material and process control. The section is equipped with a range of modern welding machines and with ancilliary apparatus for the measurement of the important process variables. In addition, techniques have been developed for the direct measurement of temperatures during spot welding. The problem is complicated by reason of the fact that the generation of heat in the production of a spot weld takes place at the interface region of two overlapping sheets, and temperature gradients are severe. A considerable amount of work has been done by the Association to overcome the difficulty by using buried thermocouples, and the results will be of importance in extending the welding process to harder steels, for which a knowledge of heating and cooling conditions is of particular importance.

The investigations mentioned and those being conducted in other departments are described in the sixteenth annual report of the British Welding Research Association, which has just been issued. For the year under review, the Association's income was £265,379, an increase of £53,252 over the year 1959–60. This increase is, in itself, greater than the total income of the Association in the year when the research station was inaugurated, and is evidence of the rapid growth of the Association to a position in its field which is probably unequalled outside the U.S.S.R.

R. P. NEWMAN

THE NUFFIELD FOUNDATION

THE sixteenth annual report of the Nuffield Foundation*, covering the year ended March 31, 1961, in which grant allocations exceeded £2 million, comments on the extent to which the Foundation sometimes participates in the management of the programmes it supports, thus keeping closely abreast of present-day thought and discovery in its fields of interest. Sometimes its neutrality and independence enable it to take the initiative in bringing together many varied, and sometimes conflicting, interests. Again, it can also, as in the establishment with the Joseph Rowntree Memorial Fund of a National Institute for Social Work Training, or in planning a medical school for the University College of Rhodesia and Nyasaland, draw on its long and varied experience to render important advisory services. Furthermore, its activating role is illustrated by the promotion, at the invitation of the Colonial Office, of an informal but widely representative study of the problems associated with the provision of an adequate and proper supply of British television material to television stations overseas, particularly to those in the less-developed countries. Two conferences were convened for such a purpose by the Foundation, and the resulting document, summarizing the broad conclusions of the study, and making detailed and costed proposals for action, may result in the establishment of a special organization in Great Britain to promote the supply of British television material to overseas countries by all possible means.

Of the allocation of £165,000 for science, including technology, £50,000 went to the Madingley Field Station for the Study of Animal Behaviour, Cambridge, for new buildings and recurrent expenses up to ten years, and £36,000 over five years to the Department of Medical Biochemistry and Pharmacology, Birmingham, for work under Prof. A. C. Frazer on the biological effects of oxidized fats. An additional grant of £3,500 a year for four years to the Department of Chemistry, King's College, Newcastle upon Tyne, in support of Prof. J. Baddiley's work on the structure of cell walls will enable investigations into the biochemical aspects of the cell wall and teichoic acids to be initiated, and a grant of £11,500 over three years is in support of the microbiological aspects of Prof. C. H. Hassall's work at the University College of Swansea on the biosynthesis of complex phenolic compounds; a grant of £4,950 to the Gatty Marine Laboratory, University of St. Andrews, will provide Dr. A. J. Matty with research assistance over three years in his investigations of the thyroids of lower vertebrates.

In technology, a grant of £3,250 for five years was made to the National Trades Technical Societies of Sheffield to assist the introduction of their organization and educational services for adult workers in industry to other industrial areas; £15,000 to the Loughborough College of Technology will provide four postgraduate studentships in ergonomics for each of the years 1961–64 in the newly created Department of Ergonomics and Cybernetics; £5,500 to the Department of Mathematics, Royal Technical College, Salford, is to finance an investigation of mathematics in the electrical engineering industry; and an additional £1,200 to the Department of Chemistry and Food Technology, Borough Polytechnic, will allow Mr. P. D. S. Wood to continue the work on lipids until Easter 1962.

Of grants totalling £600,000 for medical projects, £220,000 was to meet the capital cost of the Nuffield Institute of Nuclear Medicine and running costs in its early years, while, also at the Middlesex Hospital Medical School, up to £45,000 during its first seven years goes to the establishment of a new research unit in biology as applied to medicine. £60,000 to the University of Manchester is to provide the Department of Audiology and Education of the Deaf with more accommodation for clinical and research work for the young deaf child, and a further grant of £29,350 over three years is to go to the audiology unit at the Royal Berkshire Hospital for work on hearing and deafness in early infancy. A capital grant of £70,000 has been made for an extension to the Liverpool School of Tropical Medicine to further co-operation with schools of tropical medicine and endemic disease in Ghana and Thailand, and a further £40,000 to the Zoological Society of London for building the Nuffield Institute of Comparative Medicine. A grant of £30,000 was made to the Central Council for Health Education for an investigation into the present patterns of sexual behaviour and attitudes towards sex and marriage among young people between the ages of thirteen and twenty, which is expected to take three years to complete; one of £6,600 over three years to cover the salary of a research biochemist to work under Prof. G. Belyavin at University College Hospital Medical School on the response of selected cell lines to infection with influenza virus; and another of £3,200 a year for two years to the Institute of Orthopædics to enable Dr. C. H. Lack to expand his work on the role of plasmin and plasmin inhibitors in the breakdown of connective tissue matrix, especially that of cartilage.

---

* The Nuffield Foundation. Report for the year ended 31 March, 1961. Pp. xv+210. (London: The Nuffield Foundation, 1961.)

A grant of £25,000 has been made to the London School of Hygiene and Tropical Medicine, mainly to cover the first year's cost of a training course in industrial hygiene under the direction of Prof. R. S. F. Schilling, head of the School's newly created Department of Occupational Health, and the Foundation has also set aside £250,000 specifically for the further development in Britain of practical schemes of co-operation in industrial health and occupational hygiene. Of this, £15,000 has been allocated to provide the Central Middlesex Industrial Health Service, Ltd., with a permanent clinic, and £20,000 on a tapering basis for the re-organization and reconstitution of the Slough Occupational Hygiene Service, on the understanding that the unit can be made self-supporting within five years.

From the £165,000 for social research and experiment, £12,500 for a period of four years went to the scheme for an experimental family welfare centre at Stevenage New Town to cover the salary of the organizer, rent, maintenance and administrative expenses; £2,000 for a study by Prof. T. Ferguson of Glasgow young people who have been in the statutory care of the local authority and particularly of their assimilation into the community; £20,000 over three years for an inquiry by the Nature Conservancy and the Department of Estate Management, University of Cambridge, into the management of common lands; £9,500 over three years to the Women's University Settlement for developments in the after-care of discharged prisoners; £7,600 to the University of Cambridge for an investigation by Mr. Z. A. Silberston into the economic impact of the patent system in Britain; £5,000 to the Institute of Strategic Studies for the development of the Institute's Library, and £5,000 over five years to the London School of Economics and Political Science to enable Prof. W. A. Robson's group to undertake a more comprehensive study of local government in Greater London.

Among grants totalling £220,000 in education, special attention is directed to two of the smallest: £300 towards the cost of a five-day residential meeting at the Battersea College of Technology, arranged by Dr. L. R. B. Elton, to consider policy and future action in regard to the proposed revision of syllabuses and teaching methods for Ordinary- and Advanced-level physics for the General Certificate of Education; and £1,500 in support of experiments in the teaching of French at East Ham Grammar School for Boys and Talbot County Primary School, Leeds. Grants were made of £100,000 to the Royal National Institute for the Blind for the change-over of the Nuffield Talking-Book Library from records to long-playing tapes; £20,000 to the University College of North Staffordshire for provision of multiple copies of texts and other documentation for the foundation year with an additional £5,000 towards the cost of an assessment of the foundation year; £30,000 over five years to the University of Cambridge for the continuation of its aerial reconnaissance over the British Isles; £6,650 over two years to the Department of Extra-Mural Studies, University of Liverpool, for a Senior Research Fellow to undertake a review of the nature and extent of adult educational provision at the present time; £4,250 for a critical analysis by the Acton Society Trust of management education courses; and a capital grant of £5,000 to Westminster School to form the "Tizard Research Fund" to assist research activities by the science staff of the School. The grant to Prof. P. L. Krohn's gerontological research unit at the University of Birmingham has been renewed a third time at the rate of £7,000 for two years, and an additional £1,800 allocated for Mr. F. Le Gros Clark's studies of women of mature age in paid employment and of occupational opportunities for people in retirement.

Grants totalling £385,000 for the Commonwealth overseas, distributed in forty grants to fifteen different countries, include £85,000 to finance for the next ten years a scheme at the University of Cambridge for a Nuffield Unit of Tropical Animal Ecology; £35,000 over five years to the Plunkett Foundation for Co-operative Studies for training courses aimed at raising agricultural standards in Africa; £10,000 for a survey with the Colonial Office of the incidence of deafness in East and West Africa; £18,000 over six years to the Cotton Research Station, Namulonge, Uganda, for a study of soil fertility in East Africa; £29,000 over five years to the East African Institute of Malaria and Vector-Borne Diseases for study of the effects of malaria on African vital statistics; up to £20,000 for angio-cardiological research equipment for the University College Hospital, Ibadan; a further £16,400 over two years to the University of Edinburgh to continue the study under Dr. K. L. Little of urbanization and the effects of industrialization in Sierra Leone. A further £19,000 was offered to the University of New South Wales in support of the Nuffield research chair of mechanical engineering for an additional five years; £8,000 over three years to the University of Adelaide for Prof. D. Rowley's studies of natural immunity to infectious disease; and £10,000 to the Young Women's Christian Association, Belize, British Honduras, for repayment of a loan for a community centre and hostel for girls.

Allocations to fellowships and scholarship schemes totalled £205,000. United Kingdom awards in medicine included three Heinz fellowships of the British Pædiatric Association, four scholarships at University College, Ibadan, two medical fellowships, and four scholarships and three fellowships in dentistry. One scholarship and two bursaries in biology were awarded, and four senior awards made in sociology. Under the schemes for the Dominions and Colonies there were eleven awards in medicine, fourteen in natural science (including one in engineering) and seven in the humanities and social sciences, in addition to ten Canadian travel grants and twelve farming scholarships (three for Africans). Two travelling fellowships were given to Indian Civil servants and fifteen Royal Society and Nuffield Foundation Commonwealth bursaries were awarded, while 124 grants were made from the Elizabeth Nuffield Educational Fund covering a wide range of projected careers.

EFFECTS OF IONIZING RADIATION ON ORGANIC AND BIOLOGICAL SOLIDS

THE Société de Chimie Physique and the British Biophysical Society combined during July 3–4, in the Laboratoire de Chimie Physique, 11 rue Pierre Curie, Paris, to hold an informal discussion on the effects of radiation on organic and biological solids.

Opening the meeting on the first day, Prof. R. L. Platzman (Argonne National Laboratory, Illinois) outlined very clearly the present state of the theory of primary processes, and the recent developments due to Prof. U. Fano. In systems containing strongly interacting atoms, interaction may influence the primary energy absorption. Molecular structure, and particularly the presence of π-electrons, may affect the proportion of energy absorbed by different components in the primary process. In simple molecules, for example, methane, there is no evidence for such selective mechanism. More information is needed, in particular about the influence of water molecules, before this theory can be applied to biological materials.

Prof. M. Magat (Laboratoire de Chimie Physique, Paris) reviewed reactions in the solid state, in particular low-temperature radiation-induced changes such as polymerization, radical transfer and aromatic ring-opening, which occur by free-radical mechanisms. Members of the Paris group dealt in detail with these reactions, for example, Dr. E. Migirdycian and Dr. S. Leach showed that benzene, if irradiated in the solid state, de-cyclizes and adds on aliphatic groups derived from the ethanol with which it is mixed in solid solution. Similar ring-opening was reported by Dr. K. Hyashi and Dr. S. Okamura (Osaka Laboratories, Japanese Association for Radiation Research on Polymers, Osaka) in the case of lactones, when it is followed by linear polymerization, and favoured by a well-ordered crystalline state.

A feature of the meeting was the use of electron-spin resonance to identify and measure the free radicals produced by irradiation. Drs. R. Bensasson, C. Chachaty, M. Bodard and R. Marx (Laboratoire de Chimie Physique, Paris) used the technique to establish the free-radical nature of low-temperature radio-polymerization of such monomers as acrylonitrile, and Dr. H. Szwarc (Institut de Chimie Physique, Paris) used it effectively to demonstrate the rapid recombination of radicals which occurs on heating irradiated cyclohexane through its transition point at 186° K. However, other factors may be involved, apart from a phase-change, in facilitating radical reactions in the solid. Dr. E. Collinson and Prof. F. S. Dainton (University of Leeds), while demonstrating that scavenging of radicals is more effective in the solid and with aromatic compounds, conjectured that this could be due to the π-electron configuration of the phenyl groups. They also found that a glassy solid behaves more like a liquid than a crystalline solid. The important distinction between aromatic and aliphatic compounds was further emphasized in work by Dr. R. Mason (Imperial College of Science and Technology, London) on post-irradiation thermo-luminescence, when the intensity of emission was found to be a thousand-fold greater in aromatic than in aliphatic amino-acids.

Prof. J. A. V. Butler (Chester Beatty Research Institute, London) introduced the second session by stressing the need for a re-appraisal of such terms as 'direct' and 'indirect' effect, 'target', etc., and emphasized that in living systems, the balance is dynamic, and that radiation need be damaging at only one of a large number of places.

A question of continuing interest is the role of oxygen in radiation damage, and a number of contributions dealt with this factor. Drs. A. Müller, G. Hotz, and K. G. Zimmer (Institute of Radiobiology, Nuclear Research Centre, Karlsruhe) found a modified electron-spin resonance signal when bacteriophage was pressed into pellets in such a way as to expel oxygen, and Dr. L. Ehrenberg (Institutionen för organisk kemi och biokemi, University of Stockholm) on irradiating *Agrostis stolonifera* seeds could distinguish two types of electron-spin resonance signal, one of which is closely correlated with oxygen, and is decreased by pre-heating, that is, when oxygen is expelled. Dr. E. L. Powers (Argonne National Laboratory, Illinois) described recent work on bacterial spores, which offer a convenient experimental system for radiation work. Part of the damage is toxic only in the presence of oxygen. This can be estimated directly, and it is also possible to observe the effect of heat by using high linear energy transfer radiation, when annealing occurs during irradiation. The heat generated during heavy-ion bombardment may be an important and neglected factor, and in the work of Dr. T. Brustad (Norsk Hydro Institute for Cancer Research, Oslo), to be mentioned later, may in part explain the apparent lack of effect of additives.

The nature of the increased damage brought about by oxygen is much under discussion, and whereas the signals observed by Dr. L. Ehrenberg are not characteristic of peroxy-formation, Prof. G. Stein, (Hebrew University, Jerusalem) found a signal when polymethylmethacrylate was irradiated in the presence of oxygen which appears to be peroxidic. This system, moreover, provides a convenient method of measuring rates of oxygen diffusion. In certain circumstances, the influence of oxygen may be minimized by limited diffusion; for example, A. B. Robins and Prof. Butler (Chester Beatty Research Institute, London) found that a high dose-rate can obscure the oxygen effect completely in the case of trypsin.

The use of electron-spin resonance in free-radical investigations has already been mentioned, and Prof. D. J. E. Ingram (University College, Keele) outlined how this can be used in the study of proteins, where electron trapping may occur. It may be possible to correlate denaturation of a protein with an interference in this trapping process since the electron-spin resonance signal does not disappear on warming in the normal way. However, it must be remembered that when applying electron-spin resonance to biological materials, water, for example, plays a part which is little understood.

Sulphur compounds are of much interest on account of their use as protective agents. Dr. R. Koch (Freiburg) investigated more than a hundred compounds by electron-spin resonance, but no simple correlations between structure and function can be seen at the present time. The radical nature is considered to be localized on the sulphur atom, and Dr. P. Alexander (Chester Beatty Research Institute, London) and Mr. M. G. Ormerod (Royal Military College of Science, Shrivenham) provided evidence that in the case of nucleoprotein protected by cysteamine, such localization can occur, minimizing the damage. There seems little doubt that the radicals produced on irradiation of keratin are cystine-like (Dr. A. Redhardt and Prof. B. Rajewsky, Max Planck Institute for Biophysics, Frankfurt), but unaccountably, cysteine and related compounds do not appear to protect by a factor of more than two in a system such as yeast, when judged by quenching of electron-spin resonance signals (Dr. B. Smaller, Argonne National Laboratory, Illinois).

In general, it appears that dry solids are more sensitive than wet solids or solutions, and Dr. R. A. Braams (Physical Laboratory, University of Utrecht) reported a ratio of three between dry and wet tendon. Dr. Robins and Prof. Butler found solid trypsin to be more sensitive than its solutions, possibly due to the self-annealing processes in the presence of water. The last-mentioned authors also reported that the radiosensitivity of trypsin is modified by the medium from which it is evaporated and a low *p*H leads to a highly sensitive state, possibly by aggregation. It is significant that at high linear energy transfer Brustad obtained target sizes in excess of the accepted molecular weight for some enzymes; this also raises the question of energy transfer in the solid state. The effect of added materials depends on their being intimately mixed with the substrate, and the state of the solid is thus again seen to be important.

Two papers were presented dealing particularly with chemical changes on irradiation. Dr. W. M. Garrison (Crocker Laboratory, Lawrence Radiation Laboratory, Berkeley) found good evidence for the conversion of the —NH—CH— configuration in amino-acids into keto-acids, and as little as 10^{-8} mole can be detected as derivatives. Dr. H. A. Dieu (Laboratoire de Chimie Physique, Université de Liège) pointed out that irradiation of ovalbumin leads to a more ready attack by proteolytic enzymes, and an 'unmasking' of sulphydryl groups with the heaviest doses. Moreover, since the rate of subsequent attack by pepsin depends on the dose, and that by trypsin does not, it is probable that the aromatic amino-acids have been preferentially destroyed. In the myoglobin molecule it appears that possibly the leucine residues are the foci of damage, in particular those in more-exposed parts of the molecule, and Mr. C. C. F. Blake and Dr. D. C. Phillips (Davy Faraday Laboratory, Royal Institution, London) provided evidence for this in which the effect of radiation was studied directly by X-ray crystallography.

In summing up, Dr. L. H. Gray (Radiobiology Unit, Mount Vernon Hospital, London) stressed that physical theories, such as that of Prof. U. Fano, must be cautiously applied to biological systems, bearing in mind their complexity and such unknown factors as water content. It appears that the degree of crystallinity of the solid phase may be of great importance, and electron-spin resonance has helped to emphasize this. Concerning the role of oxygen, the accessibility of this gas may be a factor that has not received enough attention hitherto.

Finally, I was struck by the different interpretations that were placed on electron-spin resonance signals, and feel that this useful technique needs to be used with reserve when drawing conclusions.

A. B. Robins

BACTERIA OF THE INTESTINE

THE summer conference of the Society for Applied Bacteriology was held at Wye College, Ashford, Kent, during July 11–13, and included a symposium on "Bacteria of the Intestine".

Dr. H. Williams Smith, in his paper entitled "The bacterial flora of the fæces of animals with particular reference to its development in the young", described experiments on the development of normal flora in healthy animals. Rectal swabs were shaken in phosphate buffer, and after passing the suspension through muslin, colony counts of *Escherichia coli*, staphylococci and *Clostridium welchii* were made.

Calves, lambs, piglets and a baby were examined daily for 2–3 weeks, weekly for three weeks, monthly for nine months and twelve months (baby). One rabbit was examined weekly.

In the calf, *E. coli*, streptococci and *Cl. welchii* predominated on the first day, but bacteroides domination began at two days and these organisms rapidly multiplied up to fourteen days, when lactobacilli followed. Counts slowly dropped to 10^7–10^8/gm. of fæces after thirty weeks.

Similar results were obtained from lambs and piglets, except that streptococci dominated later with *E. coli* in lambs, and the piglet flora was dominated ultimately by lactobacilli. Results for the baby were similar also, with counts of 10^{11} for *E. coli* at first, followed by a bacteroides count of 10^{10}; *Cl. welchii* rose sharply at twenty-five weeks when the child started eating solid food. The counts remained high after a year; this was different from the animals. *Staph. aureus*, 10^2–10^6/gm, was frequently found in the baby but not in the animals. The rabbit showed a constant bacteroides count of 10^9; the lactobacilli and streptococcal counts were 10^4 and 10^5. Gram-negative anaerobic cocci up to 10^8–10^9, and yeasts in older calves, were also found. There was a constant population of *E. coli* but frequent changes in phage types.

Adult animals, including cats and dogs, showed a high count of *Cl. welchii* which varied in degree according to the diet, being alternately high and low when fed on meat or bread. Similarly, if pigs were starved and fed alternately the count went down and up accordingly. The floras of adult guinea pigs were dominated by lactobacilli.

Dr. H. Haenel ("Micro-ecological rules in the composition of the intestinal flora of man") said that before birth the baby was germ-free, at birth infection was acquired from the mother's vagina and fæces, and after 3–4 days lactobacilli predominated. The effect of the mother's milk was to replace aerobic lactobacilli by *Lactobacillus bifidus* and to depress clostridia but not *E. coli.* After weaning, *L. bifidus* stayed at a high level, but aerobic lactobacilli and clostridia returned later. Similar results were obtained for poorly developed children in hospital. Factors ruling the flora were easily disturbed; when stools were stored the lactobacilli diminished and streptococci increased and under abnormal conditions there was a reduction of lactobacilli and an increase in proteolytic organisms.

Antibiotics such as terramycin abolished *L. bifidus* and there was an increase in streptococci and aerobic lactobacilli, with an occasional predominance of *Proteus*; the normal flora returned quickly when the antibiotic was stopped. Under antibiotics salmonellæ disappeared but they could return later; they sometimes shared the normal flora without disturbance. After gastrectomy, the anaerobic lactobacilli disappeared, *E. coli* counts became higher than normal; enterococci, clostridia and other organisms increased also and the large intestine showed high counts. In the adult the flora was stable. Normally the small intestine was nearly sterile, and the large intestine showed mostly anaerobic lactobacilli. Under abnormal conditions there could be a predominance of *E. coli* in the small and no anaerobic lactobacilli in the large intestine; the flora might be the same throughout the intestine with anaerobic lactobacilli absent.

Dr. Anne Dickinson and Dr. G. Mocquot ("Studies on the bacterial flora in the alimentary tract of pigs: 1, Enterobacteriaceae and other Gram-negative bacteria"), observed pigs of 20–100 kgm. in individual pens; the diet was supplemented with antibiotics in some animals. The object was to identify Enterobacteriaceae and other Gram-negative flora isolated on deoxycholate citrate agar after 24–28 hr. at 37° C. Details were given of ten groups classified mainly on morphology, colonial appearance, motility, whether mucoid or not, glucose agar stab cultures, lactose fermentation, growth at 45° C., indole, lysine decarboxylase, urea hydrolysis, production of hydrogen sulphide, liquefaction of gelatine, and ornithine and ammonia. There was no change in the distribution of types under antibiotic feeding. Group 1 usually dominated and the other groups varied for no apparent reason.

Drs. P. Raibaud, M. Caulet, J. V. Galpin and G. Mocquot ("2. Streptococci: selective enumeration and differentiation of the dominant groups") described the isolation of 415 strains of group D streptococci from cæcal and fæcal swabs, using their own medium and also those described by Barnes, Slanetz and Kjellander; thirty-eight types could be distinguished by fermentation reactions differing in at least one carbohydrate. Urea hydrolysis was used for differentiation and the results were regarded as of taxonomic significance. The predominant streptococci were related to *Streptococcus bovis* or *Strep. equinus*, but the classification of these organisms is at present extremely confused.

Dr. M. Lev's paper on "Germ-free animals and their use in elucidating the action of the gut flora on the host" was read by Dr. Cuthbert. Using an apparatus consisting of a nylon tube over a frame, all of which could be autoclaved, chickens and turkeys were hatched from washed and sterilized eggs and the young mammals, monkeys and guinea pigs removed by cæsarean section. Sterilized foods with and without antibiotics were given through tubes, and the effect on the germ-free birds and animals noted. Normal chicken fæces fed to germ-free chicks depressed growth, but feeding penicillin depressed *Cl. welchii* and stimulated growth. Feeding *Cl. welchii* to germ-free chicks depressed growth, but the effect was partly reversed by penicillin in the diet; growth was not increased when germ-free animals were given penicillin. Toxins of *Cl. welchii* caused the gut to thicken and this was prevented by penicillin. Feeding lactobacilli, streptococci and *E. coli* to germ-free creatures had no effect, but the addition of *Cl. welchii* depressed growth, which again was partly reversed by penicillin.

Deficiency in vitamin A led to infection, and gross deficiency caused death; lesions could be seen in the germ-free animals. Germ-free animals on a vitamin K-deficient diet suffered prolonged gut bleeding and the blood had no clotting power. Menedian (four vitamins) did not restore the clotting power, and it is suggested, therefore, that gut bacteria are needed to convert the menedian to some form which can be used.

Entamoeba histolytica did not attack the germ-free gut but survived for a few days only when *coli-aerogenes* were present; they did not survive when autoclaved cæcal contents were fed. There appeared to be complex factors involved in harmless organisms promoting a lethal effect in contact with pathogens. *Shigella flexneri* did not attack the normal guinea pig, but killed the germ-free animals; this was prevented by prior feeding with *E. coli,* non-colicine forming and not demonstrably toxic *in vitro*.

Germ-free animals were equally affected by hæmorrhagic shock caused by the endotoxins from gut Gram-negative flora. Germ-free chicks after five weeks exposure to conventional conditions suffered severe setbacks. Tests are needed on synthetic diets.

Dr. Joan Taylor, describing the "Host specificity and enteropathogenicity of *Escherichia coli*", said that the typing of pathogenic *E. coli* was based on '*O*' (somatic), '*K*' (surface) and '*H*' (flagellar) antigens. Infantile diarrhœa was due to types 0111, 055 and 026 mainly, which were found in all parts of the world. 0128 and 0127 could be found in the United Kingdom and United States respectively, but they were now beginning to cross-spread.

Epidemiological correlation confirmed the role of these organisms in infantile diarrhœa. With the three major types, it was possible to follow the rise in numbers until diarrhœa occurred, beginning when there was a pure culture and ending when other organisms were re-established. But there were similar occurrences with no symptoms. Volunteer feeding had confirmed the pathogenicity of 0111 in students, prisoners and a baby, and of 055 more feebly in prisoners.

Calf scours was related to *E. coli,* particularly 078, which was widely distributed, and may become septicæmic. Swine œdema due to 0138 and 0139 was frequent in the United States, United Kingdom and Canada. Enteritis in lambs due to type 078 occurred in the United Kingdom and Australia; hen septicæmia was caused by type 02.

There was little information about the occurrence of these organisms in healthy animals, but the human types 026, 055, 0111 were found in cats, dogs, and kittens without symptoms. Surveys suggested limited distribution in different species and disease in some only.

Infection experiments were carried out on alternate loops of sterile gut, in anæsthetized rabbits; the rabbits were killed 24 hr. later by injection of air. Inflammatory reactions with exudations occurred in the infected loops, but non-infected loops were sterile and normal. Many strains from human babies, also chicks, water, calf and swine strains, gave no reaction, although some calf-strains were positive. Living cells were necessary for infection.

Dr. J. G. Collee, Miss J. A. Knowlden and Dr. Betty Hobbs, in their paper on "Studies on the growth, sporulation and carriage of *Clostridium welchii* with special reference to food poisoning strains", observed that typical *Cl. welchii* type *A* strains were completely β-hæmolytic, and that strains were called non-hæmolytic if the hæmolysis was not complete. Food poisoning strains were non-hæmolytic and resisted 100° C. for 1 hr. 80/80 samples of fæces yielded *Cl. welchii*. 39/50 (78 per cent) stool samples from students gave non-hæmolytic strains, but spores from three (6 per cent) strains only were remarkably heat-resistant, as demonstrated by tests on fæces and tests on sporing cultures. Previous reports had given 2 per cent as the average carrier-rate of non-hæmolytic heat-resistant types in normal people; hospital personnel had shown 20 per cent or more. Heat-resistance tests for spores in stock strains revealed the protective effect of cooked meat, which was most apparent with heat-resistant strains. Preliminary findings indicated that the heat-resistant property of typical food-poisoning strains was genetically determined and was not primarily dependent on the presence of large numbers of spores.

Food-poisoning strains seldom produced spores in cooked foods and it was suggested that food should be streaked on neomycin blood agar for non-hæmolytic anaerobic colonies, which should be picked off, grown in Ellner's sporulation medium and the heat-resistance tested. It should be noted that hæmolysis on blood agar was not entirely consistent and spore yields from Ellner's medium were not reliable. Confirmation was given by slide agglutination with the thirteen antisera available; serological cross-reactions and untypable strains still occurred occasionally. It was possible to type 75 per cent of 298 strains submitted during 1960-1961.

An unusual growth pattern at 50° C., the Phœnix phenomenon, was observed with both heat-sensitive and heat-resistant strains; there was no difference between the growth curves of food-poisoning and non-food-poisoning hæmolytic strains over the normal range of temperature, and both could grow under nearly similar conditions, which accounts for occasional outbreaks caused by the heat-sensitive β-hæmolytic types. These strains were unlikely to survive cooking, but may be protected mechanically by lack of heat penetration or may be introduced and find a favourable anaerobic environment during the cooling period.

It was stressed that the relationship of these observations to the bulk cooking of meat and its known association with *Cl. welchii* poisoning of food merited further investigation.

Dr. Betty Hobbs, describing "The public health significance of *Salmonella* carriers in livestock and birds", considered the carriage of salmonellæ by animals and birds in relation to the contamination of foods provided for human consumption; human carriers now appeared to be less important than animal carriers. Particular attention was directed to poultry and egg products and to the contamination of boneless and carcass meats, horse meat and pet food. A parallel was shown between *Salmonellae* isolated from abattoirs and in local populations.

It was suggested that improved conditions and speed of transport for animals passing from farms to abattoirs and more care and attention over hygiene in processing may reduce the spread of infection among animals and the spread of contamination on carcass meat; also, that the pasteurization of egg products and pelleting of animal foodstuffs, both of which eliminated *Salmonellae*, would help markedly to reduce the introduction of *Salmonellae* into bakeries and farms. The increase in salmonellosis due to exogenous types was most probably due to the introduction of egg products, meat, and now coconut contaminated with these types.

Drs. R. Buttiaux and D. A. A. Mossel ("The significance of organisms of supposed fæcal origin in food and water") suggested that the enumeration of organisms indicative of fæcal contamination was necessary because: (*a*) direct tests for pathogens were difficult and statistically uncertain, and (*b*) repeated absence of indicators gave virtual certainty of absence of fæcal contamination, and also (*c*) guaranteed absence of non-pathogenic fæcal contamination. Human indicator organisms had been preferred hitherto but animal indicators might be equally or more important.

The test should be quantitative and foods classified as stable, that is, dried, or perishable, raw or heated. The indicator organisms should be frequent in the gut and scarce outside, but they must be able to survive outside the enteric environment.

E. coli I was common in fæces but not outside. *E. coli II* was fairly common in fæces but occurred elsewhere also. *Klebsiella*, non-motile and urease-positive, were frequent in human stools, also in swine stools but seldom elsewhere. Lancefield Group *D* streptococci were common in animals but little was known about their survival in the environment. *L. bifidus* and bacteroides were unsuitable.

Dr. J. H. McCoy, introducing the discussion, emphasized the fact that examination of water was chiefly concerned with measures against typhoid fever, dysentery and cholera and none of the bacteria responsible was carried by animals; thus interest was centred on human contamination. The survival of *E. coli* in water meant recent pollution; if these organisms were absent there had been time for pathogens to die, as the survival-rate of *E. coli* was similar to that of pathogens. The treatment of sewage aimed to reduce nuisance, not bacteria; *Salmonellae* could be isolated easily from treated sewage. In food the organisms had opportunity for growth, hence numbers of fæcal organisms at time of delivery bore no relation to the degree of original contamination. In untreated food the presence of intestinal organisms led to an assessment of cleanliness and not to safety; therefore there should be direct examination for pathogens also.

Dr. N. P. Burman, who continued the discussion, showed tables which gave the optimum growth temperature characteristics of coli-aerogenes from various sources and also the coli-aerogenes and streptococcal flora of shallow wells and mains. IMVIC types other than *E. coli* could be found in a variety of places, for example Wilson's irregular type 6.

Coliforms were stimulated by copper treatment, and *Cl. welchii* could be found in chlorinated water supplies. Streptococci found in river waters were mostly animal types, although many strains on membrane filters at 37° C. were untypable; these were eliminated if incubation at 37° C. was exchanged for 45° C. after 4 hr.

In more general discussion, Dr. Blanche Koelensmid and others expressed satisfaction at the authoritative indication that fæcal bacteria in foods cannot be regarded with the same significance as in water.

VITAMIN B_{12} AND INTRINSIC FACTOR

ABOUT 150 leading workers from forty-five laboratories in fifteen different countries attended the second European Symposium on "Vitamin B_{12} and Intrinsic Factor", organized by Prof. J. Kühnau and Drs. W. Friedrich and H. C. Heinrich, and held in the Institute of Physiological Chemistry in the University of Hamburg during August 2–5. Prof. Kühnau, in his opening address, emphasized the importance of the newly revealed structure of vitamin B_{12} coenzyme, endowing it with remarkable activity. In the first symposium at the same place five years ago a notable feature was the disclosure of the structure of vitamin B_{12}, the culmination of several years work by Dr. Dorothy Hodgkin *et al.* at Oxford. This was then the most complex molecule of which the structure had so far been elucidated. In this second symposium, the climax of years of patient work by Drs. Hodgkin and P. G. Lenhert came just in time for the disclosure of the structure of a still more complex molecule, that of a vitamin B_{12} coenzyme, the form in which the vitamin appears mainly to exist in the animal and human body.

Crystals of the 5 : 6-dimethylbenziminazole cobamide coenzyme were grown and photographed with copper X-radiation while in contact with their mother liquor. A complete X-ray analysis of the structure revealed some interesting differences from the structure of cyanocobalamin, which at present is the official form of the vitamin. The new unsaturated pentose previously reported to be liberated from the coenzyme by mild acid hydrolysis has now been found to be an artefact produced during the hydrolysis from ribose through which adenine is linked to the cobalt in the molecule. There may be a free valency in the coenzyme molecule that could play a vital part in metabolic reactions yet to be elucidated.

These differences in chemical composition and molecular structure between vitamin B_{12} and its coenzyme are reflected in differences in their absorption spectra. H. A. Barker *et al.*, at the University of California, where pioneer work on the coenzyme was done, found that in place of the characteristic sharp band of cyanocobalamin at 361 mμ the coenzyme shows a broader band at about 380 mμ and a very slight band at 340–345 mμ. The fairly broad cyanocobalamin band with maxima at about 520 and 550 mμ is replaced by a very broad B_{12} coenzyme band with maximum at about 520 mμ and a slight shoulder at about 495 mμ. The cyanocobalamin band at about 278 mμ is replaced by an inflexion at 288 mμ in alkaline solution shifting to 284 mμ in acid solution and considered specific for the coenzyme. Characteristic differences in absorption spectra of purine- and benzimidazole-containing coenzyme analogues appear to depend on differences in the strength of the bond between the base and cobalt. There is evidently scope for further spectroscopic studies, including a search for isosbestic points that are so prominent in mixtures of cyano- and hydroxocobalamin, now considered to be artefacts obtained from B_{12} coenzyme in the liver and other body stores. E. E. Gabbe and H. C. Heinrich (Institute of Physiological Chemistry, University of Hamburg) emphasized the importance of the freedom of B_{12} coenzyme from cyanide, which they investigated in experiments using radioactive preparations.

B_{12} coenzymes catalyse various reactions that can be used for their enzymic assays. These include conversion of glutamate to β-methylaspartate by the bacterial glutamate isomerase system, the methylmalonyl isomerase reaction and the conversion of certain glycols to deoxyaldehydes. Experiments with deuterium oxide exclude reaction mechanisms involving the intermediate formation of a free proton. These reactions have been studied in bacterial extracts but the methyl-malonyl isomerase reaction occurs in higher organisms.

These findings apply to different B_{12} coenzymes, of which several have been isolated by H. A. Barker *et al.* They appear to be the most abundant corrinoid compounds in various bacteria (for example, *Propionibacterium*) and in mammalian, including human, livers. However, D. Perlman and his colleagues at the Squibb Institute for Medical Research, New Jersey, obtained only 5,6-dimethylbenzimidazolyl cobamide coenzyme from 30 cultures of *Streptomyces*.

B_{12} coenzymes are highly sensitive to light and cyanide. Photolysis yields hydroxocobalamin, which the minute traces of cyanide always present in blood can partly convert to cyanocobalamin. Polarographic studies of these reactions have been carried out by K. Bernhauer *et al.* at Stuttgart. While body tissues usually contain a mixture of hydroxo- and cyanocobalamins, the latter, being at present the officially accepted form of vitamin B_{12}, has been chosen as the standard of comparison with B_{12} coenzyme by a number of investigators. M. E. Coates *et al.* (National Institute for Research in Dairying, Shinfield) detected no difference between the absorption of B_{12} coenzyme and that of cyanocobalamin (both labelled with cobalt-58) through rat intestine in presence of rat stomach extract. Chick assays showed the coenzyme to have only 78 per cent of the activity of cyanocobalamin when administered intramuscularly, but the coenzyme appeared more effective than cyanocobalamin in restoring hatchability in depleted chick embryos. On the whole the coenzyme does not seem to have any therapeutic advantage over cyanocobalamin.

A. W. Johnson (University of Nottingham), described synthetic approaches to the corrin ring system by Sir Alexander Todd *et al.* (Cambridge). Using radioactive delta-amino-lævulinic acid, porphobilinogen has been shown to be a common biogenetic precursor of vitamin B_{12} and of the natural porphyrins. Biosynthesis by different pathways has been studied by K. Bernhauer *et al.* (Stuttgart) and by A. Di Marco *et al.* (Laboratori Richerche Farmitalia, Milan).

A valuable indication of an important biological function of vitamin B_{12} was obtained by L. A. Manson (Wistar Institute, Philadelphia), who observed deoxyribose synthesis by vitamin B_{12} in a murine leukæmia cell of thymic origin which by leading to nucleoprotein synthesis may explain one of the roles of the vitamin in cellular metabolism. B. Connor Johnson *et al.* (University of Illinois), using the DR-aldolase system, found no relationship between B_{12} deficiency and deoxyribose biosynthesis by C_2 + C_3 condensation, and when investigating the role of B_{12} in thymidine synthesis showed that carbon-14 in glutamate was incorporated into the DNA-thymine of regenerating liver. H. R. V. Arnstein and A. M. White found cyanocobalamin to increase biosynthesis of phenylalanine, tyrosine and valine and concluded that neither general inability to oxidize and reduce one-carbon units nor to synthesize thymine can represent the main metabolic lesions in vitamin B_{12} deficiency.

In the search for specific effects of vitamin B_{12} deficiency much attention has been directed to the production of antimetabolites to the vitamin which could be used to produce and investigate controlled deficiencies. E. Lester Smith (Glaxo Laboratories, Ltd., Greenford) found the amides of the monocarboxylic acid, preferentially produced on mild hydrolysis of B_{12}, to prevent conversion of the vitamin to its functional form, but while they competed effectively with B_{12} for uptake by intrinsic factor and inhibited enzyme systems *in vitro* they produced no changes in the blood or bone marrow. W. Friedrich, H. C. Heinrich and P. Riedel (Hamburg) succeeded in producing still more effective antimetabolites from factor V_{1a} isolated from sewage sludge. The resulting alkanolamine B_{12} analogues showed very high inhibitory activity on the growth of *E. coli* and *Ochromonas malhamensis*. H. Heinrich related B_{12} specificity to the structure and position of the alkanolamine, nucleotide, and side chains in the corrin ring. Some attention is now being directed to human dietary deficiency of vitamin B_{12} which may occur in vegans (strict vegetarians consuming no animal food) and was first described by F. Wokes, J. Badenoch and H. M. Sinclair to the International Congress of Nutrition in Amsterdam in 1954. F. Wokes (Vegetarian Nutritional Research Centre, Watford, Herts) and A. D. M. Smith (Middlesex Hospital Institute of Clinical Research, London) gave at the Hamburg B_{12} Symposium further details of a B_{12} deficiency characterized by low serum B_{12}-levels and neurological manifestations with lesions in the peripheral and central nervous systems, well marked in some vegans, and of slight occurrence in vegetarians with low intakes of animal protein and vitamin B_{12} from eggs, milk and cheese, as well as in about 1 per cent of the general population. In India, where the Vegetarian Nutritional Research Centre has been asked to help, strict vegetarians consuming scarcely any animal food encounter much more marked B_{12} deficiency than is found in vegetarians consuming dairy produce, while meat-eaters encounter no vitamin B_{12} deficiency. To avoid widespread protein malnutrition in India an extra 2 million tons of protein will be needed annually, which should be fortified with B_{12} to improve its biological value.

Vitamin B_{12} seems to be missing from all staple vegetable proteins. Slight traces in certain leaf proteins (for example, alfalfa, turnip tops) are not significant sources in human diets. However, A. Pfau and G. Kallistratos (Max-Planck Institute for Animal Breeding and Nutrition, Mariensee, near Hanover) found that broad bean (*Vicia faba*) plants can take up vitamin B_{12} from nutrient solutions, about 27 per cent being absorbed in 24 hr. from solutions containing physiological concentrations of B_{12} labelled with cobalt-60. The absorbed B_{12} was found mainly in the roots (87 per cent of total absorbed) and much less in the leaves (3 per cent). In the ensuing discussion F. Wokes reported that in an investigation at Watford, using plants of Russian comfrey (*Symphytum peregrinum*), 200 μgm. per gm. total solids were found in roots and 76 μgm./gm. in total solids in leaves after 24 hr. immersion of the undamaged roots in 50 ml. of aqueous solution containing 40 mgm. B_{12}. These findings may find application in manuring, especially with sewage sludges rich in B_{12}.

The Symposium agreed that the term hydroxocobalamin should be used to describe products in which the cyanide group of cyanocobalamin is replaced either by —OH (in alkaline solution) or by [H_2O], hitherto termed aquocobalamin (in acid solution). Hydroxocobalamin obtained by photolytic decomposition of vitamin B_{12} coenzyme is present in body tissues in amounts at least equal to those of cyanocobalamin. R. F. Schilling *et al.* (University of Wisconsin) found hydroxocobalamin to be absorbed as efficiently as cyanocobalamin and better retained. After intramuscular injection hydroxocobalamin gives much higher serum B_{12}-levels than are given by cyanocobalamin. (G. B. J. Glass and colleagues, New York Medical College.)

Hydroxocobalamin is at present excluded by stringent spectroscopic tests from the cyanocobalamin which is recognized officially as vitamin B_{12} in leading pharmacopœias. Because of the increasing importance attached to hydroxocobalamin its acceptance as an alternative and perhaps also improved form of vitamin B_{12} seems likely to take effect during the near future, partly for the more efficient treatment of pernicious anæmia, but especially to cope with demyelinating diseases or tobacco amblyopia in which cyanide may be an important factor.

Vitamin B_{12} deficiency occurring through lack of intrinsic factor has led to intense efforts to purify and isolate intrinsic factor. L. Ellenbogen (Lederle Laboratories, American Cyanamid Co., Pearl River, New York) reported on the purest preparation so far obtained, active in doses of 50 μgm. or less, with very high binding capacity for B_{12} and B_{12} coenzyme, very low carbohydrate content, no peptic activity and only trace amounts of blood group substances. W. W. Bromer and E. O. Davisson (Lilly Research Laboratories, Indianapolis) obtained intrinsic factor preparations, effective in treatment of pernicious anæmia in daily doses of less than 100 μgm., by *XE*-64, followed by calcium phosphate gel, chromatography, combination with B_{12}, ultra-centrifugation and electrophoresis. R. Gräsbeck and colleagues from the Minerva Institute for Medical Research, Helsinki, used DEAE cellulose column chromatography with gradient elution and found one major B_{12}-binding peak that, under present conditions, is sole carrier of intrinsic factor activity. A 'releasing factor' similar to that in the fish tapeworm which liberates B_{12} bound to human gastric juice has been found in human small intestine, kidney, liver, thyroid, heart muscle, brain, spleen and lung, and has been partially purified with the aid of DEAE cellulose chromatography.

Radioactive vitamin B_{12} used in many investigations on its absorption, storage and utilization is available with different labellings. R. Gräsbeck (Helsinki) described how earlier use of cobalt-60 involved large doses of radioactivity. These are considerably reduced when it is replaced by cobalt-58 but solutions of this are unstable. The recently introduced cobalt-57 has several advantages in clinical diagnosis, when either urinary or fæcal excretion, hepatic uptake, plasma radioactivity or total body retention may be measured. Different forms of radioactive B_{12} have also been used to study complex problems concerned with the action of vitamin B_{12} as well as difficult questions regarding the possible role of vitamin B_{12} and its absorption with or without the aid of intrinsic factor.

The last five papers dealt with relationships between vitamin B_{12} and folic acid. J. R. Guest and D. D. Woods (Microbiology Unit, Department of Biochemistry, University of Oxford) described metabolic interrelationships in the synthesis of methionine by *E. coli* and postulated two pathways for the methylation of homocysteine, the first relatively independent of cobalamin metabolism and with a strict requirement for a conjugated folic acid co-factor, the second dependent on cobalamin but functioning with pteroylmonoglutamates as well as conjugate forms. L. Jaenicke (Biochemical Institute, Munich) described how the structure of different forms of folic acid affects their efficiency in the first pathway. D. L. Mollin and A. H. Waters (Postgraduate Medical School, London) found uncomplicated folic acid deficiency completely cured by very small doses of folic acid (50–150 μgm. daily) in persons with megaloblastic anæmia due to idiopathic steatorrhœa who absorb B_{12} normally, obtain adequate amounts of B_{12} in their diets and excrete very large amounts of formimino-glutamic acid in their urine. In patients with idiopathic steatorrhœa and tropical malnutrition syndrome there is defective absorption of both folic acid and vitamin B_{12}. The very low serum B_{12}-levels may be raised (but not to the normal range) by small doses of folic acid which completely remove other effects of deficiency. E. V. Cox *et al.* (General Hospital, Birmingham) found serum iron high in untreated megaloblastic anæmia and reduced to normal after satisfactory therapy with B_{12} or folic acid. Blood 'folic acid' was temporarily increased, especially in patients with adequate iron utilization and status. In some patients with subnormal serum B_{12}-levels, folic acid administration raises these levels; in others it either has no effect or still further reduces them.

Round-table discussions, to which all members listened, were held on the nomenclature of B_{12} vitamins, intrinsic factor assays and standardization of diagnostic radioactive B_{12} absorption tests, vitamin B_{12} pool, turnover-time and requirements, stability of radioactive B_{12} and B_{12} therapy, under the guidance of Dr. H. A. Barker, Prof. K. Bernhauer, Dr. Dorothy Hodgkin, Prof. A. W. Johnson, Dr. S. K. Kon, Dr. Rosenblum, Dr. R. P. Schilling, Dr. Lester Smith and Prof. L. S. Witts. Full details will be published in the Symposium Proceedings.

MEDIATION OF DIVALENT METAL IONS IN THE BINDING OF TETRACYCLINE TO MACROMOLECULES

By DR. KURT W. KOHN

Clinical Pharmacology and Experimental Therapeutics Service, General Medicine Branch, National Cancer Institute, Bethesda, Maryland

SEVERAL biological and biochemical effects of the tetracycline antibiotics depend on the presence of divalent metal ions. These effects include the inhibition of certain enzymes[1], the precipitation of β-lipoproteins[2], and the localization of tetracyclines in tumour tissues[3,4]. These phenomena probably involve the formation of tetracycline-metal chelates[5]. Calcium chelation may account for the binding of tetracyclines in newly formed bone[6] and for the interference with calcification caused by these antibiotics[7].

The metal ions may act in these systems by simultaneously binding tetracycline and suitable macromolecular sites. In order to test the possibility that such metal-bridge complexes may generally form with macromolecules having binding sites for divalent cations, we studied the interaction of tetracycline with deoxyribonucleic acid (DNA) and with serum albumin in the presence and absence of divalent cations.

Equilibrium Dialysis. Macromolecule solutions (1·0–1·5 ml.) in bags of ¼-in. transparent cellulose tubing were dialysed (40 hr. at 4°) against 15 ml. of buffers containing tetracycline and various concentrations of divalent metal ions. The transparent cellulose bags were weighed before and after dialysis and appropriate corrections were made for any changes in macromolecule concentration. Donnan effects were estimated to be negligible. Tetracycline concentrations inside and outside the dialysis bags were determined by fluorometry of extracted calcium–barbital complexes[8].

The preparations of DNA used were relatively undenatured, as indicated by the absence of any lowering of optical density (260 mμ) in response to 0·01 magnesium chloride[9]. Crystalline human serum albumin was dissolved in 0·15 *M* sodium chloride containing 0·01 *M* ethylenediaminetetraacetic acid and dialysed extensively at 4° against 0·12 *M* sodium chloride plus 0·03 *M* sodium bicarbonate–carbon dioxide buffer at *p*H 7·4. The concentration of the dialysed albumin solution was determined gravimetrically on heated trichloracetic acid precipitates[10]. (Salmon sperm DNA and crystalline human serum albumin were purchased from the Mann Research Laboratories, New York. Calf thymus DNA was obtained from the Worthington Biochemical Corp., Freehold, New Jersey.)

Little or no tetracycline became bound to either DNA or albumin in the absence of divalent metal

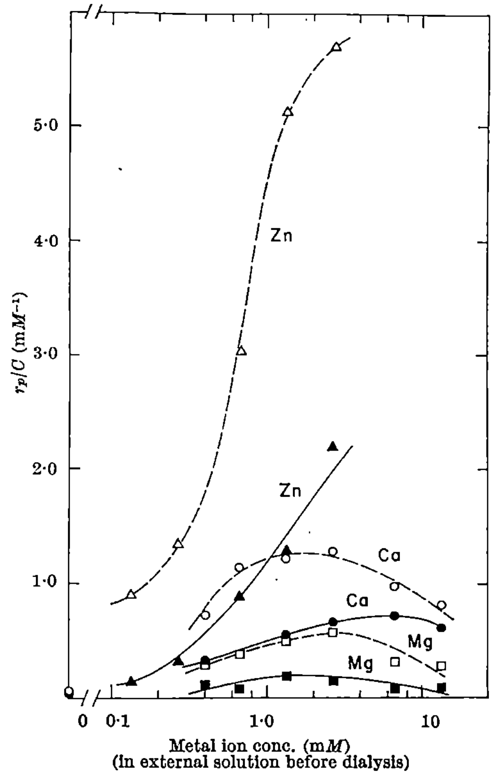

Fig. 1. Effect of divalent metal ions on the extent of tetracycline binding by 'native' (——) or heat-denatured (– – –) DNA, as determined by equilibrium dialysis of salmon sperm DNA solution (2 mgm./ml. in 10^{-2} M potassium chloride) against 10 volumes of 10^{-5} M tetracycline in 0·04 M *tris*-hydrochloric acid buffer at pH 7·8 (23°). Ionic strength 0·06 was maintained with potassium chloride. (r_p = mean number of tetracycline molecules bound per DNA phosphorus; C = concentration of unbound tetracycline at equilibrium)

ions. Binding to DNA did take place in the presence of zinc, calcium, manganese or magnesium, in decreasing order of effectiveness (Fig. 1). Heat-denatured DNA (100° for 15 min.) exhibited markedly increased binding. The results were qualitatively similar for DNA derived from salmon sperm or calf thymus. In the case of serum albumin, tetracycline binding occurred in the presence of zinc, but no significant binding was detected with calcium (Fig. 2).

At the low concentrations used, the amount of tetracyline bound was proportional to the concentration unbound. The maximum binding, represented by the highest points on the curves with zinc in Figs. 1 and 2 corresponded to 1 molecule tetracycline bound per 120 nucleotide units of heat-denatured DNA and 1 molecule bound per 40 molecules of albumin, respectively.

Fluorescence. The tetracycline chelates of calcium and zinc fluoresce in aqueous solution. DNA and albumin were observed to enhance this fluorescence. Tetracycline (10^{-5} M) was titrated with zinc chloride or calcium chloride at several pH values between 6·5 and 8·0, and fluorescence intensity (excited at 405 mμ, observed at 530 mμ) was plotted against the amount of metal added. The presence of DNA or albumin in such titrations caused much greater fluorescence to appear on addition of the metal (Fig. 3). The macromolecules did not, however, increase fluorescence in the absence of divalent metal ions. DNA and albumin gave qualitatively similar results. Heat-denatured DNA produced greater enhancement of fluorescence than did the undenatured material.

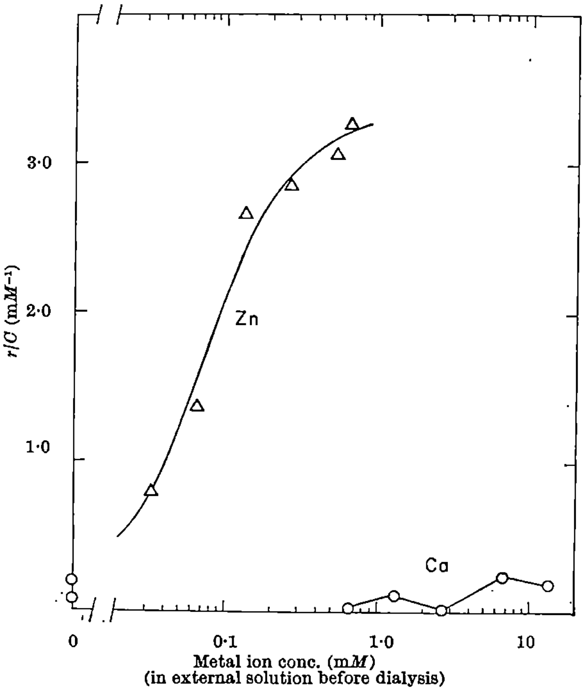

Fig. 2. Binding of tetracycline to human serum albumin. Equilibrium dialysis of 1·0 ml. protein solution (*c*. 30 mgm./ml.) against 15 ml. of 10^{-5} M tetracycline at pH 7·52 ± 0·04 (23°) (0·12 M sodium chloride, 0·03 M sodium bicarbonate–carbon dioxide buffer). (r = moles of tetracycline bound per mole of protein; C = concentration of unbound tetracycline at equilibrium)

In other experiments, the concentration of macromolecules was varied while other factors were held constant (Fig. 4). Zinc or calcium were present in sufficient excess to assure nearly complete chelation of unbound tetracycline. Fluorescence enhancement

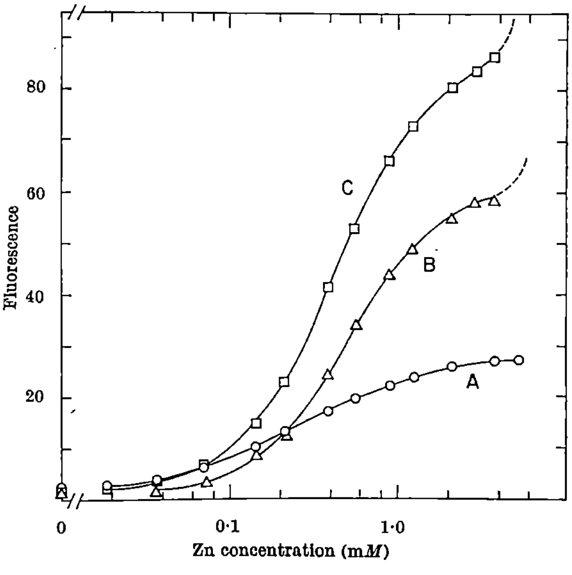

Fig. 3. Fluorescence titration of tetracycline with zinc chloride (0·06 M NaAc–HAc buffer, pH 6·65 ± 0·04). A, in the absence of DNA; B, in the presence of salmon sperm DNA (1·4 mgm./ml.); C, same with heat-denatured DNA. (Above 4 mM zinc, the DNA solutions became turbid and the fluorescence rose sharply)

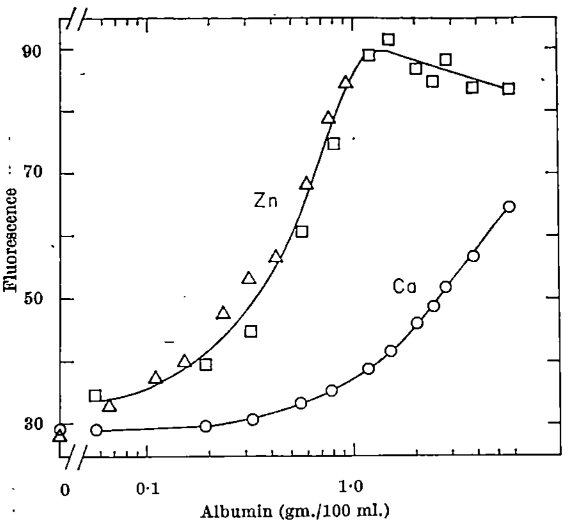

Fig. 4. Enhancement of fluorescence of tetracycline chelates by human serum albumin. Solutions of 10^{-5} *M* tetracycline in 5·8 gm. per cent albumin at *p*H 7·6 (0·04 *M* sodium bicarbonate–carbon dioxide, 0·12 *M* sodium chloride) and in buffer without albumin were mixed in various proportions. Both solutions also contained either 10^{-3} *M* zinc chloride or 10^{-3} *M* calcium chloride. (Activation at 405 mμ, fluorescence measured at 530 mμ)

occurred at much lower macromolecule concentrations in the presence of zinc than with calcium. The results for DNA and albumin were again qualitatively similar. The rise in fluorescence occurred at lower concentrations with denatured DNA than were required with 'native' DNA.

The enhancement of tetracycline chelate fluorescence produced by DNA and serum albumin might be explained by: (1) binding of tetracycline chelates to specific macromolecular sites; (2) electrostatic attraction of tetracycline chelates into the hydration layers of the macromolecules; or (3) increases in viscosity of the solutions. Electrostatic effects alone cannot account for the large differences in the effectiveness of albumin (or DNA) in enhancing the fluorescence of the zinc versus calcium chelates (Fig. 4), since, under the conditions of these experiments, nearly all the unbound tetracycline was in the form of 1 : 1 chelates which should have the same charge with zinc as with calcium. If viscosity were the major factor, undenatured DNA solutions, which have much higher viscosity than denatured solutions, should produce the greatest increases in fluorescence. The reverse was found to be the case. It appears, therefore, that the changes in fluorescence result mainly from binding which, at least in the case of the zinc complexes, occurs at specific macromolecular sites.

The divalent metal ion probably mediates this binding by serving as a connecting bridge between macromolecule and tetracycline. This conforms with previously reported instances of metal-mediated binding of chelating agents to proteins[11,12].

The results of both the dialysis and fluorescence experiments indicate that the binding of tetracycline chelates to DNA is increased after heat-denaturation. This is in accord with the increase in cation-binding ability brought about by heat-denaturation of DNA[13]. Serum albumin was observed to bind tetracycline in the presence of zinc, but not of calcium. The albumin sites for zinc are probably imidazole groups[14] which would be expected to have very little affinity for calcium. These relationships support the picture of a bond between DNA (or albumin) and the metal component of the tetracycline chelate.

The results strengthen the view that the tetracyclines may exert some of their biological effects by complexing with macromolecules through metal ions. The binding of tetracyclines in human plasma, for example, may be through this mechanism, since purified serum albumin, by itself, does not bind these compounds.

DAMAGE IN STAINLESS STEEL DUE TO FISSION FRAGMENTS

By P. R. B. HIGGINS and A. C. ROBERTS

Metallurgy Division, Atomic Energy Research Establishment, Harwell, Berks

An investigation has been made by transmission electron microscopy on the changes in the microstructure of stainless steel bombarded by fission fragments at 60° C. The steel used was a niobium-stabilized 20 per cent chromium, 20 per cent nickel austenitic stainless steel which was received as hot-rolled strip, 0·020 in. thick. The steel had been vacuum-melted twice prior to rolling and its analysis is given in Table 1.

The material was reduced to foil 0·001 in. thick by successive heat treatments and cold rolling. This was followed by a solution heat treatment at 1,145° C. for 20 min. and a water quench. The foils were then thinned electrolytically in a stabilized phosphoric–sulphuric acid polishing solution (solution kindly given by Messrs. Electropol, Ltd., Farnham, Hants), and given an electrolytic cleaning treatment in a mixture of 75 per cent sulphuric acid, 18 per cent glycerol and 7 per cent water. The thickness of the prepared foils was determined by measurements of

Table 1

	Cr	Ni	C	Mn	S	P	Si	Nb	Fe
Chemical composition (per cent)	19·6	20·1	0·02	0·72	0·004	0·008	0·69	0·44	~58·4

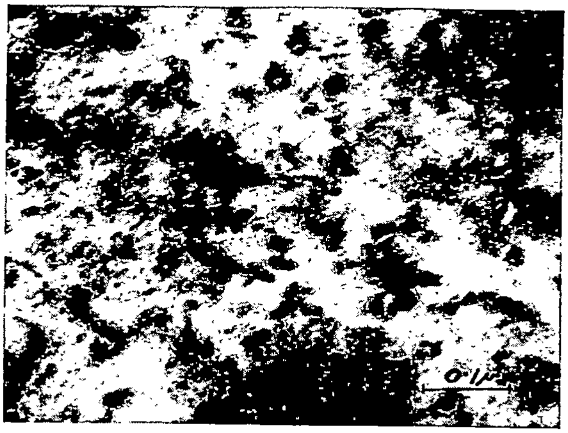

Fig. 1. Damage observed in stainless steel after an irradiation of 8·4 × 10^{15} fission fragments cm.$^{-2}$ at a rate of 1·6 × 10^{10} fragments cm.$^{-2}$ sec.$^{-1}$

slip traces and found to be a few hundred angstrom units.

Individual foils were held between strips 0·001 in. thick of either natural uranium or 93 per cent uranium-235 by an aluminium clamp. This assembly was sealed in silica and irradiated in the *Bepo* reactor in a thermal neutron flux of 1·3 × 10^{12} n. cm.$^{-2}$ sec.$^{-1}$. After irradiation it was necessary to clean the steel surface in the cleaning bath already described; however, this treatment did not remove a significant fraction of the steel from the surface. The steel was then examined by transmission microscopy in an Elmiskop I operating at 100 kV.

The fission-rate (R) in uranium of unit area and thickness y is given by $R = \varphi\sigma y n$, where φ is the thermal neutron flux, σ is the capture cross-section of uranium-235 (590 barns), and n is the number of uranium-235 atoms per unit volume.

Since the distance travelled by a fission fragment in uranium is about 4 × 10^{-4} cm., it is only necessary, in the arrangement used, to consider the fissions occurring in a layer of this thickness next to the steel surface, and geometrical considerations show that fragments from approximately 30 per cent of these fissions will pass through the foil. Each fission results in two fragments, and since there is uranium on both sides of the steel the flux of fission fragments is given by: $\varphi_f = 4{\cdot}8 \times 10^4 \varphi\sigma n$ cm.$^{-2}$ sec.$^{-1}$.

For natural uranium this gives a flux of 1·2 × 10^8 fragments cm.$^{-2}$ sec.$^{-1}$ and for 93 per cent uranium-235 a flux of 1·6 × 10^{10} fragments cm.$^{-2}$ sec.$^{-1}$.

Small defects, about 25 Å. in diameter, are first seen in the steel after a fission fragment dose of 1·8 × 10^{14} fragments cm.$^{-2}$. Increasing the dose results in an increase in size and number of defects until they are resolvable as dislocation loops, similar to those observed in other face-centred cubic metals after neutron irradiation or quenching from a temperature near the melting point. Fig. 1 shows a typical damaged area after a dose of 8·4 × 10^{15} fragments cm.$^{-2}$ at the higher dose-rate.

The steel will also be subjected to neutron irradiation, and to determine how much of the observed damage was due to neutron irradiation similar foils were irradiated at 60° C. in a thermal neutron flux of 1·3 × 10^{12} neutrons cm.$^{-2}$ sec.$^{-1}$ (epithermal flux 3 × 10^{11} neutrons cm.$^{-2}$ sec.$^{-1}$) for 700 and 2,000 hr. No defects were observed in the electron microscope, but tensile tests show a characteristic increase in yield stress.

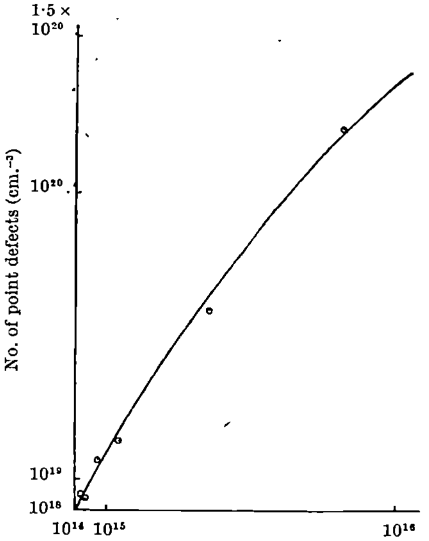

Fig. 2. Increase in concentration of point defects with dose of fission fragments

An estimate of the number of defects observed in the foil has been made by measurement of the integrated area of the defects and a knowledge of the thickness of the foil. Fig. 2 is a plot of the concentration of point defects against fission-fragment dose at a dose-rate of 1·6 × 10^{10} fragments cm.$^{-2}$ sec.$^{-1}$. It will be seen that saturation has not been reached at a concentration of 1·2 × 10^{20} point defects cm.$^{-3}$. A possible reason for such a large number of defects without saturation has been put forward by Barnes (unpublished work), who suggests that the observed defects are due to interstitial atoms[1]. However, after a dose of 1·7 × 10^{16} fragments cm.$^{-2}$, the dislocation loops appear to have grown to form the dislocation network shown in Fig. 3, which may mean that saturation has been reached at this dose.

The number of pairs of point defects produced by each fission event has been obtained from the slope of the initial part of the curve of Fig. 2, which gives a maximum of 45. This is 2 or 3 orders of magnitude lower than the estimated number of defect pairs

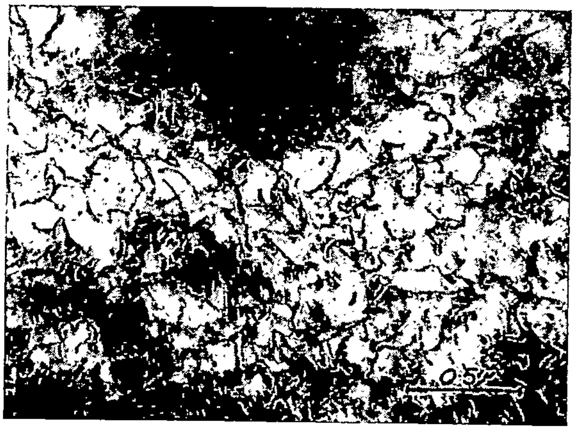

Fig. 3. Dislocation network observed in stainless steel after an irradiation of 1·7 × 10^{16} fission fragments cm.$^{-2}$ at a dose-rate of 1·6 × 10^{10} fragments cm.$^{-2}$ sec.$^{-1}$

produced by a fission event[2]. A higher number of defect pairs per fission event can be obtained by either irradiating at a higher temperature or at a lower dose-rate. For example, after irradiating the steel at a rate of $1 \cdot 2 \times 10^8$ fragments cm.$^{-2}$ sec.$^{-1}$ at 60° C., the number of pairs of defects per fission is 250. This last figure is of the same order as that found in uranium by B. Hudson, K. H. Westmacott and M. J. Makin (unpublished work), where the observed number of point defects will account for the irradiation growth observed experimentally.

The low number of defects per fission event obtained with the specimens subjected to the higher dose-rate at 60° C. is thought to be due to a large number of unobservable defects being present. Higher temperatures, or lower dose-rates, allow these small defects to grow to observable sizes.

Further experiments to study the effects of dose-rate and temperature of irradiation are in progress and will be reported later.

ELIMINATION OF THE ABSORPTION CORRECTION IN THE VISCOMETRY OF DILUTE SOLUTIONS OF HIGH POLYMERS

By H. van OENE and PROF. L. H. CRAGG

Department of Chemistry, University of Alberta, Edmonton

IN a recent paper[1] we directed attention to the fact that values of both intrinsic viscosity $[\eta]$ and the viscosity slope constant k', obtained in the usual way, may be significantly in error because of an apparent reduction in capillary radius. As Öhrn[2] has demonstrated, this apparent reduction in radius may be due to absorption of polymer from solution; it may also be due in part to other effects[1]. Öhrn has described a method of evaluating the 'absorption correction', but it is discouragingly demanding of time and careful experimentation. We have devised a means of calculating intrinsic viscosity which makes an 'absorption correction' unnecessary even when the 'absorption' effect is large.

Öhrn has shown that the absorption effect on the relative flow-time t_r may be expressed thus:

$$t_r = \eta_r(1 + 4a/R) \qquad (1)$$

where η_r is the relative viscosity (the ratio of the viscosities of solution and solvent) and a is the apparent reduction in R, the radius of the capillary.

From this it follows that, in sufficiently dilute solutions:

$$t_{sp}/c = (1 + 4a/R)[\eta] + (k' + 4a/R)[\eta]^2c + 4a/R\,.\frac{1}{c} \qquad (2)$$

and

$$\frac{\ln t_r}{c} = [\eta] - (\tfrac{1}{2} - k' - 4a/R)[\eta]^2c + 4a/R\,.\frac{1}{c} \qquad (3)$$

for, in such solutions:

$$\frac{\ln t_r}{c} = \frac{\ln(1 + t_{sp})}{c} = \frac{t_{sp}}{c} - \frac{\tfrac{1}{2}(t_{sp})^2}{c}$$

Subtracting (3) from (2), we obtain:

$$\frac{t_{sp}}{c} - \frac{\ln t_r}{c} = 4a/R\,.[\eta] + \tfrac{1}{2}[\eta]^2c$$

The correction term $4a/R$ has disappeared from the slope. Hence a value of $[\eta]$ that is unaffected by 'absorption' can be evaluated from the slope of the plot of:

$$\left(\frac{t_{sp}}{c} - \frac{\ln t_r}{c}\right) \text{vs. } c$$

We applied this procedure to Öhrn's very precise data[2] which he obtained with a solution of a polystyrene fraction in toluene. His measurements were made in three different viscometers over a very wide range of concentrations, 0·000470–0·196 gm./dl. Values of t_{sp}/c, $(\ln t_r)/c$, and $\dfrac{t_{sp}}{c} - \dfrac{\ln t_r}{c}$, calculated from the data for the concentration range 0·00232–0·196 gm./dl. (ref. 2, Table 5), are collected in Table 1. The marked effect of absorption at the low concentrations is clearly evident in the values of $\dfrac{t_{sp}}{c}$ and $\dfrac{\ln t_r}{c}$, as is the greater effect in a capillary of smaller

Table 1. VALUES OF t_{sp}/c, $\ln t_r/c$, AND $(t_{sp}/c - \ln t_r/c)$, CALCULATED FROM ÖHRN'S POLYSTYRENE–TOLUENE DATA (ref. 2, Table 5)

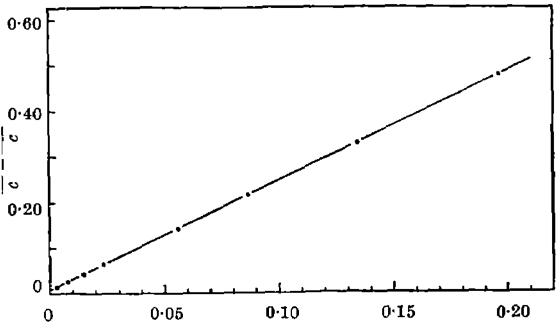

Fig. 1. Plot of ($t_{sp}/c - \ln t_r/c$) vs. c for data obtained in viscometer S_2. (The S_1 and S_3 data give equally good straight lines parallel to, but slightly displaced from, this line)

radius. A typical plot of $\frac{t_{sp}}{c} - \frac{\ln t_r}{c}$ vs. c is given in Fig. 1.

If the method is valid, it should give the same value of [η] for each of the three viscometers even though, because of differing radii, the absorption errors in the three viscometers are very different. In Table 2 are the results obtained, by least-squares analysis, for the data in the concentration-range 0·0230–0·196 gm./dl.

Table 2

Viscometer	Diameters (mm.) 2R	Slope $\frac{1}{2}[\eta]^2$	[η]
S_1	0·5	$2{\cdot}34_7$	$2{\cdot}16_8$
S_2	0·3	$2{\cdot}36_9$	$2{\cdot}17_7$
S_3	0·2	$2{\cdot}37_6$	$2{\cdot}18_8$
	Average	$2{\cdot}36_4$	$2{\cdot}17_5$

The agreement among these values of [η] is excellent, the maximum difference being 1 per cent (or less than the experimental error in the usual determination of [η]). Öhrn's corrected values, obtained by evaluation of a and R and application of his correction formula, is 2·14. It differs from our average value and from the value we obtained from the measurements in S_1 (the viscometer in which absorption was least and the capillary radius of which corresponds most closely to that of the viscometers generally used) by less than 2 per cent.

For concentrations less than 0·023 gm./dl., high-precision data are needed, for otherwise the difference between $\frac{t_{sp}}{c}$ and $\frac{\ln t_r}{c}$ would be within the experimental error of either. Since Öhrn's measurements were very carefully made, we calculated values of [η] for the concentration ranges 0·196–0·00232 gm./dl. and 0·0230–0·000232 gm./dl., obtaining, respectively, 2·18 and 2·21 dl./gm. Even the latter value is within 3 per cent of Öhrn's value, 2·14.

It is evident that our method makes possible a simple and rapid calculation of a 'true' intrinsic viscosity even when 'absorption' effects are so prominent as to introduce large errors into the values obtained by the usual methods or even to make it impossible to apply the usual methods. It is not necessary either to know the radius of the capillary in the viscometer or to measure (or estimate) the thickness of the absorbed layer. Furthermore, in any dilute-solution-viscosity study in which 'absorption' is suspected, a comparison of the value of [η] obtained by this method with that obtained by the usual methods $\left(\text{from values of } \frac{t_{sp}}{c} \text{ or } \frac{\ln t_r}{c}\right)$ will indicate whether or not the 'absorption effect' is significant.

Grateful acknowledgment is made of a grant-in-aid from the National Research Council of Canada and of the award of a fellowship (to H. v. O.) by the Shell Oil Company of Canada, Ltd.

COLORIMETRIC DETECTION OF PENICILLINS AND CEPHALOSPORINS ON PAPER

By ROBERT THOMAS

Squibb Institute for Medical Research, New Brunswick, New Jersey

A WIDELY used technique for the detection of antibiotics on paper chromatograms and ionograms consists of placing the paper strip in contact with an agar suspension of a sensitive organism and observing the growth inhibition zones which result after a suitable incubation period. Thus, with the aid of the Gram-positive bacterium *Sarcina lutea*, as little as 10^{-2} μgm. benzylpenicillin can be readily detected. However, despite the established value of this bio-autographic procedure for work on penicillin, inherent limitations include the delay necessitated by the incubation period and also the prerequisite of bio-activity, which precludes the possibility of detecting structurally related products which may be biologically inactive. In an attempt to overcome these disadvantages, a colorimetric reagent has been devised which is based on the penicillin iodometric assay procedure of Alicino[1]. This is dependent on the finding that, although the intact penicillin molecule is inert to iodine in neutral aqueous solution, after hydrolysis of the β-lactam ring with alkali or penicillinase the resulting penicilloic acid rapidly consumes nine equivalents of iodine.

This procedure can be easily adapted to paper chromatograms as a two-stage spray consisting of dilute alkali followed by a starch–iodine solution in aqueous acetic acid. Under suitable conditions it was found that both penicillins and the related products cephalosporin *C* and cephalosporin *N* were readily detected as white zones against a dark blue background, with a sensitivity of 1–2 μgm. Thus, chromatogram *A* (Fig. 1) received a preliminary spraying with 0·5 *N* sodium hydroxide then, after an interval of 10–15 min. to allow partial drying, it was further sprayed with a reagent composed of a mixture of 1 per cent aqueous starch, glacial acetic acid and 0·1 *N* iodine in 4 per cent potassium iodide solution (50 : 3 : 1 v/v). Decolorization of the iodine reagent by the hydrolysed penicillins was fairly rapid, yielding maximum contrast after 5–10 min.

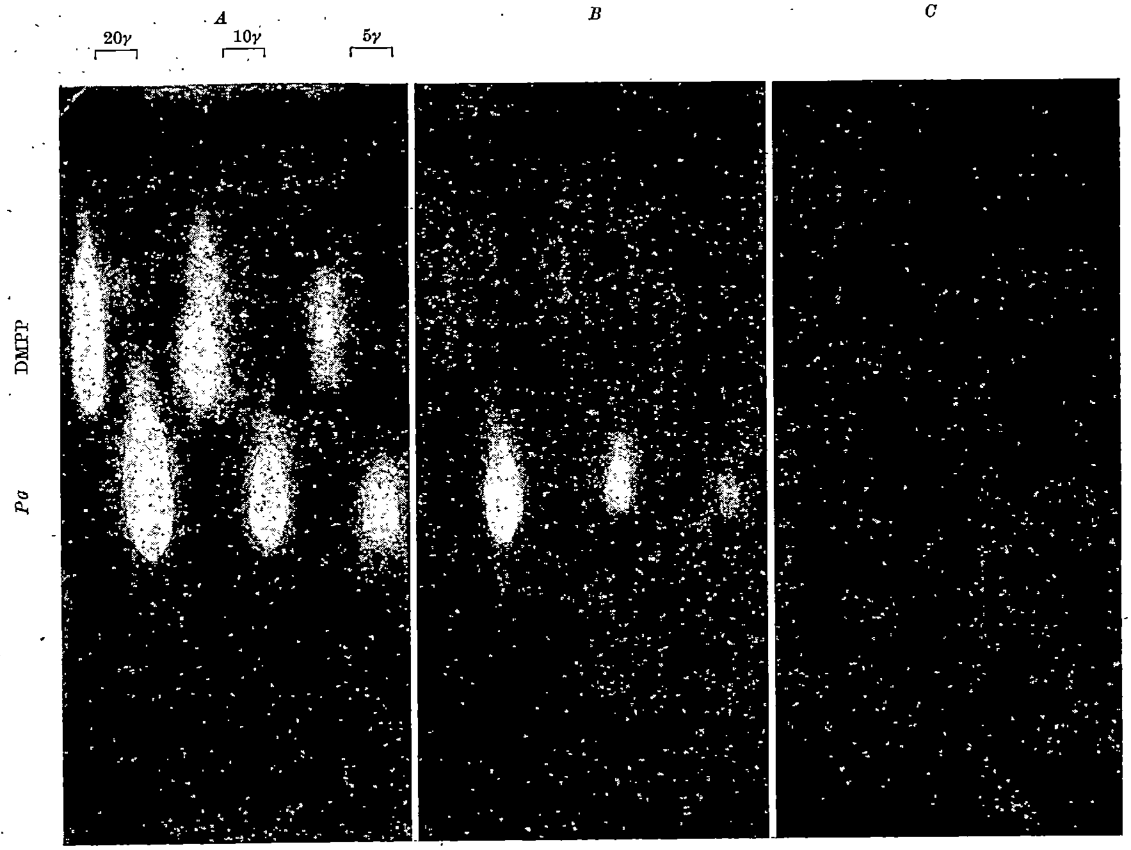

Fig. 1. Chromatograms of benzyl penicillin (*Pc*) and 2 : 6-dimethoxyphenyl penicillin (DMPP) at three concentrations, 20 μgm., 10 μgm. and 5 μgm. Solvent, water-saturated diethyl ether. Whatman No. 1 paper buffered with 10 per cent sodium citrate at *p*H 5·7. After 2 hr. the chromatograms were dried and sprayed with: *A*, 0·5 *N* sodium hydroxide, followed, after partial drying, by a mixture of 1 per cent starch, glacial acetic acid and 0·1 *N* iodine in 4 per cent potassium iodide (50 : 3 : 1); *B*, SchenLabs *B. cereus* penicillinase (10,000 units/ml.), 1 per cent starch, 0·1 *N* iodine, and *p*H 7 *M* sodium phosphate buffer (5 : 50 : 1 : 1); *C*, as in *B*, minus the penicillinase solution

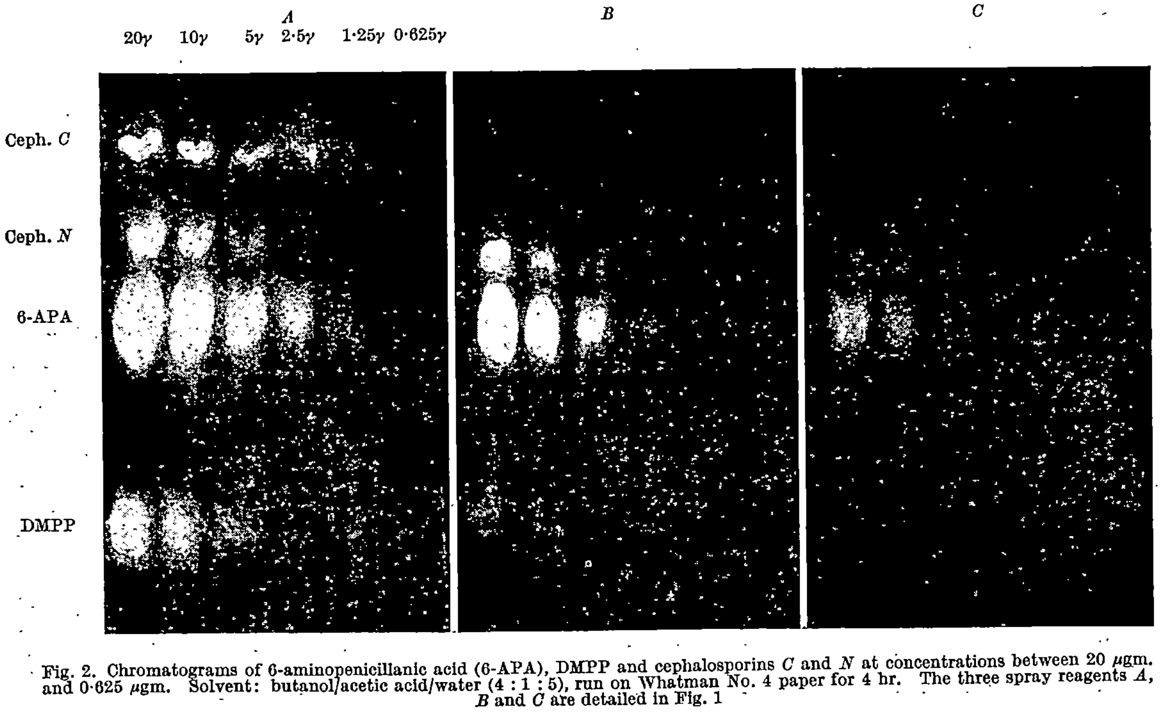

Fig. 2. Chromatograms of 6-aminopenicillanic acid (6-APA), DMPP and cephalosporins *C* and *N* at concentrations between 20 μgm. and 0·625 μgm. Solvent: butanol/acetic acid/water (4 : 1 : 5), run on Whatman No. 4 paper for 4 hr. The three spray reagents *A*, *B* and *C* are detailed in Fig. 1

An identical chromatogram (*B*) was sprayed with an alternative reagent, in which the required preliminary hydrolysis of the β-lactam ring was effected enzymatically with penicillinase. By this means it proved possible to use a single-stage spray for the detection of benzylpenicillin and other penicillinase-sensitive penicillins. The reagent contained a mixture of SchenLabs (SchenLabs Pharmaceuticals Inc., New York) purified *Bacillus cereus* penicillinase (10,000 units per ml.), 1 per cent starch, 0·1 *N* iodine and *p*H 7 *M* sodium phosphate buffer, in the ratio 5 : 50 : 1 : 1. The rate of decolorization of the spray by the penicillin substrate was found to be dependent on the penicillinase concentration and, with this mixture, development was complete at room temperature (*c*. 22°) in 10–15 min.

It is evident from the chromatogram *B* that, while benzylpenicillin was readily detected by this reagent, 2 : 6-dimethoxyphenylpenicillin was relatively insensitive. This is in keeping with the known partial resistance of this recently described semi-synthetic penicillin (trade names, 'Celbenin' 'Dimocillin' and 'Staphcillin') to the action of the penicillinases of *B. cereus* and *Staphylococcus pyogenes*[2]. The necessity for cleavage of the β-lactam ring is apparent from the negative results obtained when the penicillinase component of the second spray reagent was omitted (see chromatogram *C*).

Thus, in addition to providing a sensitive system for the colorimetric detection of penicillins, by the combined use of the alkali and penicillinase variants of the starch–iodine reagent, it appeared to be applicable to the differentiation of penicillinase-sensitive and -resistant penicillins. This aspect was further examined by a comparison of cephalosporin *C*, known to contain a penicillinase-resistant β-lactam moiety, with cephalosporin *N* and 6-aminopenicillanic acid, both of which are penicillinase sensitive. The results (Fig. 2) clearly show that cephalosporin *C* is even more resistant to penicillinase than 2 : 6-dimethoxyphenylpenicillin.

It can be seen from the third chromatogram (*C*) which, as before, was sprayed with a neutral buffered starch–iodine solution, that in contrast to the results shown in Fig. 1, the penicillinase-sensitive penicillins were still detectable, although with reduced sensitivity. However, since this second chromatographic solvent contained acetic acid then some decomposition of acid-labile penicillins would be anticipated, particularly during the final drying stage, and this could possibly account for the enhanced iodine absorption.

The blue background of the paper chromatogram, after spraying with the penicillinase reagent, faded far more slowly than that obtained with the alkali spray and in both instances the colour was more stable when stored in the dark. In addition, it was shown that the original dark blue colour of the freshly sprayed sheet could be regenerated, even after several days, by spraying again with water.

The sensitivity of the iodometric spray reagent towards certain clinically valuable penicillins is considerably less than that of the bio-autographic procedure. However, for cephalosporin *N*, their relative sensitivities are of the same order and for the detection of both 6-aminopenicillanic acid and cephalosporin *C*, the iodometric reagent is considerably superior when compared with bio-activity against either *Sarcina lutea* or the Gram-negative *Salmonella gallinarum*.

In practice, the sensitivity of these reagents has proved adequate for routine use in the direct examination of chromatograms of mould culture filtrates containing penicillins and cephalosporins. Furthermore, it was found that amino-acids and the normal constituents of corn steep media do not interfere with the detection of these antibiotics in culture broths.

Preliminary experiments have shown that a simple modification of this technique also permits the detection of penicillinase on paper by taking advantage of the ability of the enzyme to render penicillin iodine-sensitive. Thus on spraying initially with a solution of benzyl penicillin (200 units/ml.) followed, after drying, by the *p*H 7 buffered starch–iodine reagent (*C*) described above, *Bacillus cereus* penicillinase could be detected on paper as a white zone against a blue background with a sensitivity of 5–10 ShenLabs units.

An alternative colorimetric reagent for the detection of penicillins has been previously described, which is based on the well-known hydroxamic acid reaction[3]. However, this is much less sensitive than the starch–iodine reagent, which has the additional advantage of permitting the rapid differentiation of penicillinase-sensitive and -resistant penicillins.

I am indebted to Miss Evelyn Albu for her technical assistance.

ESTIMATION OF SPECIFIC PROTEINS IN SERUM AND OTHER MIXTURES

By Dr. D. A. DARCY

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital,
Fulham Road, London, S.W.3

THE purpose of this article is to report the increase in accuracy and simplicity brought about by certain modifications of a method previously described[1]. The method is based on the agar-gel immune precipitation method of Ouchterlony[2]. It consists essentially of placing the protein solution in a hole made in an agar-gel and allowing it to diffuse towards a specific antibody for the protein diffusing towards it from a nearby hole. After the two reactants meet, a band of precipitate is formed composed of both substances. The more concentrated the protein, the faster will the band migrate towards the antibody source, and this phenomenon is used to estimate the concentration of the protein. This is achieved by standardizing the conditions of the reaction and by calibrating the antiserum against a solution of the protein (antigen) which has been selected as the standard.

The details of preparation of the agar plates, the antiserum, the calibration curve, and the incubation conditions, etc., have been described in the earlier paper: it was shown there that an average error of about ± 14 per cent (95 per cent confidence limits) was obtained routinely. The modifications introduced here reduce this error to less than ± 5 per cent.

Incubation conditions. It was found after numerous experiments that a major source of the ± 14 per cent error was that the gels were not incubated on the level. When ordinary Petri dishes are stacked they invariably tilt a few degrees from the horizontal and this is sufficient to cause large errors. Furthermore, even the bottom plates of the stacks were found to give irregular readings, and this was ascribed to the uneven thickness of their bottoms, which lead to an uneven depth of agar-gel in a given plate. Both these troubles were remedied by the use of flat Petri dishes. It was also found necessary to check (with a small spirit-level) that the platform of the moist chamber on which the plates were stacked was likewise level when in place in the incubator. If a moist chamber consisting of a desiccator jar with a plate glass platform was used, it was found that wrapping the jar with household aluminium foil speeded up the band migration during the 3 days at 37° C.

Preparation of the agar plates. The agar was made up as described previously. No general advantage was found in using lower concentrations of agar than 1 per cent. Although these gave clearer gels and faster migration of precipitates, accuracy was not appreciably increased thereby. Nor, curiously, was readability appreciably increased on these weaker gels—for the precipitate formed was less dense so that the band-gel contrast was about the same as on the 1 per cent agar.

The chief modification introduced in the plates was the use of round holes (wells) in place of the square ones previously employed. The round wells had the advantage that they could be punched out by a commercially available cutter; furthermore, they could be spaced farther apart than the square wells while giving the same density of precipitate, thereby extending the range of protein concentrations that could be measured. The excellent method of Feinberg[3] was followed in making up the plates. A precision cutter and special flat 2·5-in. Petri dishes were obtained from the Shandon Scientific Co. Each dish, after silicone treatment, was filled to a depth of 3 mm. with 1 per cent agar (9 ml.) and allowed to set for a day or more before the wells were punched. The wells were 1 cm. in diameter and the distance between them and the centre (antiserum) well was also 1 cm. (Fig. 1).

Measurement of the precipitate. This was carried out, very simply, with a segment of 'Perspex' ruler enclosing a centimetre ruled in half-millimetres to which a small 'Perspex' handle was attached. The ruled centimetre was laid on the gel surface and lined up so that its limits coincided with the centimetre distance between the centre well and one of the outer wells along a line between their centres (see Fig. 1). The distance from the edge of the outer well to the sharp leading edge of the precipitate was estimated to the nearest 0·1 mm., using a × 2 magnifier and a suitable illumination source. The method is an improvement on that previously used where the rule was laid across the top of the plate, but it is still subject to some parallax error; it is nevertheless capable of a high degree of accuracy as will be seen later. A second method of measurement used in this Laboratory was more elaborate but completely ruled out parallax. It consisted of using a low-power lens (about × 1) to project the image on an ocular micrometer scale of a centimetre with 0·1 mm.-divisions where it was read by means of an eyepiece (× 7). This gave somewhat greater accuracy than the rule method and has the slight additional advantage of not disturbing the plate.

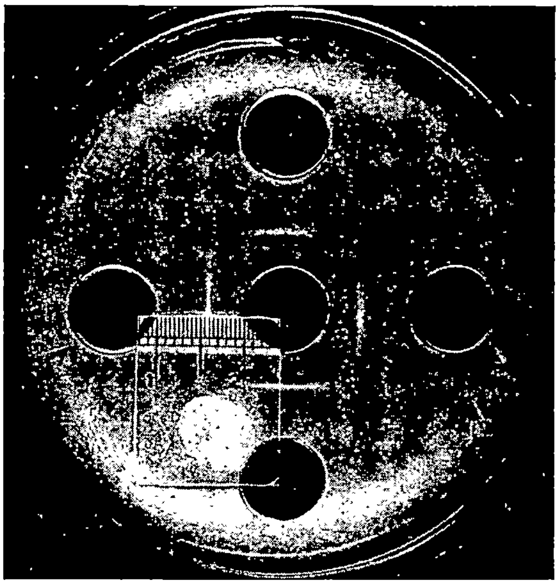

Fig. 1. Standard agar plate showing the centimetre rule lying on the surface of the gel in position for measurement

Experimental test of the method. Accuracy tests were made using rat serum and a rabbit antiserum to the α-globulin of rat serum described earlier[1]. Rat serum yielded with this antiserum one strong band (for the α-globulin) and only traces of other precipitates (Fig. 1). Tests were made with five different concentrations of the rat serum in saline; at the highest concentration the α-globulin band reached nearly to the antiserum well, with the standard conditions, and at the lowest concentration (which was barely in antigen excess) it reached a little beyond midway. Each of the five concentrations was tested against concentrations lower than itself by 5, 6 and 7 per cent. These solutions were presented as unknowns to the person carrying out the test and were indistinguishable by eye. Sixteen separate tests (equivalent to 4 plates) were made on each unknown, using the rule to measure. In every case the method gave a statistically significant discrimination between the solutions differing by 5 per cent ($P = 0{\cdot}01$ or less in every case, except one where P fell just short of 0·01). It was decided to test the method to its limit at the highest of the five concentrations of rat serum, and it was found that a statistically significant discrimination was obtained between the solutions differing by 3 per cent when the rule was used ($P = 0{\cdot}02$–$0{\cdot}01$) and between solutions differing by only 2 per cent when the more elaborate optical method was used ($P = 0{\cdot}05$).

Since, as was seen in the earlier paper[1], accuracy is proportional to the square root of the number of tests made on each unknown, then for the routine method of using only four tests for each unknown the above discriminating power will be halved, or the error doubled. The error for the routine procedure will thus be ± 5 per cent (95 per cent confidence limits) or less, and at the best ± 2 per cent. For many purposes it may be sufficient to use only a single test per unknown since the error would, on the average, be less than ± 10 per cent. Again with some sacrifice of accuracy, the incubation period could be shortened to 2 days or less if needed.

The method was found to be suitable for other serum proteins such as albumin, for enzymes such as deoxyribonuclease I, but not for xanthine oxidase (mol. wt. 300,000), except possibly if the agar concentration were to be reduced and the incubation time lengthened. The limits of sensitivity are those of the gel-diffusion method, which can at best give a visible precipitate with about 2 μgm. of protein per ml. The method is also applicable to the titration of antisera, for example, by placing a standard antigen in the centre well and measuring to the sharp edge of the precipitate, which will then be on the side facing the peripheral wells.

My thanks are due to Mr. M. S. C. Birbeck of this Institute for advice on optical matters, and to Mr. Peter Harpel of Harvard Medical School for suggesting the effect of tilt.

This investigation has been supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

CIRCUMSCRIBING IRRADIATION OF SURFACE STRUCTURES OF CYLINDRICAL ANIMAL AND PLANT CELLS WITH POLONIUM-210 α-PARTICLES

By R. M. BERGSTRÖM, R. F. BLÅFIELD and M. W. BRENNER
Institute of Physics, University of Helsinki, and the Institute of Physiology, University of Helsinki

A STUDY of the effects of ionizing radiation on living tissues provides a valuable supplement to investigation of the function of these tissues. The energy of the radiation may be used for complete or partial destruction of the cell material. It can, however, also be used in studying the normal physiological functions of the cells. To this end, irradiation energy can be used as a stimulus energy, which occasions alterations in many physiological processes.

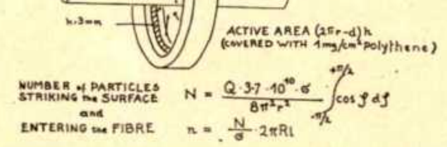
Use of radiation energy for physiological research on cell functions is favoured by the possibility of reaching microscopic structures within the cell, and of partial destruction of fractions of them. As pointed out by Zirkle and Bloom[1], it complements micro-surgery.

This article is concerned with a method which makes use of a cylindrical polonium-210 α-particle source. This renders possible the destruction or the stimulation of surface structures of cylindrical animal or plant cells. The results of the irradiation of single nerve fibres and cells of some algae will be presented elsewhere. This article refers briefly to the ultrastructural changes in the cells of the algae *Nitella flexilis* obtained by this method.

The aim was to produce significant, graded destruction or stimulation of the surface layers of the living nerve and plant cells, with the view of facilitating study of the alterations in the electrical functions of the cells due to the irradiation. Thus, the choice of the ionizing radiation had to fulfil some basic requirements. The ionizing power of the radiation should be as high as possible in order to produce the structural changes. For this reason, heavy-particle radiation was to be preferred. To reduce the effects to a limited surface layer of cells with a small diameter, the depth of penetration of the radiation in organic tissue should be small. For these reasons, and because the aim was to irradiate the membrane of the cylindrical cells from all directions, polonium-210 α-radiation was considered the most satisfactory choice. The reasons for this decision were based on the high ionizing power of the heavy, charged α-particles and the low penetration in organic material.

The half-life of polonium-210 is 138·4 days and the energy of the α-particles emitted 5·298 MeV. The polonium-210 is deposited on the cylindrical inner surface of a silver ring. The nerve or plant cell is held in the centre of the ring, along the axis of the active cylindrical area (Fig. 1). The radius of the active area is 10 mm., and the height, h, is 3 mm. On beginning the irradiation, the ring must be placed rapidly in position around the material to be irradiated. This is made possible by the provision of a slot for the passage of the cell from the outside to the interior of the ring. Thus the whole periphery cannot be used for the active area since it is reduced by an amount, d, of 7 mm. The active area is 167 mm.^{2}.

The source was supplied by the Radiochemical Centre, Amersham, United Kingdom. Its strength, as stated by the manufacturer, was 1·1 mc. ± 20 per cent at the time of delivery, November 3, 1959. The measurements were carried out 11 months later, the activity then being 0·21 mc. The activity was also measured using the nuclear plate technique. The results of this measurement were consistent with the strength stated by the manufacturer. The nuclear plates were kept in a diametrical plane of



V = πϱ(2R − ϱ)l

Fig. 1. A schematical representation of the circumscribing irradiation of a nerve fibre from a cylindrical polonium-210 α-source

the active cylindrical surface. By counting the density of the tracks along the cylindrical axis, the intensity of the α-radiation and the activity of the source could be determined.

To avoid contamination, the active area was covered with a 1 mgm./cm.^{2} film of polythene. Strong α-particle bombardment may destroy this and, consequently, it does not provide sure protection. Thus the source was enclosed in a container, from which it could be removed and put in position around the cell by means of a lever. The entire equipment is kept in a special cabinet intended for this particular experiment. Possible contamination originating from the source is detected by means of an end-window type Geiger-counter tube. The window of the tube consists of 2 mgm./cm.^{2} mica.

There are certain advantages in using a cylindrical source. The cell membrane is bombarded equally from all directions. All α-particles pass through equal distances of air and tissue. However, only those particles which enter the surface of the cell perpendicularly will penetrate radially into the cell to a distance which corresponds to the residual range, ρ, in tissue. Evidently, the effect of the radiation is concentrated in only a certain volume, V, of the cell. V is bounded by the surface of the cell and a surface defined by the largest depth of penetration. In order to calculate the dose, we thus have to evaluate the depth of penetration in tissue.

The range in air of the 5·3-MeV. α-particles from polonium-210 is 38 mm. (ref. 2). The loss of energy due to the penetration of the polythene film covering the source is 0·6 MeV. The loss of energy due to the distance covered in air between the source and the cell is 1·1 MeV. Thus the particles entering the tissue have an energy of 3·6 MeV. This value is in accordance with the length of the tracks, observed in nuclear emulsions. The corresponding range in air is 21 mm. (ref. 2) and in tissue 20μ approximately.

Assume that the organic cell is cylindrical and has radius R. Now the volume, V, reached by the particles is:

$$V = [\pi R^2 - \pi(R - \rho)^2]l = \pi\rho(2R - \rho)l \qquad (1)$$

where l is the length of the irradiated part of the cell. Each particle will lose an amount of energy 3·6 MeV. or $5{\cdot}75 \times 10^{-6}$ erg in the cell. If length l is much shorter than the radius, r, of the source, every surface element, σ, of the irradiated part is struck at the same rate of α-particles. We recognize that the height, h, of the cylindrical area is small and thus we can approximate the source by an infinitely thin closed ring. This approximation is regarded as being perfectly satisfactory. The number of particles, N, striking the surface element, σ, in a second can then be written:

$$N = \frac{3{\cdot}7 \times 10^{10}\, Q\sigma}{8\pi^2 r^2} \int_{-\pi/2}^{+\pi/2} \cos\varphi \, d\varphi \qquad (2)$$

φ is the angle between the normal of the surface element and the direction of the particle. Q is the strength of the source given in curies. The rate of α-particles, n, entering the cell is obtained by summing over the surface of the irradiated part of the cell. We get:

$$n = \frac{N}{\sigma}\, 2\pi R l \qquad (3)$$

The energy dissipation in a unit volume of tissue and in unit time is obtained by combining equations (1), (2) and (3). If we assume that the density of the tissue is 1 gm./cm.^{3}, and divide by 83 ergs, we get the dose-rate in rep/min.:

$$\text{The dose-rate} = 7{,}800\rho \frac{Q}{\left(2 - \frac{\rho}{R}\right)} \text{ rep/min.} \qquad (4)$$

If the nominal strength of the source, 1·1 mc., and the range 20μ are substituted in this equation, we get $4{,}300/(2 - \rho/R)$ rep/min. Because of the inaccuracy of the value for the activity of the source and the error in the residual range, ρ, we expect an error in the dose-rate of ± 15 per cent, as calculated by means of equation (4). It should be pointed out that the calculated dose-rate is a mean value taken over the volume reached by the α-particles. When $\rho < R$, there is a volume in the interior of the cell which is not influenced by the radiation at all. When $\rho > R$, the equation (4) will give too high values, because a considerable number of α-particles escape from the cell.

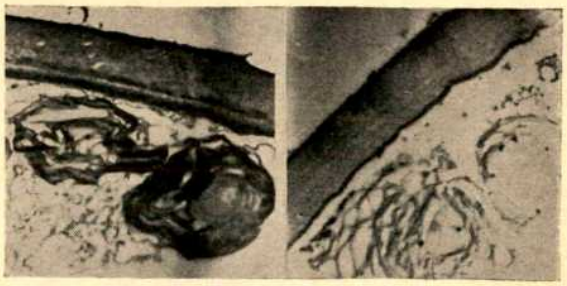

Fig. 2. An electron-micrograph of the cell wall and protoplasm of *Nitella flexilis*, irradiated with polonium-210 α-particles. A normal cell is shown on the left. Magnification: left, × 5,500; right, × 4,400

Here, only one application of the method is described, that is, some ultra-structural changes of the internodal cells of the alga *Nitella flexilis* caused by α-irradiation. The cells, cultured in sea-water from their original environment, were placed in the centre of the polonium-210 ring. Exposure of the cell surface to the α-irradiation was carried out at short intervals, after which the cell was moved to its water environment to prevent it from drying. The whole procedure was performed under a microscope.

In Fig. 2 is shown an electron-micrograph of a *Nitella* cell irradiated with 8,900 rep. The non-irradiated control is shown to the left. The protoplasmic layer of the irradiated cell is separated from the cell wall, whereas it is connected to the wall in the non-irradiated cell. Separation of the protoplasm in the irradiated cell is seen where osmiophilic grains (usually situated near the wall) are displaced to the inner part of the cell. Arrangement of the particles in a row near the wall due to the irradiation with α-particles possibly indicates the existence of a membrane normally connecting the inside of the cell wall. The large chloroplasts, with definite structure in the control, show a diffuse structure with a prominent vacuolization near the cell wall after irradiation.

This work was supported by grants from the Finnish State Committee for Natural Sciences.

We wish to thank Prof. L. Simons for advice and encouragement.

MUTAGENIC EFFECT OF RADIANT HEAT SHOCKS ON PHANEROGAMOUS PLANTS

By DR. BROR PETTERSSON

Botanical Museum of the University of Helsinki

In order to prove a possible mutagenic effect of physical and chemical agencies liberated and activated by volcanic eruptions I have made a number of experiments with various phanerogamous plants during the past eight years. The plants chosen for this purpose belonged chiefly to native species, but foreign ones were also represented; these were obtained from the seeds of some Canarian endemics collected by me; there were also fresh herbarium specimens from Madeira, the Cape Verde Islands and Ethiopia. Finally, the material included a few garden plants.

The experiments with the native plants were carried out either on individuals of small island populations easily kept under observation at the place of growth, or on plants of other species settled on an island where they had not grown before. As regards the foreign plants, some were cultivated as common pot-plants and the remainder in garden beds. No particular care was extended to the experimental plants. Pollination control, namely, selfing and crossing, was performed in some cases; otherwise, the rule was free cross-pollination within the population. Only when the fruits were approaching the ripening stage were they protected from scattering by a gauze envelope.

Although the most important occurrence in the evolutionary process of organisms is the genesis of individuals which are distinguished by new characteristics quite different from those characterizing the members of the population within which they had arisen, there can be no question of a new taxon before a mutation has shown itself capable of propagating and stabilizing the new genotype in the environment of the parent population or elsewhere. Accordingly, the aim of my experiments was not only to investigate factors causing mutations in Nature, but also to study the evolutionary pattern of the mutated plants, and the time, measured in generations, necessary for an eventual establishment of new biotypes. Strictly speaking, therefore, the experiments were not exactly genetical in the orthodox sense.

The first stage of this investigation was concerned with the effect of momentary strong radiant heat (such as that caused by incandescent pyroclastic material scattered over surrounding vegetation by an active volcano) on flower buds in various stages of development. In order to obtain the necessary momentary high temperature, use was made of a common burning glass, with a magnification of × 3; by this means, the young flower buds or bud clusters were subjected to the 'burning' rays until some smoke appeared, or until there could be observed a visible change in the colour of the bud, which generally occurred within 2–15 sec.

In conjunction with radiant heat, treatment with sulphur dioxide as sulphurous acid, hydrochloric acid and boric acid was also given in some cases. A small cotton pellet, drenched with one of the solutions, was wrapped round a bud or cluster of buds, kept in this position, and heated during a period of some minutes by means of the burning glass. However, these chemical tests have been too few in number so far to permit any definite conclusion as to differences in mutagenic effect.

The seeds obtained by these rather rough treatments were generally few in number and of inferior germination capacity. The effect of radiant heat could be observed already in the seedlings, principally as teratological deformities. Depending on the severity of the injuries caused by burning, the number of such mutated seedlings varied between 2 and 40 per cent. Frequently, the cotyledons were either already deformed, or their number and position altered. The rather common occurrence of seedlings with three cotyledons was most obvious with *Aichryson dichotomum* (Fig. 1), *Celsia insularis*, *Cynoglossum lanceolatum*, *Dimorphotheca pluvialis*, *Kallanchoë glauca*, *Knautia arvensis*, *Lythrum salicaria* and *Nemophila menziesii*, or with one of them more or less forked; if they were split to the base it was often a difficult matter to distinguish them from true tricotyledons (*Aichryson dichotomum*, *Celsia insularis*, *Centaurea cyanus*, *Kallanchoë glauca*). Of less frequent occurrence were seedlings with only one cotyledon, a

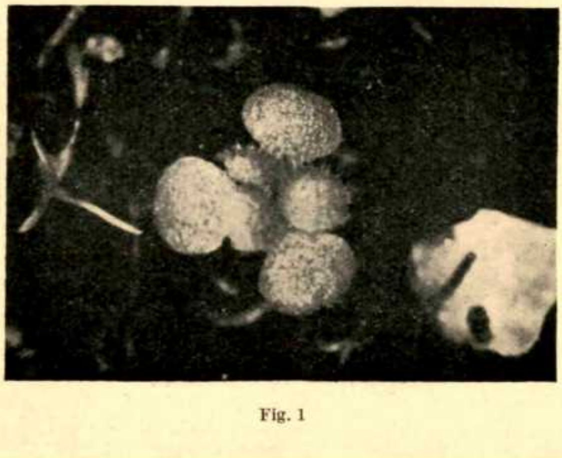

Fig. 1

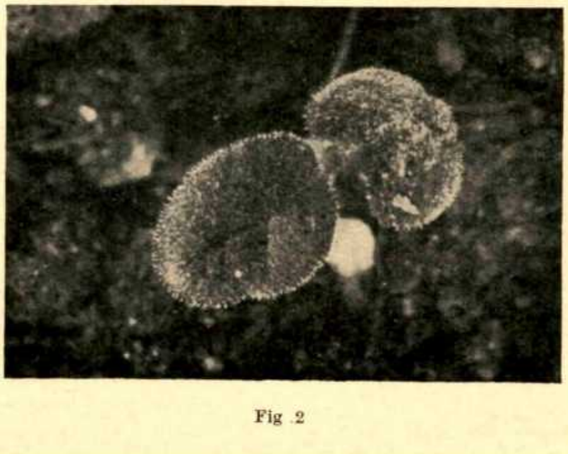

Fig 2

syncotyly clearly formed by fusion of the normal ones and appearing as a single organ, often bent in various ways, such as with *Achillaea millefolium*, *Celsia* (Fig. 2), *Solidago virgaurea*, *Spiraea ulmaria*, *Tanacetum vulgare*. Only in two species, namely, *Angelica silvestris* and *Allium schoenoprasum* did seedlings occur which were entirely lacking in chlorophyll, or were of a more or less yellow-green colour.

As a rule, the true 3-cotyledons developed into plants with a leaf position which was other than that of the parent plants; thus plants originating from parents with opposing leaves became verticillate with three leaves in the whorl (*Kallanchoë*, *Lythrum*); again, those with scattered leaves mutated to an almost pseudo-verticillate leaf position (*Dimorphotheca*, *Nemophila*, *Centaurea* and *Aichryson*) with very densely scattered leaves, sometimes growing into giant individuals.

As is known, both polycotyledonous and monocotyledonous seedlings of a number of different dicotyledonic species have on occasion been found to occur spontaneously in Nature. Among my control cultures, only *Lythrum salicaria* showed a slight tendency to produce tricotyledons spontaneously; of 400 seedlings, one was found to have three cotyledons.

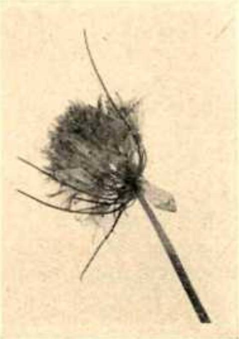

Fig. 3

However, some of the anomalous seedlings developed quite normally with no teratological characteristics, although the majority were subject to fasciations of various kinds. Most important and interesting was the occurrence of bud mutations, which sometimes appeared as early as at the seedling stage, but most commonly in more developed young plants. In the majority of cases they appeared as more or less strange fasciations with anomalous leaves and flowers. However, insufficient study has been devoted so far to the hereditary pattern of these 'thermomorphoses'. Apart from these teratological malformations in the progeny of the experimental plants, a number of other mutations also took place, both with plants and buds. In this category were included all individuals with strange characteristics which were observed neither in the parent population nor were known as existing in the species concerned elsewhere. So far as space permits, the following gives a survey of the most important cases investigated:

Seeds obtained from a burnt *Allium schoenoprasum* plant gave rise to 21 young plants, of which not a single one agreed in all its characteristics with the parent. The most marked peculiarities were discovered in seven of these plants; these displayed quite strange characteristics which had not been observed in the parent population nor had hitherto been known to occur elsewhere in any population of this species. In five of them, there developed among the flowers in the umbel bulbils which varied in number from few to many (Fig. 3), in a very similar fashion to *Allium oleraceum*; the remaining two became drooping umbels, as the single flower of *Galanthus*.

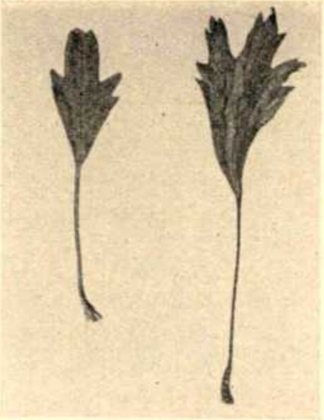

Fig. 4

The results of experiments with *Angelica sylvestris* were no less surprising. Unfortunately only a small number of healthy seeds were obtained, and these gave rise to 26 seedlings. Even as early as in the first summer, the young plants showed many peculiar characteristics which were to be observed neither in the controls nor in the natural populations, One plant in particular was remarkable: as a seedling, it showed two plumules, the second of which sprouted from the root neck, obviously as a kind of bud mutation. The normal plumule developed common trifoliate leaves, but the bud mutation gave rise to only simple cuneate leaves (Fig. 4) tapering into a petiole with a broad apex irregularly toothed or incised, and thus bearing a strong resemblance to those of the Malesian *Trachymene koebrensis* and *T. novoguinëensis*. During the following summer, the same shoot had only pinnate leaves, with two to three pairs of leaflets, broadly ovate, serrate and somewhat convex, with some resemblance to the leaves of *Sium latifolium*. The main shoot gave rise to quite normal double pinnate leaves. In the third summer, this 'Siamese' twin plant reached the flowering stage. By then, the vegetative parts seemed to belong to two different plants, with a main stem 110 cm. high, pale green in colour, with double pin-

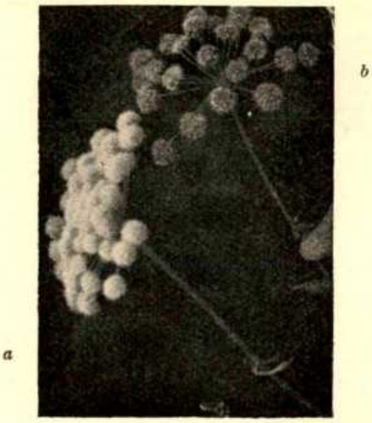

Fig. 5

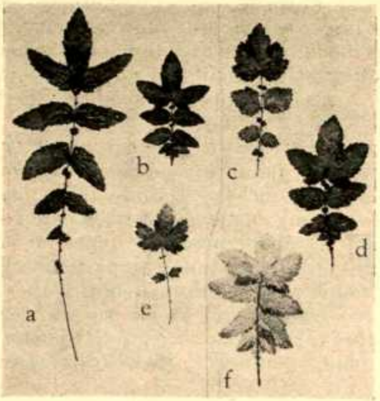

Fig. 6

nate *Angelica* leaves which were normal in every respect. The stem of the bud mutation grew only 70 cm., and was coarser, dark green in colour, with leaves which were broader and darker, with fewer and broader leaflets than those of the main stem. The umbels of the bud mutation were almost flattened, the umbelets depressed; rather few flowered, with flowers which were conspicuously larger than those of the parent population and of a milky white colour. The main stem had almost spherical umbels with dense globular umbelets and remarkably small, whitish, slightly purple-sprinkled flowers. The fruits of the main shoot were narrow lanceolate, approximately one-third longer than those of the parent, and of a vivid brownish shade. The mericarps of the bud shoot had a thick flattened corky rim instead of the normal thin membraneous one of the parent population, and had a greyish sooty colour.

These odd twins were crossed in both directions, but only the bud mutation gave viable seeds. Of 42, only 15 germinated, and these resulted in the same number of healthy young plants. Ten of these F_1 plants flowered last summer. They represented as many forms, not one of them resembling either the others or the individuals of the parent population. Some plants were strikingly different in appearance; they had not been observed before in any *Angelica silvestris* population known to me. Their mode of growth approached that of *Angelica littorialis* rather than that of the wild *Angelica*. One of them is worthy of special note: the plant itself was low, large and richly ramified, with short internodes and broad leaves, with conspicuous sheaths which were entirely milky white in colour. The lower part of the stem and the branches were also glossy white. The umbels (Fig. 5*a*) were large and very irregular in size, extremely dense, and composed of about twice as many umbelets as normally occur in any plant of the parent population (Fig. 5*b*); these were irregular and almost flat, bearing a closer resemblance to some Japanese *Angelica* species than to those in Finland. The umbelets were also conspicuously dense, hemispherical, and the flowers ivory white. Another similar plant had the white stem and leaf sheaths striped with purple.

No less surprising results were obtained from the experiments with *Spiraea ulmaria*. About 31 per cent of the young plants of the first summer were mutated in various ways; during the last, that is, the second summer, the mutations were more pronounced. Some could be termed giants (Fig. 6*a*), with the leaf attaining a length of 34 cm., and four pairs of large leaflets. Others displayed a smaller number of leaflet pairs, but had a prominent terminal leaflet, often of peculiar form, either circular or lobed, toothed, undulated or crispate (Fig. 6*b*, *c*, *d*), and in several instances with the leaves white-spotted or striated (Fig. 6*f*). One plant had a dwarfish growth, densely tufted, with numerous small delicate leaves with only one pair of small leaflets and a large terminal leaflet which strongly resembled the leaves of some *Ribes* species (Fig. 6*e*).

Generally speaking, all the species treated in this way had teratological progenies, which provided evidence for either mere malformations of different parts of the plant or more 'normal' alterations in the size of the leaves and in colour, structure and number of the various parts of the flower.

My experiments have shown that a common burning glass may have the same effect in producing mutations as the Röntgen tube and radium needle.

EFFECTIVENESS OF LIPID AND LIPIDOPHILIC SUBSTANCES AS ADJUVANTS

By D. W. DRESSER*

Department of Zoology, University of Edinburgh

FREUND[1] has stated that adjuvants of the Freund type may act in one or more of three ways: (1) by storing antigen at the site of injection and releasing it slowly; (2) by stimulating the migration of macrophages and lymphocytes to the injection site; (3) by stimulating antibody production in some way which is not understood. This preliminary article is a brief description of a method whereby the effectiveness of different substances as stimulants of antibody production can be tested. In these experiments the antigen and adjuvant have been injected by different routes so that Freund's categories (1) and (2) can be eliminated as the cause of the observed effect, for which the name 'adjuvanticity' seems to be suitable.

It has been known for some time that intravenous injection of protein solutions into rodents is an unreliable method of immunization. This has been confirmed[2] using BGG (bovine gamma globulin, Armour and Co.) in *CBA* strain mice. Intravenous injection of a freshly made solution in 0·9 per cent saline was found to immunize 5 out of 23 mice when the effectiveness of the first injection was tested a month later by the antigen-elimination technique[3] with BGG labelled with iodine-131 (BGG–^{131}I).

In some recent experiments, summarized in Table 1, it has been shown that no mice at all out of

---

* Present address: Division of Biology, California Institute of Technology, Pasadena, Calif., U.S.A.

43 tested were immunized when the BGG solution first injected into the mice was centrifuged at 30,000*g* for 15 min. A very small amount of precipitate was always found after centrifugation, and it is thought that it is this material removed by centrifugation which enabled some of the mice injected with uncentrifuged BGG solution to be immunized. Freund's adjuvant containing BGG injected subcutaneously has been shown to be an effective means of immunizing mice. In Table 1 the secondary responses obtained after challenge with BGG–^{131}I, a month after the first antigen injection, have been arbitarily divided into five categories ranging from no response at all (=0) to the degree of response obtained after previous immunization with BGG in Freund's adjuvant (=4).

It was found that an intravenous injection of centrifuged BGG was effective in conferring immunity if a separate subcutaneous injection of Freund's adjuvant, made up without the antigen, was given at the same time. Several substances have been tried in place of the Freund's adjuvant without antigen. The results of these experiments are included in the table. Of the substances tested, 'Crill 16', oleic acid and powdered mycobacteria all have a marked adjuvanticity.

There seem to be two possible mechanisms responsible for adjuvanticity: (1) the adjuvant may affect the lymphoid cells of the animal, perhaps by stimulating them to take up the antigenic protein, or (2) the adjuvant, even when injected subcutaneously, may affect the stability of the circulating antigen, causing it to precipitate, thus immunizing the mouse in a similar way to alum-precipitated BGG. The latter alternative seems unlikely when the antigen is injected intravenously and the adjuvant subcutaneously, because a large part of the injected substances, for example, 'Crill 16', can be found 2 months later in subcutaneous vesicles. Although some of the 'Tweens' are known to affect the electrophoretic mobility of gamma globulins[4], it seems unlikely that they could affect the circulating BGG in preference to the large amounts of mouse protein present. Furthermore, 'Tween 60', although soluble in water and affecting gamma globulin, does not appear to have a marked adjuvanticity, whereas oleic acid is insoluble in water but is a good adjuvant. The first alternative, that the adjuvant affects the cells of the injected animal, seems to be the more likely.

Recent work has shown that mycobacterial waxes contain oleic acid, palmitic acid, various triglycerides and related substances[5]. It has been known for some time that mycobacterial waxes can be responsible for the establishment of hypersensitivity to complex antigens and simple chemicals[6]. A suspension of mycobacteria, oleic acid and some esters of sorbitol have been found to be substances with a marked adjuvanticity as measured by the method described here. Some of these esters (non-ionic detergents) are known to have deleterious effects[7], including carcinogenic effects[4], on animal tissues. It is possible that some lipids and non-ionic detergents, either in pure form or as mixtures in mycobacterial waxes or croton oil, may owe their adjuvanticity or carcinogenicity to their ability to damage cell membranes. In the first instance, adjuvanticity may be postulated as being due to a non-specific effect on cells, which might act in either or both of two ways: first, damaged cells may be stimulated to take up antigen by phagocytosis or pinocytosis; secondly, as a result of damage, lymphoid cells might be stimulated into a hypercompensatory reaction, one aspect of which could be the production of antibodies.

It seems that the observations recorded here may have a theoretical connexion with some auto-immune phenomena. BGG solutions centrifuged free of traces of particulate matter lack adjuvanticity in mice. When the BGG is particulate, for example after precipitation by alum, it possesses adjuvanticity on its own. It is not unlikely that most of the antigens with which an animal comes in contact during its life must have sufficient adjuvanticity either in themselves or closely associated with them for the immune mechanism to receive the necessary stimulus. There may, in fact, be two mechanisms preventing an animal from becoming immunized

against its own tissues; (1) lack of antigenicity (immunological tolerance); (2) lack of adjuvanticity. An example of the latter might be spinal cord or brain tissue. Allergic encephalomyelitis may in some cases be caused by prolonged injections of dried spinal cord tissue, but a single injection of spinal cord or brain in Freund's adjuvant will always lead to this condition[8]. This effect of Freund's adjuvant is unlikely to be due to the breakdown of a previously acquired state of tolerance, as mice tolerant to BGG do not give an immune response even when challenged by an injection of BGG in Freund's adjuvant[9]. It would seem from this that mammals are not normally immunologically tolerant to brain or spinal cord, and that the lack of an immune response is due to some other factor. It has recently been shown that tolerance to brain or spinal cord may possibly be induced experimentally[8]. It is a possibility, therefore, that this and some other auto-immune phenomena may be initiated by a gain of adjuvanticity by a tissue which normally lacks adjuvanticity, but to at least one antigen of which the animal is not normally immunologically tolerant.

I am grateful to Dr. R. A. Kille for the benefit of discussion.

INCREASE OF THE RATE OF RELEASE OF THYROIDAL IODINE-131 AND OF CIRCULATING THYROTROPHIC ACTIVITY AT EARLY STAGES OF PROPYLTHIOURACIL TREATMENT IN THE RAT

By Dr. F. ESCOBAR del REY, G. MORREALE de ESCOBAR, M. D. GARCÍA GARCÍA and J. MOURIZ GARCÍA

Instituto G. Marañon, Consejo Superior de Investigaciones Científicas, Velázquez, 138, Madrid

THE idea that induction of goitrogenesis by propylthiouracil (PTU) and related compounds only involves those effects of such drugs which lead to the blocking of thyroid hormone synthesis is generally accepted. The hypothesis that these goitrogens do not have an extrathyroidal effect on thyroxine metabolism which might be playing a part in thyroid–pituitary interrelationships was confirmed in the case of thiourea when Griesbach and Purves[1] showed that thyroxine requirements for the maintenance of normal pituitary cytology of thyroidectomized animals were the same for control and treated rats. It has been widely assumed that this conclusion is valid for propylthiouracil also.

Observations have, however, been reported which are not in complete agreement with such hypotheses. Rawson[2] has observed a 50 per cent increase in the mean acinar cell height in rat thyroids as soon as 24 hr. after onset of PTU treatment, at which time no differences are yet demonstrable in the plasma protein-bound iodine. This finding was interpreted[2] as the result of an enhancing effect of PTU on thyrotrophic hormone (TSH) effectiveness[3,6]. Van Middlesworth[5] found that thyroxine doses necessary for suppression of PTU-induced goitrogenesis raised the plasma protein-bound iodine of the rat well above normal.

We have reported[6], moreover, that as soon as 5 hr. after onset of PTU administration to thyroidectomized, l-thyroxine-maintained rats, a depression of the peripheral deiodination of the hormone is demonstrable, this extrathyroidal effect of the drug lasting until suppression of treatment. The possibility was suggested that the peripheral effects of PTU which result in a decreased thyroxine dehalogenation might be triggering secretion of TSH by the pituitary, and that this response might be mediated by a factor related to the alteration of intracellular metabolism of thyroxine. Observations such as those summarized above[2,5] could then be interpreted along such lines.

This article reports an attempt to investigate the early phase of PTU treatment in the rat, when blocking of hormone synthesis by the drug has not yet resulted in a decreased plasma protein-bound iodine. Young adult male rats of a giant Wistar strain were used. They were fed a medium residue low-iodine diet. 10–15 μc. iodine-131 were injected intraperitoneally and the activity over the neck plotted against time. About 70 hr. after the injection of the tracer half the experimental group received 15 mgm. PTU intraperitoneally, and the radioactivity over the thyroid was followed for 24 hr., at which time all animals were killed. Fig. 1 shows typical results: immediately after PTU administration a sharp increase in the slope of the thyroidal iodine-131 disappearance curve has been consistently observed. These results do not exclude, among several possible interpretations, that the change in rate was due exclusively to blocking of iodine-131 recirculation by PTU. This possibility was investigated in a group of rats receiving 200 mgm./rat/day potassium perchlorate in order to avoid recirculation of radioiodide and thus measure the rate of release of labelled compounds from the thyroid. Half the group received later 2 × 10 mgm. PTU intraperitoneally, all animals being killed after 24 hr. As may be seen in Fig. 2, an increase of the thyroid iodine-131 release curve is observed soon after onset of PTU treatment. Due to the fact that the potassium perchlorate dose used is more than enough to block recirculation of iodine-131, the finding is interpreted as indicating a 100 per cent increase in the rate of secretion of labelled compounds from the gland. The protein-bound iodine-131 of the plasma was the same for both experimental groups or somewhat higher for PTU-treated rats. The histological appearance

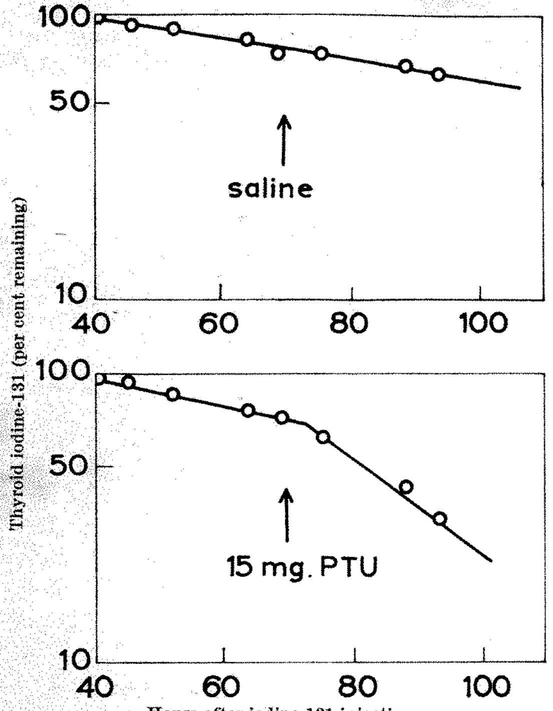

Fig. 1. Influence of 15 mgm. PTU injected intraperitoneally on the disappearance rate of iodine-131 from the thyroid, in male rats, injected with 10 μc. iodine-131. The radioactivity over the thyroid is expressed as percentage of the iodine-131 content 40 hr. after injection of the tracer; mean values of four animals in each group are given

of the thyroids of these PTU-treated animals showed clear signs of an increased activity when compared with their corresponding controls. The pooled plasmas of the animals the thyroidal data of which are shown in Fig. 2 were assayed for TSH activity by McKenzie's method[7]: the increase in blood radioactivity 2 hr. after intravenous injection of the sample is measured using mice injected with iodine-131, treated with thyroxine and thyroid powder to block endogenous TSH secretion. With 0·3 ml. of pooled plasma from the potassium perchlorate-treated controls the response was 119 ± 8 per cent (mean ± *S.E.*); with plasma from potassium perchlorate + PTU-treated animals it was 187 ± 15 per cent ($P < 0{\cdot}01$). Injection of saline gives a response of about 95 per cent.

Two pools were made with plasmas from 4 male rats and with those from another group of animals injected 24 hr. previously with 15 mgm. PTU and assayed for TSH activity: the responses were 100 ± 6 per cent and 158 ± 5 per cent for control and PTU-treated rats respectively, $P < 0{\cdot}001$. When 2 mgm. PTU were added per ml. of control plasma, the response was higher (130 ± 8 per cent) than that obtained without addition of the drug, though still significantly lower ($P = 0{\cdot}01$) than that given by the plasma of PTU-treated animals. When the acetic acid (0·25 per cent)–saline extracts of the pooled pituitaries of these animals were tested for TSH activity, it was found to be significantly lower for PTU-treated animals as compared with controls. This finding was confirmed with pituitary extracts from two other experiments carried out as just described.

The thyroid iodine-131 release curve of perchlorate-treated rats receiving daily 2 × 20 μgm. l-thyroxine to block endogenous TSH secretion was not altered by the administration of 2 × 10 mgm. PTU.

Since the hypotheses tested with the above experiments assumed that alterations in the peripheral metabolism of thyroxine induced by PTU might influence pituitary secretion of TSH, it was necessary to ascertain whether potassium perchlorate might be interfering with such extra-thyroidal effects of PTU or itself have an effect on peripheral thyroxine metabolism. On the basis of data reported by others[8] it seemed unlikely; however, the point was investigated in thyroidectomized, l-thyroxine-maintained rats, isotopically equilibrated with radiothyroxine as described elsewhere[6]. Administration of 200 mgm./rat/day of potassium perchlorate alone or together with 15 mgm. PTU showed that perchlorate neither inhibits the peripheral deiodination of thyroxine nor interferes with the depressing effect of PTU.

As referred to above, Griesbach and Purves[1] found that 0·25 per cent thiourea in drinking water did not affect thyroxine requirements of thyroidectomized rats for the maintenance of normal pituitary cytology. Using the same experimental procedure indicated above we found that such doses of thiourea did not result in peripheral alterations of l-thyroxine metabolism similar to those induced by PTU.

Some of the present findings are in good agreement with results recently reported by Mayberry and Astwood[9] while the present work was in progress: they found that the rate of disappearance of thyroid iodine-131 was greater for PTU-treated than for potassium perchlorate-treated rats. Moreover, a progressive disappearance of labelled thyroxine was observed from the hydrolysated thyroid of animals treated with PTU starting 24 hr. after injection of iodine-131. With either control, iodide- or perchlorate-treated animals, the proportion of thyroid radioactivity appearing as thyroxine remained unaltered during the seven-day observation period. This point is suggestive in view of the following hypotheses:

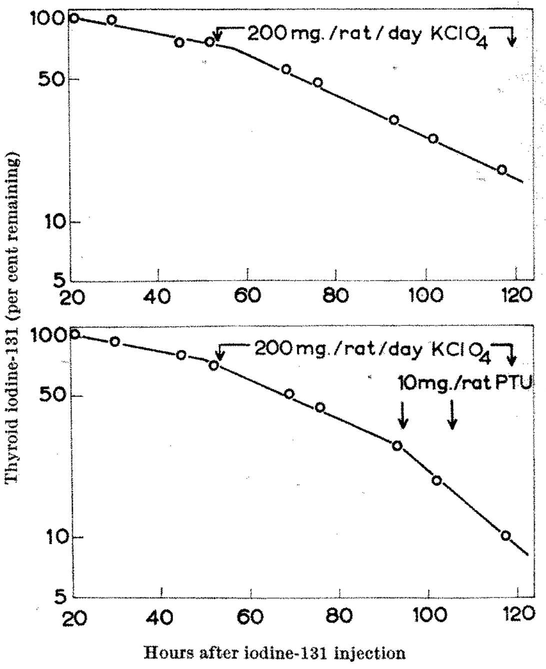

Fig. 2. Effect of PTU on the rate of release of iodine-131 labelled compounds from the thyroid of perchlorate-treated rats. Radioactivity over the thyroid is expressed as percentage of iodine-131 at 20 hr. after injection of 12 μc. Mean values of four animals in each group are given

We believe the present preliminary results may be tentatively interpreted as follows:

(*a*) At very early stages of treatment with PTU there is a considerable increase in the release of labelled compounds from the rat thyroid.

(*b*) Blocking of endogenous TSH secretion with thyroxine interferes with this effect of PTU.

(*c*) Within 24 hr. after onset of PTU treatment there is a higher thyrotrophic circulating activity than that corresponding to controls, as shown both by TSH bioassay of plasmas and thyroidal histology. The activity of pituitary TSH is lower, as shown by bioassay.

(*d*) The three points summarized above strongly suggest that PTU administration results very soon in an increased TSH secretion by the pituitary. Data reported by others[2,5,9] may be interpreted as leading to the same conclusion.

(*e*) It is further suggested that the rapid and intense alteration of the peripheral metabolism of thyroid hormone induced by PTU administration[6] plays an important part in this early response. Moreover, it might aggravate the effects of a low thyroxine pool in later stages of PTU treatment. The fact that blocking of endogenous TSH secretion abolished the effect of PTU makes a direct action of the drug on the pituitary or thyroid gland, not mediated via the thyroid hormone, rather unlikely. This finding does not disagree with the present interpretation: though PTU decreases the deiodination of such high doses of thyroxine to about half that of the corresponding controls (Escobar del Rey and Morreale de Escobar, unpublished results) the amount of thyroxine dehalogenated is still much higher than that corresponding to a physiological dose of the hormone. Neither do the findings of Griesbach and Purves[1] disagree with the present interpretation, since treatment with thiourea does not result in extrathyroidal alterations of thyroxine metabolism comparable to those exerted by PTU.

We should like to emphasize that the present interpretation is merely tentative and needs further experimental confirmation.

TRANSFER FUNCTION OF A BIOLOGICAL PHOTORECEPTOR

By Dr. LAWRENCE STARK and Dr. HOWARD T. HERMANN

Neurology Section, Electronic Systems Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

A FULL description of the function of a sensory organ or sensory element should include definition of the limits of signal transfer. This can be done if the stimulating energy is monitored, and, at the same time, the nervous impulses emanating from the sensory receptor are detected and studied. It is believed that the signal which represents the input stimulus and which is transmitted to other centres of the central nervous system is the average frequency of these nerve impulses. By correlating the instantaneous values of the stimulus and the nerve impulse signal, it is possible to make a rigorous statement regarding the transfer characteristics of the sensory receptor. The task then is to find the equation (generally an integro-differential equation) which characterizes the functional relationship between input and output[1–4].

To explore the problem, we have chosen to study the photosensitive tail ganglion of *Cambarus astacus*, the common crayfish[5–8]. Behaviour and reflex studies have demonstrated a physiological role for the receptor[9–10].

Through a window in the ventral abdominal exoskeleton, large electrodes were applied to the ventral nerve cord. The animal was kept in a humidity- and temperature-controlled environment (100 per cent saturation, 19° ± 0·5° C.). An electronically controlled light source was used to generate transient steps as well as sinusoidal variations of light[11]. Relatively small light fluctuations in a darkened environment permitted small signal linearization.

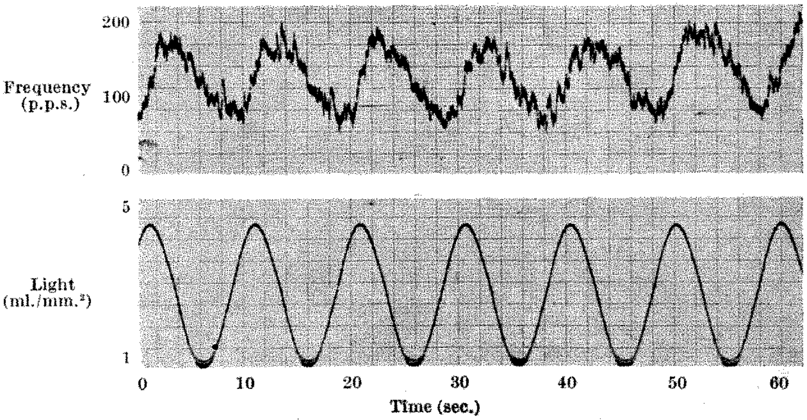

Fig. 1. Response of a photoreceptor to sinusoidal light changes. Note that the harmonic distortion is minimized by small signal approach. The 0·1 c.p.s. input produces an output with amplitude of ± 50 c.p.s., a mean of 130 p.p.s., and a phase-lag of 105°

The nerve impulses were averaged over a time period (*T.C.* = 0·24 sec.) long with respect to pulse-intervals, but short with respect to the response-frequency of the receptor. A combination of operational amplifiers, pulse-shaping circuits, and low-pass filters carried out the averaging. An amplitude window screened from the averaging process any pulses with heights greater or smaller than the medium-sized pulses which carry the light energy information[12].

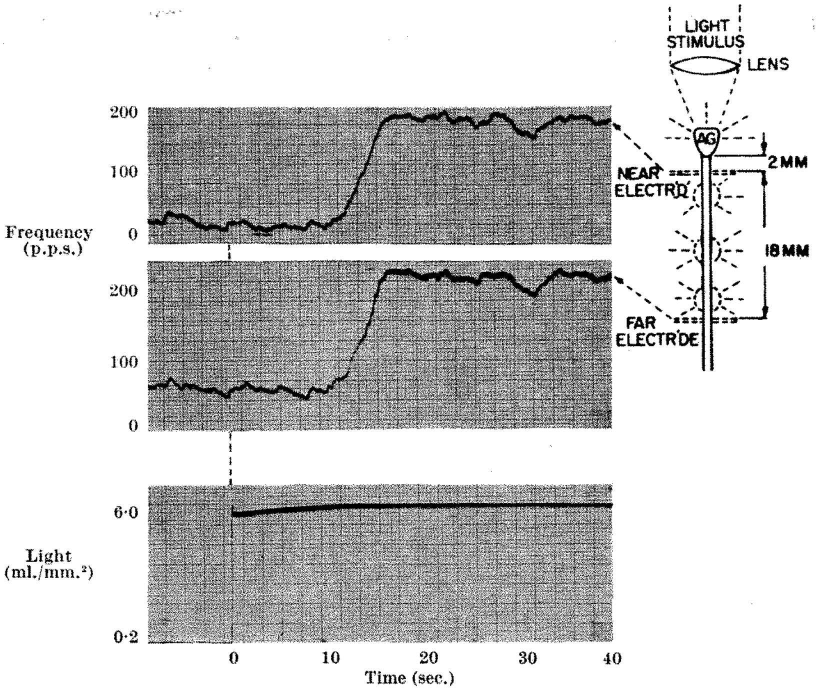

Fig. 3. Transient experiment. The lack of contribution of nerve conduction time to the non-minimum phase element (time delay) is shown. Thus, processes in the photosensitive ganglion are responsible for this operator. Conduction velocity is approximately 4 m./sec. It is interesting to note that details of the response are preserved over the 18 mm. conduction path, through three abdominal ganglia. This step of light was rather large, violating completely the theory of small perturbation analysis. Damping is inversely proportional to amplitude of forcing function

A response of the photoganglion to a sinusoidal stimulus is shown in Fig. 1. The noise seen comes in part from random groupings of pulses from different fibres. Harmonic distortion was minimized by the small-signal experimental conditions, but still is apparent here. The mean amplitude of response over a number of cycles and the mean phase relationship between stimulus and response were determined from such a recording. The parameter triplet—gain, phase and frequency—completely specifies a linear system.

The frequency response of the photosensitive ganglion was obtained by means of a series of experiments at different driving frequencies. Note in Fig. 2: the static or d.c. gain, the absence of adaptation, the break frequency, the attenuation slope, and the large phase lag, composed of both minimum and non-minimum elements. A transfer function:

$$G(s) = 32 \frac{e^{-s}}{(1 + 1{\cdot}2s)^2} \; p \text{ sec.}^{-1} \text{ mlm.}^{-1}$$

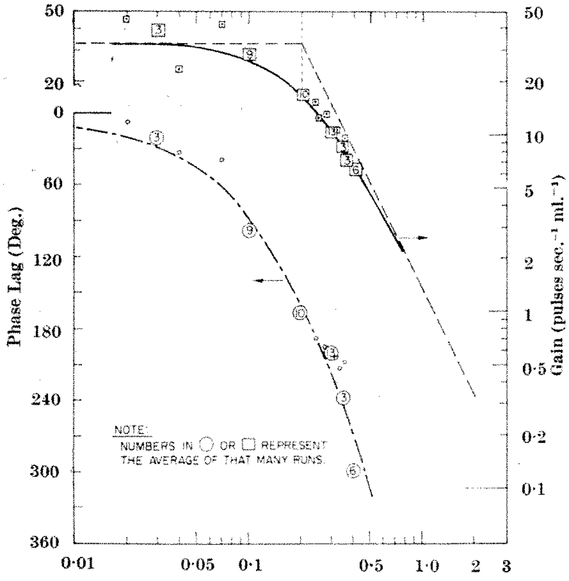

Fig. 2. Bode plot of photosensitive ganglion response. The solid curve represents the theoretical behaviour of a system described by the transfer function. The dashed lines are asymptotes showing the break frequency and attenuation slopes more clearly. The phase-lag curve is computed from the sum of minimum and non-minimum phase elements. The points are experimental

in Laplace operator ('s') notation can be quantitatively derived from this graphic display of system behaviour[3]. It is somewhat more convenient than the equivalent integro-differential equation:

$$32L(t - 1) = 1{\cdot}44 \frac{d^2P}{dt^2} + 2{\cdot}4 \frac{dP}{dt} + P$$

where L = light flux in millilumens, P = pulses per sec., t = time in sec.

The time-delay operator which accounts for the non-minimum phase lag is due, not to nerve conduction time, but rather to processes in the photosensitive ganglion, as reference to Fig. 3 demonstrates. Further investigations of non-linearities are proceeding; as can be seen in the large-signal step experiments, the law of superposition does not hold.

DISTRIBUTION OF SODIUM AND POTASSIUM IN CERTAIN CELLS AND TISSUES

By Dr. NORMAN R. JOSEPH, Dr. MILTON B. ENGEL and Dr. HUBERT R. CATCHPOLE

University of Illinois Professional Colleges, Departments of Chemistry, Orthodontics and Pathology, Chicago

IN primitive oceans, as in the waters of all other epochs, the concentration of sodium greatly exceeds that of potassium, approaching in sea-water of the present era a ratio of about 45 : 1. An excess also occurs in the blood serum of vertebrates, where the ratio is about 30 : 1. In many cells and tissues, however, the ratio is much lower, reaching states in which potassium concentration is higher than sodium concentration. One method of explaining this apparent lack of equilibrium attempts to relate concentration gradients to intracellular metabolic processes; various 'pumps' and 'ion-carriers' deriving energy from respiration have been postulated. This view seems to have been accepted by biologists for many years, and has tended to become the dominant theory[1-3].

In our work with connective tissues, in which respiration is conceded to be low, it was found that ion distributions could be described in terms of the densities of negative colloidal charge and the standard free energies of ion-exchange reactions[4]. Changes in the charge densities of tissue surfaces in relation to *p*H have been represented as titration curves of the surfaces[5-7]. Similarly, Ling, working with nerve and muscle, has supported an explanation of ionic gradients in terms of fixed charges, ionic radii, and dielectric constants[8,9].

Extension of titration studies to frog muscle showed that when respiration was lowered by cooling the tissue, there was no important change in the titration curve (hence, in ion distribution), but that application of respiratory inhibitors greatly altered the curve by lowering colloidal charge[10]. This points to a possible fallacy in all experiments where respiratory poisons have been used to support the argument that ion distribution is determined by respiration rather than by colloidal state. Respiratory inhibitors such as fluoride and dinitrophenol are nucleophilic anions which are bound to amphoteric colloids (including respiratory enzymes), changing colloidal charge and ion distribution. In cooling experiments the effects of temperature and of anions are clearly separable. In attempts to demonstrate the effect of respiration on ion distribution, the possible simultaneous effects of inhibitors on the insoluble structural colloids have been considered only rarely[10].

Changes in Free Energy in Heterogeneous Systems

Cells and tissues are heterogeneous systems[11-14]. It is assumed therefore that they are composed of a limited number of phases, including colloid-rich and water-rich phases which are heterogeneous at sub-microscopic levels, and which are in equilibrium with each other and with blood.

In the theoretical treatment to follow, the distribution of ions will be considered between blood serum, to be denoted phase 1, and a cellular or tissue phase, to be denoted phase 2. In accordance with the above definition, the properties of phase 2 should approach those of a heterogeneous aggregate rather than those of an isolable homogeneous phase. The following formulations apply to the equilibrium of sodium, potassium and chloride, but may be extended to include other mobile anions and cations. The theoretical method differs from that of Donnan[15] by introducing standard potentials of the ions in the two phases. When, for all the ions, the standard potentials are constant throughout the heterogeneous system, the resulting equilibrium conditions are those of the classical Donnan equilibrium. When the standard chemical potentials vary in different phases, the distribution ratios for sodium and potassium may be quite unequal at equilibrium. For the equilibrium of sodium and chloride in two phases:

$$\mathrm{Na}' + \mathrm{Cl}' = \mathrm{Na}'' + \mathrm{Cl}'' \tag{1}$$

Table 1. Values of Q_3 and $-\Delta F_3^\circ$ for Exchange Reactions $\mathrm{K}' + \mathrm{Na}'' = \mathrm{Na}' + \mathrm{K}''$ ($\Delta F_3^\circ = -RT \ln Q_3$)

where Na′ and Cl′ refer to phase 1, and Na″ and Cl″ refer to phase 2. Thermodynamic equilibrium is determined by the standard free-energy change, $\Delta F_1{}^0$, of reaction 1. A similar reaction describes the equilibrium of potassium and chloride:

$$K' + Cl' = K'' + Cl'' \qquad (2)$$

Equilibrium in the system depends on six chemical potentials, one for each of the three ions, K, Na, and Cl, in each of the two phases. The chemical potential, $\bar{F}_{K'}$, of K′ in phase 1, is given by:

$$\bar{F}_{K'} = (\bar{F}_K{}^0)' + RT \ln (K') \qquad (3)$$

where $(\bar{F}_K{}^0)'$ and (K′) are, respectively, the standard potential and concentration of the ion. (If equilibrium be considered for normal physiological states, it is convenient to define the standard chemical potential of an ion in any phase by equation 3. The activity coefficient referred to some other standard state (infinite dilution in water, for example) would be included in the standard chemical potential of the ion in the given phase. For such a 'physiological standard state' activity coefficients of sodium, potassium, and chloride would be 1·0 by definition, whereas the standard chemical potentials would be defined in terms of the ion concentrations at equilibrium.) Five additional equations of the same form are required for K″, Na′, Na″, Cl′ and Cl″. These yield the following expressions for ΔF_1 and ΔF_2, the free-energy changes of reactions 1 and 2:

$$\Delta F_1 = \Delta F_1{}^0 + RT \ln \frac{(Na'') \times (Cl'')}{(Na') \times (Cl')} \qquad (4)$$

and:

$$\Delta F_2 = \Delta F_2{}^0 + RT \ln \frac{(K'') \times (Cl'')}{(K') \times (Cl')} \qquad (5)$$

where $\Delta F_1{}^0$ and $\Delta F_2{}^0$ are the standard free-energy changes. By combining equations 4 and 5, and eliminating the chloride ion:

$$\Delta F_3 = \Delta F_3{}^0 + RT \ln \frac{(K'') \times (Na')}{(K') \times (Na'')} \qquad (6)$$

where ΔF_3 and $\Delta F_3{}^0$ refer to the reaction:

$$K' + Na'' = K'' + Na' \qquad (7)$$

The free-energy changes are related as follows:

$$\Delta F_3 = \Delta F_2 - \Delta F_1 \qquad (8)$$

$$\Delta F_3{}^0 = \Delta F_2{}^0 - \Delta F_1{}^0 \qquad (9)$$

The equilibrium conditions require that ΔF_1, ΔF_2 and ΔF_3 be zero. Then:

$$\Delta F_1{}^0 = - RT \ln Q_1 \qquad (10)$$

with two additional equations of the same form relating $\Delta F_2{}^0$ to Q_2, and $\Delta F_3{}^0$ to Q_3. The mass-law constants Q_1, Q_2 and Q_3 are defined by the ion ratios of equations 4, 5 and 6. They are therefore related by the formula:

$$Q_2 = Q_1 \times Q_3$$

Sodium–potassium equilibrium is expressed by Q_3:

$$Q_3 = \frac{(K'') \times (Na')}{(K') \times (Na'')}$$

When the standard free-energy change of reaction 7 is zero, $Q_3 = 1{\cdot}0$. When $\Delta F_1{}^0$ and $\Delta F_2{}^0$ are zero, Q_1 and Q_2 are also equal to 1·0. In this situation equilibrium is described by the classical Donnan conditions[15]:

$$\frac{(K'')}{(K')} = \frac{(Na'')}{(Na')} = \frac{(Cl')}{(Cl'')}$$

Otherwise the ratios Q_1, Q_2 and Q_3 depend on the three standard free-energy changes according to equation 10. From the four equations for the chemical potentials of K′, K″, Na′ and Na″, one obtains:

$$\Delta F_3{}^0 = \Delta \bar{F}_K{}^0 - \Delta \bar{F}_{Na}{}^0$$

The distribution of ions is therefore determined by the four standard potentials of the two ions in the two phases. The distribution of chloride is determined by the values of Q_1 and Q_2 (or by $\Delta F_1{}^0$ and $\Delta F_2{}^0$). Any two values of Q_1, Q_2 or Q_3 are sufficient to determine the third. The equilibrium is then described by any two of the mass-action constants or standard free-energy changes, and by the colloidal charge density, which is usually negative[4,6]. Electrostatic equilibrium depends on the negative colloidal charge, x, which is balanced by mobile ions:

$$(Na'') + (K'') = (Cl'')\,) + x$$

where it is assumed that other mobile ions are present in only small quantities. In the following discussion, sodium–potassium equilibrium is expressed independently of other ions in terms of calculated values of Q_3 and $\Delta F_3{}^0$. These values express 'potassium selectivity' according to the mass-action law. For any values of Q_3 and either Q_1 or Q_2, the equilibrium is then determined by the colloidal charge, x. These three quantities are sufficient to determine K″, Na″, and Cl″ from K′, Na′ and Cl′. In any heterogeneous system, therefore, equilibrium between blood serum and other phases depends on the colloidal charge of the given phase and the standard free-energy changes of ion-exchange reactions[4,6].

Values of Q_3 and $\Delta F_3{}^0$ for a large number of systems are given (Table 1). These show a number of standard free-energy changes of 0·1 kcal. or less, indicating values of Q_3 near 1·0 and an approach to the ideal Donnan distribution of ions. This occurs in all systems in which the colloids are in aqueous solution. When water is the dispersion medium in both phases, $\Delta \bar{F}_K{}^0$ and $\Delta \bar{F}_{Na}{}^0$, the standard changes of chemical potential of potassium and sodium, tend to approach zero. For solid or semi-solid states of aggregation, on the other hand, $\Delta F_3{}^0$ is negative, Q_3 is greater than 1·0, and potassium ions tend to accumulate in the colloidal phase. Increasing negative values of $\Delta F_3{}^0$ indicate increasing accumulation of potassium ions in phase 2. This occurs not only in cells and tissues (Table 1) but also in solid structures such as zeolites[16,17].

Effects of Ionic Size and Hydration

In all systems the tendency of potassium to displace sodium may be at least partly explained by the relative effects of the ions on the diffuse double layer at the colloidal interface[16,18]. (The total surface area of the interface between the colloid-rich and water-rich phases of ground substance of connective tissue is of a high order of magnitude. Assuming most of the tissue water to be contained in the system of vacuoles described by Gersh *et al.*[12], the total surface area of the vacuoles would be about 60 m.^{2} per cubic ml. of tissue water[31]. This estimate is based on diameters of 1000 Å. for the vacuoles and represents only extracellular active surface. Intracellular surface areas are probably of a similar high order of magnitude.) These effects are related to the 'average effective diameters' of the ions and to the dielectric constant of the solvent. The theory of Debye and Hückel yields the following expression for the electrostatic potential ψ of a univalent cation with unit charge, ε:

$$\psi = \psi^0 - \frac{\varepsilon\varkappa}{D(1 + \varkappa a)}$$

where a is the 'average effective diameter' of the ions in an electrolyte solution; $\varkappa$ is proportional to the square root of the ionic strength, and is the reciprocal of the thickness of the ionic atmosphere in centimetres; D is the dielectric constant; ψ^0 is the potential at the surface of the ion in a solution at zero ionic strength. For a univalent ion of radius b:

$$\psi^0 = \frac{\varepsilon}{Db}$$

The standard chemical potentials of ions, $\bar{F}_K{}^0$ and $\bar{F}_{Na}{}^0$, depend on values of b, while the activity coefficients depend on a. Values of a and b for potassium and sodium in water are given in Table 2, with the free energies of hydration, which depend on b. In this treatment, ionic size terms are considered in relation to thermodynamic functions which determine equilibrium. These terms may also be related to rates of diffusion and exchange, as studied by Ling[9] and by Simon[13].

For the exchange reaction:

$$K(H_2O) + Na'' = K'' + Na(H_2O)$$

the standard free-energy change is − 16·2 kcal. (Table 2). This represents a theoretical limit for exchange reactions involving hydrated ions in an aqueous phase and a co-existent phase of low dielectric constant, in which some of the ions are not hydrated.

Table 2. FREE ENERGIES OF HYDRATION OF SODIUM AND POTASSIUM (ref. 16)

Ion	Ionic radius (Å.) (crystal.) b	Ionic diameter (Å.) (av. effective) a	$-\Delta F^0$ (hydr.) (kcal.)
Na	0·98	5·2	89·7
K	1·33	4·1	73·5
Difference	—	—	16·2

Relation of Hydration to Entropy

Because of the lower hydration energy of potassium ions, the fraction of unhydrated ions in any phase would be much greater than for sodium. For this reason it would be possible for potassium to participate more readily in short-range electrostatic interactions in media of low dielectric constant. This implies a greater number of possible states of potassium ions than of sodium ions in the colloidal phase. The entropy of physicochemical systems increases with statistical probabilities of given states; for systems in which sodium and potassium are free to exchange, the negative free-energy change, ΔF_3, occurring for any spontaneous process, would be associated with a corresponding positive entropy change, ΔS_3. Because the free energy of hydration of sodium is greater than that of potassium, the standard entropy change, $\Delta S_3{}^0$, of reaction 7 would be positive. The reaction tends toward an equilibrium which yields the maximal number of ionic states, including all the interactive forms of unhydrated ions in the colloid-rich phase. This implies for all possible distributions of sodium and potassium an equilibrium state in which free energy is minimal and entropy maximal. The temperature coefficient of the ion distribution ratio, Q_3, and the temperature coefficient of the standard free-energy change depend on $\Delta S_3{}^0$. In particular:

$$\frac{\partial \Delta F_3{}^0}{\partial T} = -\Delta S_3{}^0$$

Since in general $\Delta S_3{}^0$ would be positive, $\Delta F_3{}^0$ would become increasingly negative as the temperature increases. If Q_3 is increased the equilibrium would shift towards potassium accumulation in the colloidal phase. When this is found experimentally, the usual interpretation has been to attribute the increase of potassium to increased metabolic rates. The effect of temperature on the distribution of potassium in erythrocytes has been interpreted in this way[2]. This ignores the possibility that the effect depends on the free energies of hydration of the ions. Potassium, having the lower free energy of hydration, has a greater tendency than sodium to form unhydrated ions in a colloid-rich phase; it therefore has more freedom to neutralize fixed charges[9,13]. The presence of hydrophobic charged colloids decreases the number of hydrated ions in any system and increases the entropies of all ions of the colloid-rich phase. This effect is selective for potassium. In all systems for which this is true, $\Delta S_3{}^0$ of reaction 7 would be positive, and $\Delta F_3{}^0$ negative.

Standard Free Energy and Ion Concentration Gradients

The values of $\Delta F_3{}^0$ in Table 1 range from 0·17 kcal. to about − 3 kcal. Values near zero indicate an approach to the ideal Donnan distribution, which occurs in body fluids with colloids in solution. For solid or semi-solid states of aggregation, the values range from about − 0·2 kcal. (zeolite or femur) up to − 3 kcal. High negative values are found for erythrocytes, ascites cells, leucocytes, epidermis and lens. The most actively metabolizing tissues such as muscle and nerve show standard free-energy changes in the same range (− 2 to − 3 kcal.). Changes of sodium and potassium distribution which occur during physiological activity may depend on small transitory changes of the colloids following stimulation, as observed by light-scattering[32]. Changes of $\Delta F_3{}^0$ of a few tenths kcal. would produce rather large shifts of sodium and potassium independently of mechanisms of ion-transport. Values of $\Delta F_3{}^0$ in all systems depend on states of aggregation of cells and tissues and on the nature of the colloidal components such as proteins, glycoproteins, phospholipids and nucleoproteins.

Accordingly, it is unnecessary to invoke metabolic energy to explain steady concentration gradients in tissues. Distribution of anions and cations in steady states depends only on the colloidal charge and on the standard free energies of ion-exchange reactions[4,6]. Homeostasis within heterogeneous systems of cells and tissues depends on the maintenance of constant chemical potentials of water and electrolytes[4,14]. Examples of analogous concentration gradients at minimal free energy are very numerous, and would include the distributions of surface-active substances according to their adsorption isotherms, the distribution of gases in the gravitational field of the Earth according to molecular weights (law of atmospheres), and the distribution of ions in immiscible solvents. Concentration gradients in tissues depend on the standard potentials of the ions in different phases. These values depend on dielectric constants and on the ionic radii (b values). The presence of fixed negative colloidal charges establishes electrostatic conditions for equilibrium, requiring an excess of mobile cations over mobile anions for electrical neutrality. The ratio of potassium to sodium at any charged interface depends on the 'average effective diameters' (*a* values). The distribution of cations depends on the distribution of colloidal charge, on the dielectric constants of various phases, and on hydration energies and sizes of the ions. Redistribution of ions during metabolic changes would depend on changes of colloidal charge and states of aggregation, on changes of concentration of various metabolites (lactic acid, carbon dioxide, di- and tri-carboxylic acids), and on redistributions of water accompanying these changes[31]. According to Donnan's treatment, ionic equilibrium is determined by the condition of minimal free energy. This condition is of general validity for cells and extracellular substances, but the standard chemical potentials of mobile ions in different phases of the heterogeneous system must be included in the formulation.

DISTRIBUTION OF HUMAN CHROMOSOME COUNTS IN RELATION TO AGE

By PATRICIA A. JACOBS and W. M. COURT BROWN, O.B.E.

Medical Research Council Clinical Effects of Radiation Research Unit, Western General Hospital, Edinburgh

AND

DR. RICHARD DOLL

Medical Research Council Statistical Research Unit, London School of Hygiene and Tropical Medicine, Gower Street, W.C.1

AN investigation has been made of the distribution of chromosome counts in leucocytes from blood cultures, prepared by the technique of Moorhead *et al.*[1], with the final spreading of the chromosomes achieved by drying in air. Ninety-seven people (50 males and 47 females) have been examined who, on chromosome analysis, appeared to have a normal karyotype. These subjects ranged in age from 5 months to 82 years, and were drawn from volunteers, hospital patients and the parents of patients with chromosome abnormalities. No subject had received X-ray treatment, and none was known to have a malignant tumour. While it would have been preferable for the subjects to have been a sample of the general population, there is no reason for believing that the composition of the present group has introduced any serious bias into the findings.

Two other groups were also studied. One consisted of 24 phenotypic males, all with a diploid number of 47 and a complement of *XXY* sex chromosomes. These patients ranged in age from a new-born child, to a man of 68 years. The other group consisted of 42 mongol imbeciles (26 males and 16 females), ranging in age from 3 to 51 years, and all shown to be trisomic for a small acrocentric autosome, presumed to be No. 21 (Denver Classification). There was no evidence that any patient with a chromosome abnormality was a chromosome mosaic.

For the 97 subjects with a normal karyotype, the distribution of chromosome counts has been examined in eight age-groups (Table 1). For the abnormal subjects, three age-groups were studied in the *XXY* males, and four in the mongol imbeciles (Table 2). An average of 36 cells was counted for each subject with a normal karyotype, 30 for each *XXY* male, and 32 for each mongol imbecile. Less than 25 cells were scored in only 4 normals, 2 *XXY* males and 2 mongol imbeciles. Variations from subject to subject in the number of cells scored were allowed for in calculating the average age of each age-group, by weighting the age for the number of cells counted.

The chromosome preparations were scanned under low-power for dividing cells in which the chromosomes were well spread. These were then examined under an oil-immersion lens to decide whether they were suitable for counting. Three criteria had to be satisfied. First, the cell must not be obviously broken; secondly, there must be no stray chromosomes in the same optical field; thirdly, the fixation and spreading of the chromosomes must be such that there is no ambiguity in interpretation for the purposes of counting. If any one of these criteria was not

Table 1. DISTRIBUTION OF CHROMOSOME COUNTS IN CELLS OF PERSONS WITH A NORMAL KARYOTYPE

Age-group (yr.)	No. of subjects	Mean age of subjects* (yr.)	Total No. of cells counted	No. of cells with chromosome counts of:								Hypomodal counts as percentage of modal counts	Hypermodal counts as percentage of modal counts
				< 43	43	44	45	46	47	48	> 48

* Weighted for the number of cells counted at each age.

satisfied, the cell was discarded; once the chromosomes had been counted, however, the count was always included.

Not all cells that satisfy these criteria can be analysed precisely; in particular, full analysis is often impracticable if there is excessive contraction of the chromosomes, although an accurate count is still possible.

In all, there were 66 cells with hypermodal counts (Tables 1 and 2), including 45 from persons with a normal karyotype. Of the 66 cells, 6 could not be analysed because of excessive contraction of the chromosomes, and in 5 other cells the distribution of the chromosomes between the various sub-groups recognized in the Denver classification was grossly abnormal. Among the remaining 55 cells, there were 38 from persons with normal karyotypes, with a total of 43 additional chromosomes. After two telocentric chromosomes were excluded, it was found that there was a slight excess of chromosomes in the 13–22 range of the Denver classification (24 against 18·39 expected); but this excess was not statistically significant.

Occasionally chromatid fragments, chromosome fragments and telocentric chromosomes were found. Chromatid fragments were always in proximity to their parent chromosomes, and, therefore, were assumed to have arisen from breakage of a chromatid during the preparation of the slide. They were not scored as separate bodies. Chromosome fragments were of two types depending on whether or not the fragment lay close to the parent chromosome. In the latter instance, analysis of the cell usually revealed the chromosome from which the fragment was derived, and neither type was scored as a separate chromosome.

Telocentric chromosomes do not occur in the normal human karyotype, and their presence in a cell is taken to indicate the breakage of a chromosome transversely through its centromere. They were uncommon in our preparations, and, when present, were almost always in pairs. Analysis of such cells always showed a metacentric or a sub-metacentric chromosome to be missing, the breakage of which is presumed to have given rise to the two telocentrics. A cell with two telocentric chromosomes and a count of 47 bodies was therefore recorded as having 46 chromosomes. Very occasionally a single telocentric was present, and our present practice is to score this as a chromosome.

In Tables 1 and 2, the numbers of cells in persons in each age-group with counts (*a*) greater than the modal number, and (*b*) less than the modal number, have been expressed as percentages of the number of cells with the modal number of chromosomes. The rates of change with age are indicated by the coefficients of x in the following regression formulæ:

For the proportion of hypermodal cells in subjects with a normal karyotype:

$$y = 0{\cdot}034x + 0{\cdot}369 \qquad (1)$$

For the proportion of hypomodal cells in subjects with a normal karyotype:

$$y = 0{\cdot}066x + 3{\cdot}384 \qquad (2)$$

For the proportion of hypermodal cells in subjects with an abnormal karyotype:

$$y = 0{\cdot}057x - 0{\cdot}229 \qquad (3)$$

For the proportion of hypomodal cells in subjects with an abnormal karyotype:

$$y = 0{\cdot}097x + 3{\cdot}550 \qquad (4)$$

Three of the regression coefficients are significantly different from zero: for (1), $P < 0{\cdot}01$; (2), $P = 0{\cdot}03$; and (4), $P = 0{\cdot}01$. The remaining coefficient (3) is not significantly different from zero ($P = 0{\cdot}07$).

An analysis of variance for all the data shows that the differences between the regression coefficients, considered as a group, can reasonably be attributed to chance ($P = 0{\cdot}2$), and the same result is obtained by examining separately the differences between the regression coefficients for the hypermodal and

Table 2. DISTRIBUTION OF CHROMOSOME COUNTS AMONG THE CELLS OF PATIENTS WITH KLINEFELTER'S SYNDROME OR MONGOLISM

* Weighted for the number of cells counted at each age.

hypomodal counts, and for the normal and abnormal karyotypes.

It may be noted, however, that the rate of increase with age is greater for the hypomodal counts than for the hypermodal, and for the abnormal karyotypes than for the normal. The present data are not numerous, and the fact that the differences between the regression coefficients are not statistically significant does not necessarily mean that they are not real.

When plotted, the regression lines for the proportion of hypermodal cells (equations 1 and 3) pass close to the origin; in neither case is the regression constant significantly different from zero, and it would appear that at birth hypermodal cells must be rare. In contrast, the constants in the regression formulæ for the proportion of hypomodal cells (equations 2 and 4) are both significantly different from zero (in each case, $P < 0{\cdot}01$). The two estimates of the proportion of hypomodal cells at 0 years of age are similar to one another (3·384 and 3·550 per cent, respectively), and it is reasonable to assume that, with the present technique, the ratio of hypomodal to modal cells at birth would be about 3·5 per cent.

It has been assumed in the above analysis that the data are best fitted by straight lines. In the present limited state of knowledge this seems reasonable; in only one case (hypomodal cells in persons with a normal karyotype) is there statistical evidence of a significantly better fit with a quadratic curve.

One explanation for these findings could be that all non-modal cells are artefacts arising during preparation. A study of the hypermodal cells, however, provides evidence that this is not so. The type of artefact which will give rise to non-modal counts is rupture of a cell with the loss of one or more chromosomes; if these lost chromosomes become included in a neighbouring cell, a hypermodal count can be obtained. Usually, however, a true hypermodal cell can be distinguished from one which has gained a chromosome from a neighbouring cell. Such a 'foreign' chromosome can be recognized, because the degree of contraction of the chromosomes in a preparation tends to differ between cells, as the cells will be in different stages of their division cycle when colchicine is added to the culture medium. A further type of error which can give rise to a count of 47 is the presence of a single telocentric chromosome. As noted, our present practice is to record such cells as having a genuine count of 47 chromosomes. This may be wrong, but the number of cells involved is very small.

The great majority of the cells with hypermodal counts are therefore regarded as the products of errors in division. One possible mechanism by which these cells could be produced is somatic non-disjunction in a normal diploid cell. There will, of course, be an equal number of cells formed with counts of 45 chromosomes, and, if viable, these will be represented among the hypomodal cells. Hypomodal cells are also likely to be produced by anaphase lagging. The analysis of hypomodal cells, however, cannot distinguish between those that result from artefacts and those that are the products of errors in division. That the latter do occur can be inferred only from the study of the hypermodal cells. It follows, in our view, that the presence of aneuploid cells cannot be accounted for wholly on the basis of artefacts, nor can they all be regarded as genuine aberrations. It is suggested that the figure of 3·5 per cent hypomodal cells at birth, calculated from the regression formulæ, may provide an approximate estimate of the proportion of aneuploid cells arising from artefacts with the present technique.

Several biological mechanisms could be postulated to account for these results. One is that there is an increase in the frequency of abnormal divisions with age. These abnormal divisions may have occurred in ancestral cells, so that the cells which divide in culture to produce abnormal daughter cells were themselves abnormal when taken from the body. Another mechanism could be that the rate of abnormal division is a constant; but that some of the abnormal daughter cells are viable and maintain themselves in equilibrium with the normal cells. Lastly, it may be that the cells were normal when taken from the body and that abnormal division is related to the conditions of culture. In either case there exists some age factor which leads to the presence in the cultures of more abnormal cells in an older subject than in a younger subject.

RECOMBINATION IN THE *X*-CHROMOSOME OF *DROSOPHILA MELANOGASTER*

By C. N. LAW*

Department of Agricultural Botany, University College of Wales, Aberystwyth

PREVIOUS work on *Drosophila* species has indicated that inter-chromosomal effects and genetic differences between the homologous chromosomes being studied influence recombination appreciably[1,2]. So far, few attempts have been made to determine whether or not interactions are occurring at the intra-chromosomal level. Recently, an experiment using different wild-type iso-alleles at the white-eye locus (*w*) has suggested that the presence of different alleles of major genes may influence recombination in their own vicinity[3]. In view of this, experiments have been carried out to investigate more closely the inter-relations between genes and regions within a chromosome.

Recombination was studied in an *X* chromosome, carrying the genes, yellow Hairy-wing (*yHw*), vermilion eye (*v*) and Bar-eye (*B*). The positions of these genes as indicated by Bridges are respectively, 0·0, 33·0 and 57·0. (For the purpose of this experiment, *y* and *Hw* are considered to be one gene, since they are both situated at position 0·0.) An inbred Samarkand–Bayfordbury stock was used, into which, by the use of a *CyL*/*Pm*; *Sb*/*H* technique, a single marked *X* chromosome was introduced without any appreciable alteration to the other chromosomes.

This stock was developed in such a way that all informative combinations of homozygosity and heterozygosity for two alleles at the three loci could be derived simultaneously (Fig. 1). Thus the experi-

ment permits the study of the influence of *B* and the proximal region on recombination distally, *yHw-v*; the effect of the median region containing the gene *v* on the whole marked region, *yHw-B*; and the effect of *yHw* and the distal region on the proximal segment, *v-B*. The experiment was carried out at 24° C., and recombination was estimated by the product formula.

Table 1 shows that different states of the distal region have insignificant effects on recombination in the proximal region, *v-B*, ($\chi^2_{(2)} = 0{\cdot}3414$, $P = 0{\cdot}90\text{–}0{\cdot}80$). The other two regions, however, have large influences on recombination. Thus, there are significant differences in recombination in the distal segment, *yHw-v*, when the different states of the *B* locus and the proximal region are considered ($\chi^2_{(2)} = 9{\cdot}2297$, $P < 0{\cdot}01$). Similarly, differences in the median region with the *v* locus are associated with significant effects on recombination for the whole chromosome, *yHw-B* ($\chi^2_{(2)} = 10{\cdot}7384$, $P < 0{\cdot}01$).

Table 1. PROGENY OBTAINED FROM COUPLING AND REPULSION CROSSES FOR THE NINE PARENTAL GENOTYPES

Region	Parental genotype	Progeny				Recombination (p)
		Coupling cross		Repulsion cross

	+/+	281	1,382	122	638	0·1971 ± 0·0097

The failure to detect an influence of the distal region on recombination, in contrast to the large effects produced by the other regions studied, may have a number of causes of which the following are considered here. Either the proximal and median regions are more active genetically than the distal region so far as the control of recombination is concerned, or the proximal and median regions are more active because of their position in relation to the centromere. Thus, if the recombination process commences proximally and moves towards the ends of the chromosome, and there is evidence to support this in *Drosophila*[4], direct genetic alteration of recombination in regions near the centromere must have consequences on recombination distally. On the other hand, direct genetic changes in distal recombination will have little effect proximally, because recombination will already have occurred here. Clearly, a definite distinction between these possibilities cannot be derived from the results obtained in these experiments. It seems, however, unlikely from examinations of other characters that the proximal and median regions should have a higher genetic activity than the distal region. The distributions of both genes controlling sternopleural chaetæ[5], and major genes in the *X* chromosome, are concentrated at both ends of the genetic map, so that according to such evidence the distal as well as the proximal region should show high activity. The most plausible hypothesis, therefore, appears to be the latter.

From the results it is also apparent that large variations in recombination are produced by the different genetic states used in the proximal and median regions. The possibility that some of this variation may arise as a result of the activity of the major genes used to measure recombination has, therefore, to be considered. A means of detecting such influences may be obtained from a comparison of the dominance relations expected from the normal phenotypic expressions of the genes involved and their observed level of action in recombination. Some agreement between the two may indicate that the major genes are having an effect. Evidence from the two major genes *B* and *v*, which lie in the regions producing significant effects on recombination, shows some agreement with expectation. Thus *v* acts as a recessive on eye-colour and appears to do likewise when recombination is considered, since a comparison between the homozygous recessive (*v*/*v*) and the combined homozygous and heterozygous dominant (+/+ and *v*/+), accounts for almost all the heterogeneity in this region and is highly significant ($\chi^2_{(1)} = 10{\cdot}4483$, $P < 0{\cdot}001$). Similarly, the gene *B*, which behaves as a partial dominant on eye-shape, produces analogous effects on recombination. In this case, the difference between the homozygous recessive (+/+) and the combined homozygous and heterozygous dominant (*B*/*B* and *B*/+) is also significant ($\chi^2_{(1)} = 8{\cdot}7194$, $P < 0{\cdot}01$). It appears, therefore, that some of the results could be produced by the major genes themselves and not entirely from genes closely linked to them.

The observations made in these experiments clearly demonstrate that large differences in recombination can be obtained by genetic alterations within a chromosome. Large structural changes seem to be excluded, since the combinatorial type of experimental design used here should show disturbance of this type. The lack of precision brought about by the use of large genetic map distances, which of necessity must be used in *Drosophila*, cannot allow an exact appraisal of the genetic factors responsible. Some of the differences may, however, be produced by the major genes used for estimating recombination. Further, the experiments indicate a definite relationship between regions and, moreover, one which appears to be orientated with respect to the centromere. They also illustrate the possible usefulness of such designs in recombination studies within a chromosome, particularly where small regions of a chromosome could be considered.

I thank Dr. A. Durrant for advice and guidance during the course of this work, and also acknowledge the receipt of an Agricultural Research Council studentship.

LETTERS TO THE EDITORS

ASTROPHYSICS

Terrestrial Accretion from the Solar Wind

C. M. DE TURVILLE[1] has suggested that most of the water now present on Earth has been formed from hydrogen in the solar wind, in combination with oxygen in the Earth's atmosphere. If this is so, then the process must still be going on, forming water vapour, according to de Turville, at a rate of about 2×10^{-12} gm. cm.$^{-2}$ sec.$^{-1}$. The water is presumably being formed at very high levels (above 100 km.) where oxygen in the atomic form exists. The continuous formation of water vapour at these levels must lead to a gradient of the water vapour mixing ratio (the ratio of the mass of water vapour to the mass of air) decreasing downwards until overtaken by the gradient decreasing upwards arising from evaporation of water from the surface of the Earth. What measurements there are do suggest such gradients[2], and it is interesting to consider whether the humidities found could conceivably arise in this way.

We may assume a flux equation of the form $F = K\rho \frac{d\chi}{dt}$, where χ is the mixing ratio. If we now assume that K is invariant with height, and assume that the air density, ρ, is given by the equation $\rho = \rho_0(\exp - bz)$, then we find, inserting an appropriate value for b, and putting F equal to 2×10^{-12}:

$$\chi - \chi_0 = \frac{1{\cdot}5 \times 10^{-6}}{K}\left(\frac{1}{\rho} - \frac{1}{\rho_0}\right) \qquad (1)$$

or, if m denotes the water vapour density:

$$m = \frac{1{\cdot}5 \times 10^{-6}}{K}\left(1 - \frac{\rho}{\rho_0}\right) + \frac{\rho}{\rho_0}\, m \qquad (2)$$

It will be seen that, in any layer with a more or less constant K, the water vapour density tends rapidly to the value $\frac{1{\cdot}5 \times 10^{-6}}{K}$ gm. cm.$^{-3}$. Frost points corresponding to values of K ranging from 10^2 to 10^5 are given in Table 1.

Table 1

K	10^2	10^3	10^4	10^5
Frost points	−58	−74	−88	−101° C.
	215	199	185	172° K.

Few measurements of water vapour have been made at high levels, but Barclay *et al.*[2] obtained a value at 27 km., which corresponds to a frost point of −75° C. 'Mother-of-pearl' clouds are also occasionally seen, from Sweden, at these levels[3]. There is good reason for believing that these are water clouds, and since the temperature at these levels is known to be between −70° and −80° C., this also suggests a frost point of about −75° C. A flux of water vapour of 2×10^{-12} gm. cm.$^{-2}$ sec.$^{-1}$, and a turbulence coefficient of 10^3 would provide just such a frost point. This is rather a low value, even in this region of great stability, but it is certainly not so low that it can be dismissed as inconceivable.

There are no measurements of humidity at greater heights, but clouds—'noctilucent clouds'—are also reported, from high latitudes in summer, at levels of about 80 km. These look very much like water (ice) clouds, but the great difficulty, hitherto, in explaining how the water got there has led some meteorologists to conclude that they must be dust clouds[4]. The temperature at this level, in the regions where the clouds are seen, has never been measured, but it is probable that it is, in summer, very low—perhaps −90° C. or lower. This suggests a value for the turbulence coefficient of between 10^4 and 10^5—and this higher value is consistent with the known instability in this region (temperature maximum at about 55 km. and temperature minimum at about 85 km.). Some spectroscopic measurements in a water vapour absorption band have been made from aircraft[5]. Unfortunately, the absorption coefficients, at the wave-lengths used, are dependent on pressure, so that it is not possible to deduce the amount of water vapour above the level of the highest reading; but a rough calculation suggests that the results of Houghton and Seeley are quite consistent with the amounts suggested here.

It must be concluded that if water vapour is being added at the rate suggested by de Turville, then water (ice) clouds at about 80 km. and at about 25 km., and such measurements of water vapour at these levels as have been made, are all consistent with turbulent diffusion downwards of this water vapour, and coefficients of diffusion which it is reasonable to suppose may be found at the levels concerned.

DE TURVILLE[1] has suggested that the Earth is gaining hydrogen from the Sun at the rate of 1·5 tons a second, and points out that this rate of accretion will account for all the hydrogen in the oceans in the course of 3×10^9 years. His idea is that the geomagnetic field captures the protons of an incident solar wind.

Pirie[2] has expressed some concern at the idea of a 'hydrogen hurricane' depositing hydrogen in the atmosphere at such a high rate. For if de Turville is correct, the question is where does the oxygen come from ? The suggestion therefore creates rather than solves a problem.

The values proposed by de Turville, a density of $n = 12$ protons cm.$^{-3}$ and a velocity of $v = 4{,}300$ km. sec.$^{-1}$, have indeed transformed the solar wind into a 'hydrogen hurricane'. These values yield a particle energy flux of 10^3 ergs cm.^{2} sec.$^{-1}$ at the Earth's orbit, or one-thousandth of all the radiation flux from the Sun. Where does this immense amount of energy come from? It is assumed apparently that the particles are continuously accelerated as they travel from the Sun to the Earth, but it is not explained how this is possible. Parker, who is the principal advocate of the solar wind idea, suggests that hydromagnetic waves heat the solar corona out to a distance of possibly 8 solar radii, and therefore an isothermal corona must expand hydrodynamically away from the Sun. Beyond 8 solar radii the solar wind flows at a constant velocity, and the temperature falls off adiabatically. Applying de Turville's relation of $v \propto r^{2/3}$ out to a distance of only 8 solar radii, and not to the Earth's orbit, yields a solar wind velocity of 600 km. sec.$^{-1}$, in agreement with the more modest ideas that are prevalent.

Even if de Turville's values were correct, it is doubtful whether the hydrogen in the oceans can be accounted for in the manner he suggests. The momentum flux of this 'hydrogen hurricane' would deform and compress the geomagnetic field to within a distance of roughly 3 Earth radii, and not 12 Earth radii as stated. If the incident particles are captured by the geomagnetic field, the rate of accretion is reduced to only 5 per cent of the value proposed. However, one questions strongly whether the geomagnetic field does capture entirely the incident solar wind. In every analysis of the subject published so far, starting from the early work of Chapman and Ferraro, it is seen that the Earth's magnetic field acts as a shield, and forms a cavity inside the low-energy corpuscular streams from the Sun. The particles that penetrate, as a result of complex diffusion processes, are relatively few. If magnetic fields are embedded in the solar wind, and this is quite possible, the solar wind will stream hydrodynamically around and past the Earth, very much in the same manner that a fluid flows past a submerged object.

At the present moment it is not known definitely whether there is a solar wind or not. Should it turn out that there is a solar wind, or even a 'hydrogen hurricane', it is almost certain that the rate of accretion of hydrogen is negligible and cannot by any means account for the formation of the oceans in the life-time of the Earth.

Atomic Energy Research Establishment,
Harwell,
Berks.

[1] de Turville, C. M., *Nature*, **190**, 156 (1961).

[2] Pirie, N. W., *Nature*, **190**, 706 (1961).

MR. HARRISON has raised a number of important issues which can only be answered tentatively at the present time. Presumably the oxygen is liberated from terrestrial rocks by solar ultra-violet radiation, and an estimate of the mean quantum efficiency of this photochemical process should be readily obtainable in the laboratory, by irradiation of outgassed rock samples in an evacuated chamber, using a strong ultra-violet source and an ionization pressure gauge. In the absence of hydrogen accretion, this process would lead to an evolution of oxygen trending towards zero as ultra-violet absorption by atmospheric atomic and molecular oxygen and ozone increased, and the oxygen content of the atmosphere would reach asymptotically some terminal value corresponding to complete absorption of ultra-violet radiation. The effect of hydrogen accretion is to remove atomic oxygen at levels above 100 km., and the ultra-violet absorption provides a regulating mechanism which ensures a dynamic balance between the rate of liberation of oxygen from the rocks and the rate of removal of oxygen in the upper atmosphere.

Concerning the acceleration mechanism responsible for the solar wind, it must be understood that the difference between Parker's 600 km./sec. and the 4,300 km./sec. previously proposed by me is due solely to a different estimate of the range of applicability of the relation $v = Bn^{-\frac{1}{4}}$. I accept Parker's account of the origin of the solar wind in magnetohydrodynamical terms, the ultimate source of energy being the thermal energy at the solar surface, which is clearly adequate. It is known from a study of the behaviour of solar cosmic rays that the region of disordered magnetic fields begins at about 1·2 A.U. from the Sun, and it seems plausible to suppose that the régime of flow of the solar wind is preserved until this point is reached. As pointed out by Parker[1], the assumption that the isothermal corona extends to only 8–20 $R_\odot$ and that beyond this point the temperature falls off adiabatically in the absence of any further coronal heating is merely the simplest and most conservative model consistent with observations of the intensity of electron scattering of photospheric white light; the fact that no observations are available beyond 20 $R_\odot$ is due to technical difficulties and affords no evidence of the absence of a corona beyond this point. If other evidence relating to conditions at the orbit of the Earth is also taken into account, Parker's estimates of the extent of the corona and of the velocity of corpuscular radiation turn out to be excessively conservative. The simplest model consistent with all observations is surely that of a radial solar wind the character of which is unaltered out to a distance of 1·2 A.U.

Nevertheless, it must be admitted that the numerical values previously quoted are seriously in need of revision, since the flight of *Pioneer V* has revealed that the velocity of the solar wind in the vicinity of the Earth is in fact $1{\cdot}45 \times 10^8$ cm. sec.$^{-1}$. Owing to equipartition of proton and electron energies in the terrestrial magnetic field, this implies a velocity $\sqrt{2}$ times larger in free space, so that the velocity of the solar wind in free space at the orbit of the Earth is $v_1 = 2{\cdot}05 \times 10^8$ cm. sec.$^{-1}$ and the corresponding ion concentration $n_1 = (B/v_1)^4 = 232$ cm.$^{-3}$, in better agreement with Biermann's estimate than with the values quoted by Pope and Kupperian—no theory can be expected to agree simultaneously with several discordant observations. The recalculated transit time of solar protons is then 2 days, but may well be shorter during magnetic storms. The rate of emission of hydrogen by the Sun becomes $2{\cdot}24 \times 10^{14}$ gm. sec.$^{-1}$, and implies a rate of emission of deuterium of $3{\cdot}3 \times 10^{11}$ deuterium atoms/cm.^{2} sec.

The adjusted values of n_1 and v_1 are quite compatible with van Allen's data[2] concerning the electronic energy and flux in the outer radiation belt. With the aid of these new values, it becomes possible to accept Harrison's valid objection concerning the deformation of the terrestrial magnetic field and yet recover the previous value of the rate of terrestrial accretion. The equatorial dipole field of the Earth is $H = 0{\cdot}316/x^3$ gauss, where x is the geocentric distance expressed in Earth radii, and if x_0 denotes the distance at which the pressure and magnetic energy density are equal, then $H^2/8\pi = n_1 m_H {v_1}^2/3$ and hence $x_0 = (80\pi n_1 m_H {v_1}^2/3)^{-1/6} = 3{\cdot}00$, which coincides approximately with the centre of the outer radiation belt.

The mass of hydrogen accreted by the Earth in time T is then $Q = \pi x_0^2 R_{\oplus}^2 m_H n_1 v_1 T$ and using these new values of x_0, n_1 and v_1 and the more plausible figure $T = 1{\cdot}5 \times 10^{17}$ sec. for the age of the Earth, the revised rate of accretion is $1{\cdot}37 \times 10^{23}$ gm., which is not very different from the previous value. Oxidation would yield $1{\cdot}23 \times 10^{24}$ gm. of water, but this is only a rough estimate. During magnetic storms, the rate of hydrogen capture may be greatly increased, and there are other complicating factors which indicate that the present simple treatment can only be accepted as a first approximation.

In particular, the question of the efficiency of capture and retention of particles from the solar wind is bound to be mathematically very complex, as it involves not only the combination of a radial solar magnetic field and a rotating terrestrial dipole field, but also the interaction of the incoming particles with the local plasma and the dissipation of electron energy by bremsstrahlung radiation. But if we are to judge by the recent findings discussed by Dr. Frith, the observational evidence afforded by high-altitude meteorology does suggest that the capture process is in fact fairly efficient. Thus the proposed account of the origin of the oceans remains eminently defensible, though much further work will be needed before it can be considered as established.

PHYSICS

Theory of the Red Shift and the Nature of Planck's Constant

Since the Mössbauer experiment, the definition of the frequency of light requires further attention. In the theory of General Relativity the following definitions are possible :

(1) *Based on Maxwell's Theory.* Let us call A_a (A_0, A_1, A_2, A_3) the four potential. Let us assume $A_a = a_a \rho^{i\varphi}$ as the solution of Maxwell's equations. The transition to geometrical optics follows from the assumption that $\left|\dfrac{\partial\varphi}{\partial x^a}\right| = \varphi_{/a}$ is very great. Maxwell's equations are then reduced to:

$$g^{a\beta}\varphi_{/a}\varphi_{/\beta} = 0$$

We call $\varphi/_0 = \nu_0$ the frequency, and then we can prove the following statements : (*a*) ν_0 is constant along the light ray in every static field and in every static co-ordinate system; (*b*) ν_0 depends on the gravitational field at the point of emission (red shift)[1].

(2) *Based on Quantum Theory.* We can just as well define $\nu_0 = \nu$ in a natural way as the frequency. Let us define the inertial mass μ by:

$$\mu^2\left(g_{a\beta}\,\frac{\mathrm{d}x^a}{\mathrm{d}t}\,\frac{\mathrm{d}x^\beta}{\mathrm{d}t}\right) = m^2 = \text{constant}$$

$\mu\xi/_0{}^a$ is a vector with $\xi/_0{}^0 = 1$. Einstein's fundamental assumption for light rays and de Broglie's for the waves of matter is:

$$\mu\xi/_0{}^a = h\nu\xi/_0{}^a$$

where $\xi/_0{}^a$ is the velocity of light or that of the wave packet. It is natural to identify ν with the frequency, but to do so and also in order that (*a*) and (*b*) should be valid for ν, we must assume that h is a scalar density, and a quasi-Cartesian co-ordinate system has been chosen[2].

Measurements of Heats of Adsorption of Organic Vapours on Adsorbents of High Surface Area using a Continuous Flow Calorimeter

An apparatus for the measurement of heats of preferential sorption from liquid carriers by means of a continuous-flow system has already been described[1]. It was felt that this technique might also be applied to adsorption processes taking place from the vapour phase. A later model of the apparatus originally described was therefore modified to investigate the adsorption of organic vapours on to surfaces of high specific area.

Fig. 1 shows the calorimeter, in which the temperature-sensing elements comprise four thermistors, two reference thermistors situated in the body of the apparatus to ensure that they remain at constant temperature and a further pair of thermistors embedded in the surface of the adsorbent under investigation. Nitrogen is passed through the calorimeter at a rate of 50 ml./min., and a sample of gas, saturated with the vapour being used, is injected into the nitrogen stream by means of a long hypodermic needle. When the vapour reaches the adsorbent it is adsorbed and the rise in temperature measured and recorded by the thermistors, which are connected in a Wheatstone bridge network which feeds a 10-mV. potentiometric recorder via a 'Vibron' electrometer.

In order to obtain values for the heats of adsorption of the materials used the calorimeter was calibrated

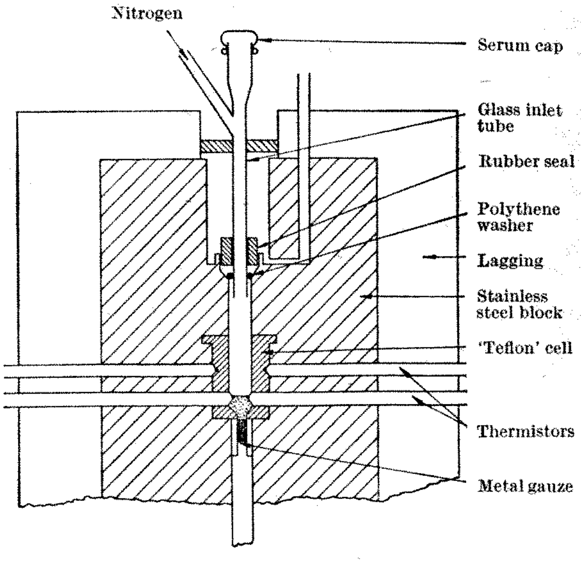

Fig. 1. Calorimeter for the determination of heats of adsorption from gases

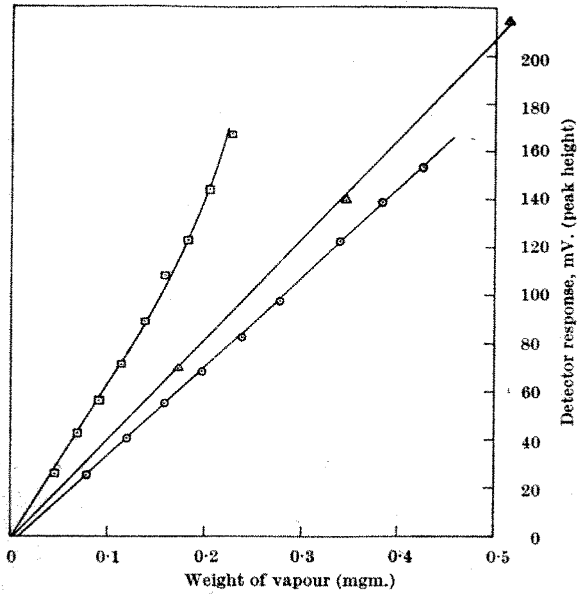

Fig. 2. Adsorption on silica gel. ○, *n*-heptane; △, benzene; ◻, isopropyl alcohol

by means of a coil of nichrome wire which was introduced into the surface of the adsorbent and through which known electric currents were passed. It was shown by this means that the response of the apparatus, in terms of peak height in mV. recorded, was linear with the quantity of heat dissipated in the adsorbent. An approximate value for the quantity of the materials contained in the samples of gas saturated with the vapour was obtained from the equation :

$$pV = \frac{w}{M} RT$$

where p is the vapour pressure of the sample at temperature $T°$ absolute, V the volume of gas in which the vapour is contained, w the weight of the vapour, M its molecular weight and R the gas constant. Vapour pressure values were obtained from the literature and from the weights thus obtained molar heats of adsorption were calculated.

Table 1. ADSORPTION ON SILICA GEL

Material	Temp. (°C.)	Response per 1·0 ml. vapour (mV.)	Response per μgm. (mV.)	Response per μmole (mV.)	Heat of adsorption (kcal./mole)
n-Heptane	22·0	71	0·33	33	12·1
Benzene	22·0	140	0·41	32	11·9
Toluene	22·0	45·5	0·38	35	12·9
Methanol	25·0	162	0·86	28	10·3
Ethanol	24·5	96	0·69	32	11·8
Isopropanol	21·0	71	0·63	38	14·0
1,2-Dichloroethane	23·5	102	0·29	28	10·3
1,2-Dibromoethane	22·0	22·5	0·18	35	12·9
Pyridine	22·0	37·5	0·63	50	18·4

Table 1 shows results obtained when 1·0-ml. samples of gas saturated with different organic vapours are adsorbed on to silica gel. It must be noted that the weights of the organic materials used are different in each case since a wide range of vapour pressures is covered; the surface coverages therefore differ widely. It was shown that for *n*-heptane the quantity of silica gel contained in the cell which takes part in the initial adsorption of the vapour was about 50 mgm., which corresponds to a surface coverage of approximately 0·1 μmol./m.², assuming that the sample is quantitatively adsorbed. The value of 12·1 kcal./mol. obtained for the adsorption of *n*-heptane is similar to values quoted in the literature for similar adsorbents[2].

When irreversible adsorption occurred it was found that on successive adsorptions of 1·0-ml. samples of vapour on to the same sample of silica gel the heat evolved decreased steadily. For example, the values obtained for benzene as shown in Table 1 are the means of a number of successive determinations. The initial response obtained for benzene adsorbed on to a fresh sample of gel was always higher than this, 155 mV. for 1·0 ml. sample of gas saturated with vapour at 22° C. This corresponds to an initial heat of adsorption of 12·9 kcal./mol., a value which might be expected in relation to 12·1 kcal./mol. for *n*-heptane[2]. For benzene and *n*-heptane the relationship between the quantity of vapour adsorbed, again assuming complete adsorption, and the response obtained, that is, the heat evolved, was found to be linear in the range of surface coverage investigated, up to about 0·2 μmol./m.² (Fig. 2).

Table 2. ADSORPTION ON ACTIVATED CARBON

Material	Temp. (°C.)	Response per 1·0 ml. vapour (mV.)	Response per μgm. (mV.)	Response per μmole (mV.)	Heat of adsorption (kcal./mole)
n-Heptane	20·0	117	0·59	59	21·7
Benzene	22·5	235	0·65	51	18·8
Toluene	20·0	86	0·78	72	26·5
1,2-Dichloroethane	19·0	167	0·50	50	18·4
1,2-Dibromoethane	20·0	30	0·27	51	18·8
Pyridine	20·0	55	0·85	67	24·6

Activated carbon has also been used as the adsorbent and results obtained are shown in Table 2. Heats of adsorption on this material can be seen to be very much higher than in the case of silica gel. It has been reported[3] that heats of adsorption of this magnitude are obtained on adsorbents of this type when the surface coverage is low. This probably explains the very high value obtained for toluene in relation to that obtained for benzene, since the amount of toluene used was much less than that of benzene.

An Experimental Apparatus for Contact Microradiography at 200–500 V.

OWING to the strong absorption of soft radiation, a sealed-off X-ray tube[1] is not suitable for contact microradiography. We have, therefore, used an X-ray tube without window.

The principle of the cathode/anode part is given in Fig. 1. A departure from conventional construction is made in order to comply with the requirements of small focus, high anode current and low accelerating

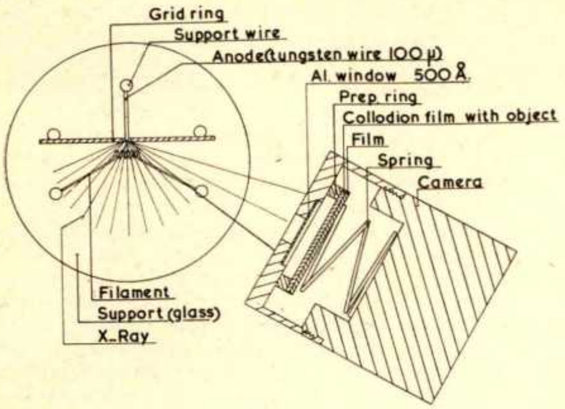

Fig. 1

voltage. The three components anode, grid, ring and filament are very simple to mount on a sintered glass bridge.

The cathode provides for the emission of the electrons which impinge mainly on the tip of the wire anode. The ring ensures that no electrons are deflected beyond the edge of the anode by either electrostatic or mechanical means; this is in order to prevent X-rays from being produced there also. A voltage of from +10 to +20 V. at the ring is sufficient. The diameter of the hole is 0·7 mm. Overload of the anode need not be feared, since the load is of the order of 0·2 W. continuous.

As can be seen from the diagram, the camera itself can be mounted in a position as favourable as possible with respect to the anode. The aperture of the camera has to be made light-proof by means of an aluminium membrane[3]. In our tests we used a shadow-casting apparatus. In principle, any evacuated vessel is suitable, provided it has three connecting wires: two for the cathode and one for the ring.

The electrical part consists of a filament-current transformer for the cathode, and a source of direct voltage for the ring and the anode, of 10 and 200–500 V. respectively.

The advantage of the microradiographic method is that the soft radiation can provide information which may be correlated with the mass and chemical composition of the microscopic objects. The resolving power is about the same as that of light microscopes[2–4].

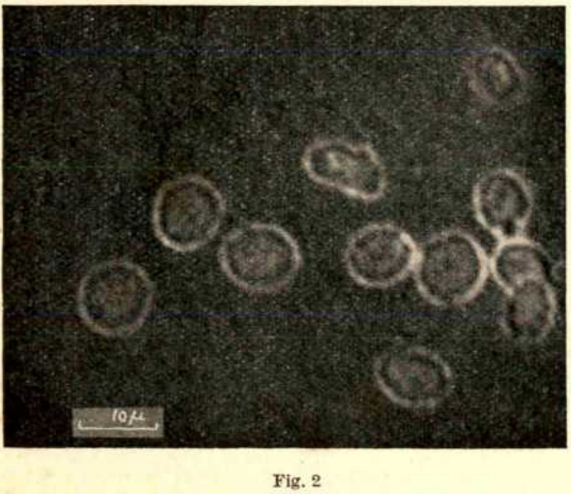

Fig. 2

The preparation techniques employed are those of Greulich and Engström[2]. An example of the results obtained is given in Fig. 2, which shows a contact microradiograph of erythrocytes (350 V., 0·4 m.amp., exposure time 5 min. Eastman Kodak Spectroscopic Emulsion 649–0. Distance from X-ray source and emulsion, 6 mm.).

Irradiated Lithium Fluoride as an Optical Filter in the Far Ultra-Violet

PHOTOCHEMICAL studies of aqueous solutions of organic compounds are being carried out at this Laboratory using the 1849 Å. radiation emitted by a low-pressure mercury resonance lamp. It has been found necessary to eliminate the contribution of the intense 2537 Å. line emitted by such a source. This has been done by using a filter of irradiated lithium fluoride. The idea of using this material as the filter for mercury resonance radiation was suggested to us by P. Yuster of this Laboratory. The absorption spectrum of X-irradiated lithium fluoride shows a sharp band with a maximum at 2420 Å. due to the formation of *F*-centres in the crystal[1]. Even with complete absorption at this wave-length, the transmission of the irradiated crystal remains high at 1849 Å.

Polished disks of lithium fluoride, 40 mm. in diameter and 0·8 mm. in depth, were prepared from a crystal obtained from the Harshaw Chemical Co. Irradiations were carried out with a high-intensity cobalt-60 source of γ-radiation at several dose-rates. Spectral measurements were made with an accurately calibrated Cary model 14 recording spectrophotometer.

The increase in absorption at 1849 Å. and 2537 Å. with radiation dose is shown in Fig. 1, where dose is plotted against T/T_0, the ratio of transmissions after and before irradiation. The absorption spectra of the irradiated filters between 1849 Å. and 4700 Å. are similar to those recently reported by Kato *et al.*[2]. The decrease in transmission at 1849 Å. is due to the tail of the *F*-band.

After irradiation the crystals were exposed to a high-intensity mercury resonance lamp for various lengths of time, and it was found that the rate of bleaching of the *F*-centres was low enough to allow the crystals to be used as filters. The experimental results for a typical filter are shown in Table 1.

Table 1. TRANSMISSION OF LITHIUM FLUORIDE FILTER AT 1849 Å. AND 2537 Å. AFTER IRRADIATION AND BLEACHING

Treatment		Percentage of transmission at 1849 Å.	Percentage of transmission at 2537 Å.
Cobalt-60 γ-irradiation	Bleaching* (2537 Å.)		
None	None	70	85

CRYSTALLOGRAPHY

X-ray Diffraction Spikes of Diamond

THE anomalous X-ray reflexions of 'diffraction spikes' from type I diamonds have been studied by a number of authors[1-5] since they were discovered by Raman and Nilakantan[1].

Frank[4] explained the diffraction spikes, on the basis of the detailed data about the intensity of spikes by Hoerni and Wooster[3], as being due to segregated (100) planes of impurity atoms. He considered one central plane of atoms with spacing $(1+\delta)$ units of length to its neighbour planes, all interplanar spacings thereafter being 1. Thus calculating one-dimensionally, the amplitude of the spikes belonging to each reciprocal point h will be ultimately proportional to $\sin h\theta$ ($\theta = 2\pi\delta$). Frank evaluated $2\theta = 180° + 2\varphi + n \times 360°$, $2\varphi = 52° 17'$ or $67° 9'$ (n; integer) from $\pm\sqrt{(5/100)} = \sin 30/\sin\theta$, using the observed value of Hoerni and Wooster in $h = 1,3$. Also, he calculated with this θ the intensity in h = 1–5 with the results as shown in Table 1. The amplitude in the case of $h = 0$ was given separately by the equation:

$$A = B - 1 - 2\delta \qquad (1)$$

where B is the scattering weight of the impurity planes when the weight of carbon planes is assumed as 1. Considering that this observed value becomes almost zero, as well as the valency condition and size effect by using the result of the above calculation, the impurity atoms were considered to be silicon.

Table 1. INTENSITY OF DIFFRACTION SPIKES OF DIAMOND

h	Hoerni and Wooster observed value	Frank calculated value		Yoneda calculated value
		$2\varphi = 52° 17'$	$2\varphi = 67° 9'$	
0	< 5	0	0	0
1	100	100	100	58
2	75	77	122	38
3	5	5	5	7
4	30	116	70	68
5	absent	53	138	17
6	—	19	20	24

Caticha-Ellis and Cochran[5], who evaluated the impurity concentration, by their detailed calculation and experiment have criticized Frank's calculation as giving a concentration of silicon more than 80 times larger than that actually present.

I have used Frank's method[4] of calculation in its original form. It is, however, not effective, since the value 5 is too small in intensity and large in relative error to determine θ only from 100/5 without recourse to other available data. Accordingly, here θ and K have been determined by using all measured values and the method of least squares, putting $K \sin^2 h\theta = L_h$ (h = 1–5). (L_h is the intensity of spikes, K is a constant.) As the result, the most probable value obtained was $2\theta = 2\varphi + n \times 360°$, $2\varphi = \pm(132° \pm 3°)$, $K = 69 \pm 19$, which is quite different from Frank's calculation in spite of the same data being used. The result of evaluating the intensity of spikes by using this value as Frank did is shown in Table 1. This result seems to be a little nearer than Frank's to the observed value as a whole. The most probable value of θ, however, is more reliable than these calculated values of intensity. Frank has calculated the Si—C bond-length as 1·95 Å. or 1·935 Å., but the calculation of the bond-length corresponding to this by using my most probable value gives 1·45 Å. or 1·64 Å.

Kaiser and Bond[6] proved that many type I diamonds contain about 0·2 per cent of nitrogen as impurity. They also confirmed that this nitrogen is characteristic of type I diamonds.

Smith *et al.*[7] have found that there is a C—N bond in about half the diamond samples by electron-spin resonance experiments. According to them, the result of electron-spin resonance can be explained by assuming the C—N bond-length of one of the four bonds as having increased by several per cent, since the nitrogen donor electron has the tendency to take an antibonding orbit due to the Jahn–Teller effect. I believe, therefore, that 1·64 Å. should be adopted, which is 6·5 per cent larger than the 1·54 Å. for the C—C bond-length and nearly corresponds with the results obtained by Smith *et al.*

Also, assuming the impurity to be nitrogen, the spike amplitude of $h = 0$ is as weak as 0·2 from equation (1), which approaches Hoerni and Wooster's observed value[3], even if it is not zero as is calculated by Frank[4].

Evaluating the concentration of nitrogen by δ from my calculation and using the result of experiment and the equation of Caticha-Ellis and Cochran[5], about 0·8 per cent is obtained. Though wide differences in the nitrogen content of various samples have been pointed out by many authors and the nitrogen content of the samples used by Caticha-Ellis is not known, this result seems to be too large compared with the result of analysis by Kaiser and Bond[6].

I wish to thank Prof. T. Futagami for valuable discussions.

THE quantity 2φ defined by Yoneda for his own calculations differs from my quantity 2φ, the definition of which he quotes earlier, by 180°. Consequently his result 132° ± 3° becomes, in my notation, 48° ± 3°, which is not very different from my 52°. Whether it is superior is very debatable. Yoneda's value increases the discrepancy from the observed spike intensities (relative to that at first order) in the second, third, and fourth orders, without gaining any satisfactory agreement at fifth order, for which he still obtains a stronger spike than at third order, instead of an absent one. I supposed another factor to be present, giving a general falling off of intensity at higher order. Yoneda's calculation does not dispose of the evidence for such a factor, but if such a factor were present, his least squares analysis is less appropriate than my method of calculation, the essential point of which is to give great weight to the location of a minimum (a zero, according to the theory) near the third order. The most remarkable result is the smallness of the change which his method of calculation brings about.

The bond-lengths 1·45 Å. or 1·64 Å. which Yoneda calculates are members of a series of bond-lengths (between carbon atoms and an assumed monolayer of impurity atoms) which would all give the same diffraction spikes except at zero order, namely :

1·399, 1·453, 1·640, 1·719, 1·955, 2·046 . . . . . .

for Yoneda's value ($2\varphi = 48°$) or

1·395, 1·457, 1·633, 1·723, 1·950, 2·053 . . . . . .

for my value ($2\varphi = 52°$)

while my less preferred value ($2\varphi = 67°$) would give bond-lengths about another 0·012 Å. alternately smaller and greater than the latter list. The associated numbers for the impurity to give minimal spike intensity at zero order are in all three cases:

2, 4, 8, 10, 14, 16 . . .

It is clear on this basis that if the impurity were to be identified as nitrogen ($Z = 7$), the third member of this series should be selected, and, as Yoneda remarks, this gives a credible bond-length, namely, 1·640 Å. according to Yoneda, or 1·633 Å. or 1·620 Å. (with preference for the former) according to me.

The basis for Yoneda's revision of Caticha-Ellis and Cochran's estimate of atomic concentration of impurity from 8×10^{-4} to 8×10^{-3} is not apparent: no acceptable change in δ should alter the result by so much. On the contrary, Caticha-Ellis and Cochran's estimate must be essentially independent of the nature of the defect, within its acceptable range, so that Kaiser and Bond's nitrogen contents are adequate to produce the diffraction spikes.

While this gives a credible interpretation of the 'spike-producing' defects, it must be borne in mind that the multiplicity of alternative magnitudes of displacement giving similar diffraction results makes the diffraction evidence alone incapable of discriminating against other possible models (such as one with nitrogen atoms in two layers). The matter can scarcely be settled before we have X-ray diffraction, infra-red absorption, and spin-resonance measurements all on the same diamond.

BIOPHYSICS

Proposed Use of Magnetic Fields in Electron Microscopic Radioautography

THE use of strong magnetic fields has been proposed as a possible way of increasing resolution in radioautography[1]. It was reasoned that a sufficiently strong magnetic field would bend the path of emitted β-particles into a circle of arbitrarily small radius, thereby restricting the resulting radioautographic grains to a small zone around the source. In recent reports[2,3], Harford and Hamlin, using the same argument, attempted to improve the resolution of electron microscopic radioautographs by placing the specimens in a 10-kilogauss magnetic field during exposure. They could not demonstrate such an improvement; but they attributed a considerable increase in the number of exposed grains to the effect of the field on the β-particles from tritium.

A simple calculation shows, however, that magnetic fields at present available can have little influence on the path in emulsion of low-energy β-particles. Tritium emits electrons of approximately 18-keV. maximum energy and 5·5-keV. average energy. Let us take the case of a 10-keV. electron (in the high-energy side of the spectrum, but with still a fairly high probability of occurrence). For such an electron moving perpendicularly to the lines of force of a uniform magnetic field the product $HR = 3{\cdot}386 \times 10^{2}$ gauss cm. (ref. 4) (where H = magnetic field intensity and R = radius of curvature). For a commonly available field of 10^{4} gauss $R \simeq 3{\cdot}4 \times 10^{-2}$ cm. = 340μ. The maximum range of a 10-keV. electron in material of density 1 is calculated to be of the order of 2·5μ (ref. 5). In emulsion it is probably about one half this value. On such a short path a curvature of radius 340μ would have no detectable effect. As the electron slows down, the radius of curvature will decrease, but, even for a 1-keV. electron with a calculated range in water of 0·053μ, the radius of curvature would still be about 100μ.

We may ask what fields would be needed to have a useful influence. A resolution of the order of 0·2–0·3μ can be theoretically expected (unpublished results), and experimentally demonstrated[6], when a monolayer of a fine-grained emulsion is used in electron microscopic radioautography[7]. We can ask, therefore, that the field be of sufficient strength to give a 10-keV. electron a curvature of 0·1μ radius. Taking $HR \simeq 3{\cdot}4 \times 10^{2}$ gauss. cm., we get, under these conditions, $H = 3{\cdot}4 \times 10^{7}$ gauss. This is approximately one hundred times stronger than any permanent field yet achieved. Since the change in electron velocity in going through matter is small we have used in these calculations the velocity *in vacuo*.

It might be added that, even with stronger magnetic fields, an increase in grain counts could not easily be explained on the basis of an altered path of the electrons. Assuming the field to be perpendicular to the horizontal plane of the section the vertical component of velocity of emitted electrons would be unaffected, while the horizontal component would be changed only in direction but not in magnitude. The total length of the path in emulsion would, therefore, remain the same, since the time spent by the electron in the emulsion depends only on the vertical component.

It does not seem that magnetic fields can be used effectively to modify the characteristics of radioautographs with tritium. A similar situation prevails in the cases of carbon-14 and sulphur-35. Only in the case of phosphorus-32 do the radii of curvature become of the same order as the ranges. But since in that case the entire path of the particle appears as a track there seems to be no great advantage in modifying its shape. It is therefore likely that the increase in grain counts observed by Harford and Hamlin is due to causes other than the effect of the magnetic field on the path of the β-particles.

GEOLOGY

Uranium in British Surface and Underground Waters

RECENT interest in the alpha-activity of potable water[1] has prompted the following summary of the results of analyses for uranium in surface and underground waters, obtained during an assessment of uranium mineral resources in Great Britain (Table 1). Most of the samples were collected by the Atomic Energy Division of the Geological Survey of Great Britain and the uranium content determined by the National Chemical Laboratory, the Atomic Energy Research Establishment, Harwell, and the Atomic Energy Division. The analytical techniques were : the colorimetric method developed by Smith and Chandler[2], with later modifications by Hunt[3] ; the simple fluorimetric method of Milner and Barnett[4] ; and the fluorimetric method normally used in the laboratory.

Average background values based on 678 samples taken from surface waters in south-west England, north England and west Scotland are 1γ/l. or less (1γ/l. equals 10^{-6} gm./litre). Higher values in streams emerging at the limestone/shale contact in the Castleton area of Derbyshire can be related to leaching of uraniferous phosphate in the limestones[5] and to high bicarbonate ion concentration, the latter being well known to influence the solution of uranium in natural waters. Conversely, the low bicarbonate ion concentration probably accounts for the occurrence of small quantities of uranium in the Dalradian rocks of Knapdale[6] not being reflected in the analyses of water samples from that area. The value of 50γ/l. in water from the Goon Vean china clay leat is due chiefly to uranium from the artificially introduced particulate matter (mica and clay minerals) suspended in the water[2]. Filtered water from the same source contains less than 1γ/l.

As is to be expected, some underground waters contain higher concentrations of uranium than surface waters. The highest recorded uranium concentration (30–50γ/l.) is in water from a shaft at the disused South Terras uranium mine. Uranium concentration in spa waters is consistent with their origin, composition, and extended contact with crustal rocks.

Lack of consistency between the results of analyses undertaken at different times on Cornish mine waters is considered to be due to the effect of differing weather conditions immediately preceding the collection of samples, since checks have shown that comparable results are obtained with the different analytical techniques used. Measurements of the uranium content of waters in Great Britain and abroad have indicated that the amount of dissolved uranium reaches a maximum when rain follows a dry spell during which normal weathering processes in the zone of oxidation have made available abnormal quantities of uranium in a readily soluble form. The range of values recorded over a period of several weeks at St. Anne's Well, Buxton (from four samples), may also be attributable to varying ground-water circulation.

Table 1. URANIUM CONCENTRATIONS IN SOME SURFACE AND UNDERGROUND WATERS

Continuation of the Great Glen Fault Beyond the Moray Firth

During 1944–45 I was stationed in Fair Isle, Shetland, during which time I was able to make a number of general observations on the geology of the island which tend to support Dr. Flinn's hypothesis[1] that the Great Glen Fault continues northwards, past the west coast of Fair Isle, to Shetland, where it is called the Walls Boundary Fault. Because of the inaccessibility of the Isle and its important position relative to the suggested course of the fault, it is worth while recording the observations; but it must be emphasized that they are recollections, supported by only a few photographs, specimens and notebook data.

Fair Isle is composed mainly of a barren series of shales, sandstones and conglomerate of Old Red Sandstone type, which the Geological Survey doubtfully identify as Lower Old Red Sandstone[2]. A detailed search for fish-beds was made but without success. The beds dip approximately to the south-east[3] with dips ranging from about 60° on the east side of the island (Fig. 1) to very nearly vertical on the west. On the east and north sides the rocks are unaltered, but towards the south-west corner of the island the shales and sandstones appear to pass into phyllites and low-grade schists containing quartz lenticles. Several of the pebble beaches in this part of the island were made up, almost entirely, of a dark, fine-grained, but porphyritic rock containing phenocrysts of plagioclase, indicating that igneous rocks were probably *in situ* just off the coast, if not in the inaccessible cliffs of Malcolm's Head at the south-west of Fair Isle. Farther north on the west coast, one or more dolerite dykes cut the cliff in an east–west direction.

When compared with Orkney, to the south, and Shetland, to the north, the most surprising feature is the attitude of the rocks, for in Orkney and Shetland the Old Red Sandstone has low dips of the order of 40° or less in the limbs of the gently rolling anticlines and synclines[4]. The fact that the dips become increasingly steep and approach the vertical towards the west coast of Fair Isle would accord with the hypothesis that a large disturbance lies to the west.

A further point is that erosion on the east side of the island reflects the lithology and structure of the rocks, soft bands being removed and more resistant beds standing up as headlands, the whole relief being aligned along the north-east–south-west strike. On the west side, however, erosion has been along joints and minor faults, and erosion features are parallel to the direction of dip. This tends to mask the fact that the general trend of the west coast does not coincide with the strike of the rocks but is about parallel to the trend of the Great Glen Fault extension as suggested by Dr. Flinn.

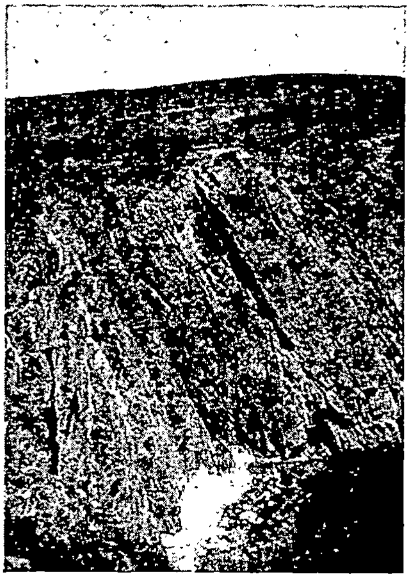

Fig. 1. Old Red Sandstone dipping to the south-east at a high angle on the east coast of Fair Isle, Shetland

Lastly, there is no large-scale shattering of the rocks in Fair Isle. This is also to be expected if the Great Glen Fault occupies the position suggested by Dr. Flinn, for in the Seli Voe area of Shetland there is shattering for distances of more than a mile from the fault, while Fair Isle lies about four miles east of the supposed position of the fault. The fault zone and the zone of shattering have been removed, as they are being rapidly removed at the present day at Seli Voe, Aith Voe and Brae.

Thus, the increase of the dip towards the west coast of Fair Isle, the trend of the west coast-line and the absence of large-scale shattering are three pieces of geological evidence which accord with Dr. Flinn's hypothesis.

Lung-books in the Devonian Palæocharinidae (Arachnida)

The typical breathing organs of most of the larger recent Arachnids are lung-books. These are thought to have arisen from the segmentally arranged gills of an aquatic ancestor. The presence of lung-books in fossil Arachnids is thus of importance in any phylogenetic studies on the group. Petrunkevitch[1-3] has reviewed the known Palæozoic and Mesozoic fossils and shown the presence of paired structures on the proximal opisthosomal sternites of a few forms, particularly among the Carboniferous Anthracomartida

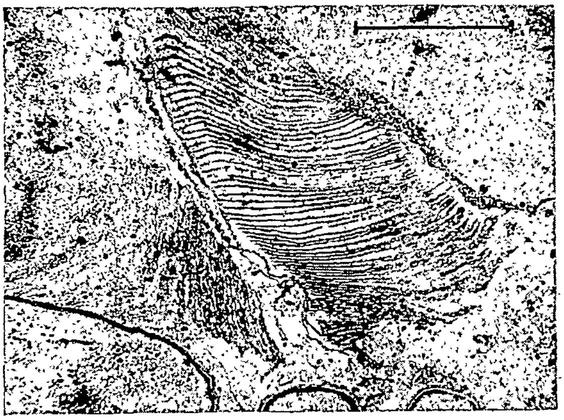

Fig. 1. Detailed structure of a single lung-book (scale 0·5 mm.)

and Trigonotarbida. These he has reasonably interpreted as representing the stigmata of lung-books. However, there seem to be no records of definite lung-book structure in any fossil.

The fine structure of lung-books may only be expected in fossils from deposits formed under exceptionally favourable conditions of preservation. Such a deposit is the Rhynie Chert (Scottish Middle Old Red Sandstone). Remarkably well preserved Arachnids attributed to the family Palæocharinidae, recently placed in the order Trigonotarbida by Petrunkevitch[1,3], have been described by Hirst[4], who was able to give full descriptions of external features but made no mention of lung-books or their stigmata.

During a re-investigation of the plants of the chert carried out by one of us (A. G. L.), numbers of these Arachnids have been encountered together with the plants among which they lie. Thin serial sections have been made by means of the palæobotanical peel method, after etching with hydrofluoric acid. Some of these sections show clear evidence of lung-book structure (Figs. 1 and 2), resembling very closely the comparable organs of modern spiders. Longitudinal sections show the presence of two pairs apparently opening by small stigmata on the sternites of the first and second opisthosomal segments (Fig. 2). With this and further sectioned material it should be possible to make detailed reconstructions and identifications.

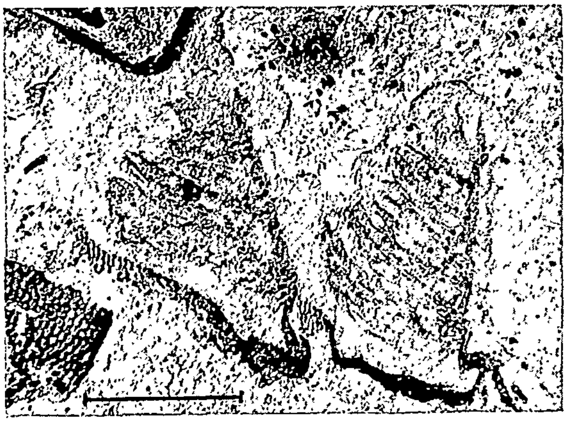

Fig. 2. Longitudinal section of successive lung-books and stigmata (scale, 0·1 mm.)

The Palæocharinidae have been recorded only from the Rhynie Chert and are of particular interest since they are among the earliest terrestrial Arachnida known with any certainty, and because they show a number of important similarities to the Araneida. To the latter can now be added the presence of two pairs of lung-books.

CHEMISTRY

Complex Compounds of Zero-valent Platinum

Recently, Chopoorian, Lewis and Nyholm[1] have indicated that the triphenylphosphine complexes of platinum(0) described by Malatesta and Cariello[2] are hydrides $[PtH_2(PPh_3)_n]$ (n = 2, 3 or 4), and question the existence of any platinum(0) complexes. Some years ago we prepared a compound $[Pt(Ph_2PCH_2CH_2PPh_2)_2]$. We have now examined it very carefully and conclude that it is indeed a complex of zero-valent platinum.

It is precipitated during the vigorous reaction which ensues on the addition of concentrated aqueous sodium borohydride solution to a hot ethanol/water (8 per cent) solution of $[Pt(Ph_2PCH_2CH_2PPh_2)_2]Cl_2$, and crystallizes from benzene/methanol in golden yellow plates, m.p. 252–255°, in an evacuated tube. It is a non-electrolyte of very low dipole moment, and oxidized only very slowly by air. The infra-red and nuclear magnetic resonance spectra show no sign of Pt—H bonds or hydridic hydrogen. On oxidation in benzene solution with an excess of iodine (3 mol.) and extraction with water no acidity is developed, as it would were the complex a hydrido-complex.

With Dr. H. R. Watson's assistance we have also obtained a purely aliphatic analogue $[Pt(Me_2PCH_2CH_2PMe_2)_2]$ by the reduction of the corresponding dipositive cation with sodium naphthalenide (NaC_8H_{10}) in tetrahydrofuran[3]. It is a colourless substance highly sensitive to air.

It is presumed that both these d^{10} complexes will have a tetrahedral configuration, corresponding to that of nickel carbonyl.

We thank Dr. N. Sheppard for examination of the nuclear magnetic resonance spectra.

Reduction of Zirconium and Hafnium Oxides

MANY attempts have been made to reduce zirconium dioxide with hydrogen. At temperatures up to 1,500° C. no positive results have been reported[1-3]. Newbury and Pring[4] reported that at 2,500° C. and a hydrogen pressure of 150 atm. no reduction took place. Mott[5] stated that in an electric arc at 6,000° C. and at a hydrogen pressure of 22 atm. reduction was difficult but that sometimes a small amount of "yellow Zr_2O_3" was produced. In the reduction of ZrO_2 with lithium or calcium hydride it has been suggested that the active reducing agent is atomic hydrogen. Simonenko[6], using a d.c. arc between tungsten electrodes, in a hydrogen atmosphere, claimed to have produced metallic zirconium from ZrO_2 placed in the cathode cavity. He believed that the ions of molecular and atomic hydrogen were responsible for the reduction, their effectiveness being increased by the negative potential.

Atomic hydrogen produced by passing hydrogen at low pressure through an electromagnetic field of 29 Mc./s. or lower (Blackwood and McTaggart[7]) will reduce many oxides but not ZrO_2. However, it was found that if the frequency of the exciting field was increased to 2,500 Mc./s. a surface layer was formed which was black or golden. This material had a specific resistivity of the order of 1 ohm-cm. although measurements were difficult for obvious reasons. It has not been possible so far to determine the Zr:O ratio, but X-ray diffraction indicated that no change of phase occurred, the pattern remaining that of the dioxide. During treatments the temperature of the samples varied from about 200° C. to 1,200° C. depending on the power supplied (50–400 watts input to the magnetron).

Hafnium oxide, when treated in the same way, also became black and conducting. Thorium oxide remained unchanged. It would appear that a reduction took place in the case of ZrO_2 and HfO_2 similar to that occurring when TiO_2 is reduced in hydrogen at red heat. In the 2,500 Mc./s. field the energy normally possessed by hydrogen atoms is presumably increased by further excitation and ionization, as visualized by Simonenko, to a value which permits reduction of the above oxides to proceed.

Irradiation Decomposition of Carbon Dioxide

DURING investigation of the reaction between carbon dioxide and graphite induced by radiation, we have examined the decomposition by irradiation of carbon dioxide in the absence of graphite. These irradiations have been carried out in transparent silica vessels into which the required amounts of carbon dioxide are condensed before sealing off. Particular care was taken to exclude organic contaminants by cleaning the silica vessels, wool and rods in hot chromic acid, followed by three washings in hot distilled water and firing at 1,000° C. for 2 hr. in an atmosphere enriched with oxygen. Carbon dioxide was prepared from 'Cardice', distilling three times before use, with rejection of first and last fractions. Mercury vapour was eliminated by the use of a trap at −78° C. placed immediately before the vessels to be filled. Analysis of the gas after irradiation was carried out by a gas chromatographic method[1]. The samples received a thermal neutron dose of $2\cdot3 \times 10^{18}$ n.cm.$^{-2}$ in the core of the Harwell reactor *Bepo*. From the integrated dose of thermal neutrons as measured by cobalt wires, the energy dose received by the carbon dioxide was calculated using the calorimetric data of Anderson and Waite[2].

Four general conclusions may be drawn from the results :

(1) The decomposition by irradiation of carbon dioxide in the absence of an oxygen acceptor is extremely small. (2) An increase in the surface area of the silica as effected by the introduction of silica wool into the vessels does not increase the efficiency of carbon monoxide production (the G_{CO} value). The higher G_{CO} values obtained using vessels packed with silica rods are inexplicable at present. (3) An increase in the carbon dioxide pressure up to 9·5 atmospheres at the operating temperature of 100° C. does not cause a major change in G_{CO}. (4) There is always a deficiency of oxygen compared with the carbon monoxide formed.

Table 1. RADIATION-INDUCED DECOMPOSITION OF CARBON DIOXIDE IN EMPTY AND PACKED SILICA VESSELS

Empty vessels, surface area ~ 50 cm.² filling pressure (at 0° C.) mm. mercury	G_{CO}	Rod-packed vessels, surface area ~ 200 cm.² filling pressure (at 0° C.) mm. mercury	G_{CO}	Wool-packed vessels surface area ~ 1,200 cm.² filling pressure (at 0° C.) mm. mercury	G_{CO}
42	<0·03	66	0·21	42	<0·007
81	<0·004	142	0·04	169	<0·002
158	<0·002	287	<0·009	307	<0·001
343	<0·001	596	<0·015	671	<0·001
629	<0·001				
807	<0·002				
1,761	<0·002				
2,130	<0·001				
3,237	<0·001				
3,967	<0·001				
5,327	<0·001				

The first of these conclusions is in agreement with the earlier work of Harteck and Dondes[3], but the second and third conclusions are in direct contradiction to their work. The formation of ozone in the radiolysis of carbon dioxide as postulated by Harteck and Dondes would explain the oxygen deficiency in the present work. This would also agree with the recent work of Mahan[4] on the photochemical decomposition of carbon dioxide.

It is hoped to publish more details of this work at a later date. The support and irradiation facilities of the United Kingdom Atomic Energy Authority are gratefully acknowledged.

Mechanism of Synthesis of Adenine from Hydrogen Cyanide under Possible Primitive Earth Conditions

It has recently been shown that adenine and the purine precursors 4-aminoimidazole-5-carboxamidine and formamidine are formed spontaneously from hydrogen cyanide in water–ammonia systems under conditions assumed to have existed on the primitive Earth[1].

I wish to propose now a mechanism for the formation of adenine from hydrogen cyanide under the conditions of the above experiments which is in line with previous observations[2]. Adenine formation from hydrogen cyanide is thought to be initiated by base catalysis and to require the participation of 4-aminoimidazole-5-carboxamidine and formamidine as the key intermediates. The different steps involved in this synthesis are summarized in Fig. 1 and briefly described below. Direct experimental evidence for the last and most important step in this synthesis is also given below.

Reaction 1. In the presence of ammonium hydroxide, cyanide ion is formed which condenses with hydrogen cyanide to form iminoacetonitrile. Indirect evidence for the formation of iminoacetonitrile as the primary product of the base-catalysed hydrogen cyanide polycondensation has been obtained from kinetic studies on the formation of polymeric hydrogen cyanide[3].

Reaction 2. As soon as iminoacetonitrile is formed cyanide ion condenses with this compound to form aminomalonodinitrile. The transformation of hydrogen cyanide into a hydrogen cyanide trimer, presumed to be aminomalonodinitrile, although not completely elucidated, was claimed a long time ago by several investigators[4], and this trimer of hydrogen cyanide, of its isomer α,β-diiminopropionitrile, has also been considered as an intermediate in the formation of tetrameric hydrogen cyanide[5].

Reactions 3 *and* 4. Hydrogen cyanide as well as aminomalonodinitrile are ammonolysed into the corresponding amidines, formamidine and aminomalondiamidine. These reactions deserve no special comment, since the ammonolysis of nitriles is well known, and is in fact one of the main methods used in the preparation of amidines.

Reaction 5. Aminomalondiamidine condenses with formamidine to yield 4-aminoimidazole-5-carboxamidine. Indirect evidence for this reaction can be found in the very similar syntheses of 4-amino-5-substituted imidazoles carried out by other workers[6]. In the experiments carried out in my laboratory the appearance of 4-aminoimidazole-5-carboxamidine as well as formamidine among the reaction products was observed very early during the course of the hydrogen cyanide condensation reaction. In addition to 4-aminoimidazole-5-carboxamidine, 4-aminoimidazole-5-carboxamide was also isolated from the reaction mixture. The latter compound was observed to be formed by hydrolysis of the former, as was to be expected from the strongly basic conditions of the reaction mixture.

Reaction 6. In the final step, 4-aminoimidazole-5-carboxamidine condenses with another molar equivalent of formamidine to yield adenine. In support of this reaction, preliminary kinetic studies on the formation of formamidine and 4-aminoimidazole-5-carboxamidine have shown that these compounds make their appearance and disappearance in the reaction mixture as if they were intermediates of adenine. The cyclization of 4-aminoimidazole-5-carboxamidine with formamidine into adenine was thus considered the key step in the elucidation of the mechanism of adenine synthesis. For this reason, and because the reactants were easily available, an independent experimental demonstration of this reaction was undertaken.

This cyclization reaction was studied under different conditions of *p*H and carried out as follows: About 50 mgm. of 4-aminoimidazole-5-carboxamidine and 90 mgm. of formamidine hydrochloride were dissolved in 1 ml. of distilled water. Exactly 0·2 ml. aliquots of this solution were mixed with an equal volume of either water, 1 *M* disodium hydrogen phosphate, or 7 *N* ammonium hydroxide. The *p*H of the resulting reaction mixtures was approximately 1, 7 and 12 respectively. These three mixtures were heated in closed vessels at a temperature of 130° C. for 12 hr. At the end of the reaction time, a very small amount of residue was separated by centrifugation from each reaction product and each of the supernatants was analysed by paper chromatography and ultra-violet

OVER-ALL REACTION: 5 HCN → ADENINE

Fig. 1

spectrophotometry as described previously[1]. In all cases adenine was formed in high yield. Some unreacted 4-aminoimidazole-5-carboxamidine was observed in the acid and neutral reaction mixtures, but none in the basic reaction mixture. The experiment has been repeated recently at lower temperatures, and similar results have been obtained.

Although alternative mechanisms cannot yet be ruled out, the evidence obtained in my laboratory as well as recent evidence on the so-called 'one-step' synthesis of purines[7] supports the imidazole pathway outlined in Fig. 1 as a mechanism for the synthesis of adenine from hydrogen cyanide under possible primitive Earth conditions.

Work is being carried out at present on the isolation of the three-carbon compounds assumed to be the precursors of the 4-amino-5-substituted imidazoles isolated, and also on the synthesis of other purines from hydrogen cyanide.

A New Phase formed by High-Pressure Treatment : Face-centred Cubic Molybdenum Monocarbide

THE attempted preparation and retention of polymorphs dependent on pressure is an important area of high-pressure research. Some of these phases are found in Nature; others were unknown prior to the recent development of equipment suitable for research at high pressure and high temperature.

Although high-pressure phases are thermodynamically unstable at ambient conditions, a few have been retained by quenching to room temperature under pressure. High-pressure polymorphs found in the Earth's crust[1] include several minerals, for example, the pyroxene jadeite, $NaAlSi_2O_6$ (ref. 2); kyanite, Al_2SiO_5 (ref. 3); and diamond (ref. 4). Previously unknown phases are coesite[5], a form of SiO_2 with a higher density than quartz; borazon[6], a cubic form of boron nitride; and several compounds of the garnet type[1]. A number of high-pressure polymorphs of pure metals, which unlike the above compounds cannot be retained at ambient conditions, have been reported[7].

High-pressure experiments on the molybdenum–carbon system have revealed a new form for the monocarbide phase. The new form, designated α-MoC, has been retained to atmospheric pressure. Synthesis was achieved from both an equiatomic mixture of molybdenum and carbon and an equiatomic mixture of the compound Mo_2C and carbon at pressures and temperatures in the range of 40–70 kilobars and 1,800°–2,500° C. The X-ray diffraction pattern for α-MoC showed the first ten lines for a face-centred cubic structure. No additional lines were observed. The average lattice parameter was $a_0 = 4{\cdot}27$ Å. In addition to high-pressure experiments in which the only product was α-MoC, other experiments carried out at lower temperatures and pressures afforded evidence for all the phases reported[8] for the molybdenum–carbon system at atmospheric pressure. A summary of the lattice parameters of the various phases is given in Table 1.

Table 1. COMPOSITION AND DIMENSIONS OF PHASES IN THE MOLYBDENUM–CARBON SYSTEM

Composition	Symbol	X-ray data Structure	a_0(Å.)	c_0(Å.)	c_0/a_0	Molybdenum atoms/unit cell
Mo_2C	β	hexagonal closest packing	3·002	4·724	1·574	2
MoC	γ	hexagonal	2·898	2·809	0·969	1
MoC	γ'	hexagonal	2·932	10·97	3·742	4
MoC	η	complex hexagonal closest packing	3·00	14·58	4·86	6
MoC	α	face-centred cubic (sodium chloride)	4·27	—	—	4

Further experimental detail and a thermodynamic analysis of the effect of pressure on the equiatomic region of the molybdenum–carbon system will be published elsewhere.

Generation of Radicals in Pairs and the Kinetics of Radical Chain Reactions in Solution

FREE radicals responsible for the propagation of chain reactions are commonly formed by the photochemical or thermal decomposition of an appropriate labile substance, and are, in such cases, inevitably produced in pairs. The restricted mobilities of radicals in solution have some special influence on the fate of these radicals, in that many pairs of radicals recombine before bringing about any reaction[1]. This effect, sometimes known as the cage effect but more recently called[2] geminate recombination, has been widely discussed. A further consequence of the production of radicals in pairs has not, however, received consideration. Even if a free radical avoids recombination with its twin radical in the primary cage, the chain carrier will in general, at least in the earlier part of its life, lie closer to its twin than to another chain carrier. There is, therefore, a finite and sometimes appreciable probability of the mutual termination of geminate chains. The proportion of mutual termination of geminate chains must depend, on one hand, on factors controlling the rate of diffusion of the radicals in the medium and, on the other, the average relative distances of a radical to its twin and other radicals, and this will depend on the rate of decomposition of the initiating molecule.

The kinetic effects of recombination of geminate chains is best demonstrated by considering the extreme case where the various pairs of chains are so isolated that termination occurs exclusively by reaction between geminate chains. The rate of propagation of the reaction is then:

$$k_p\,(A)\,2n$$

where n is the number of geminate pairs of chains (expressed in terms of moles/l.), and k_p and (A) are respectively the rate coefficient for the propagation reaction and the molar concentration of the substrate:

$$n = I\tau$$

where τ is an average lifetime of a pair of geminate chains with respect to their mutual termination and I is the rate of decomposition of the initiator molecule. The rate of propagation of the reaction in the case of long chains is:

$$2\,k_p\,I(A)\tau$$

Since τ is determined only by diffusion factors, the rate of reaction is proportional to the first power of the rate of initiation. Normally in reactions in which chains terminate in bimolecular processes the rate of propagation depends on the square root of the rate of initiation[3].

In general there will be competition between the geminate chain termination and normal bimolecular termination, in which case, assuming a stationary state in the overall concentration of radicals (R):

$$\mathrm{d}(R)/\mathrm{d}t = 0 = I - 2k_t(R)^2 - 2(R)/\tau$$

where k_t is the rate coefficient for the bimolecular reaction between radicals of non-geminate chains and τ is now the mean lifetime of chains which terminate geminately. The rate of propagation of the chain reaction is:

$$k_p(R)(A)$$

The rate of propagation will, therefore, be a complicated function of the rate of initiation, but over a restricted range it may appear to depend on a power of I that lies between one-half and one.

In most systems the exponent of the rate of initiation in the rate equation is close to one-half[3], and in these cases geminate chain termination must be unimportant. However, systems are known where the exponent is significantly higher, notably the later stages of radical polymerization[4,5]. Among effects that can formally lead to first-order dependence on I are degradative transfer[6] and trapping of radicals[7]. In the former case it is difficult to visualize an appropriate reaction that is operative only at high conversion, and this, together with the observed electron-spin resonance spectra of trapped radicals[8,9] at very high conversions, has given support to the second explanation. This explanation is itself not without difficulties as the exponent begins to rise relatively early in the polymerization when the medium is far from rigid, and small radicals, particularly primary radicals, termination by which leads to an exponent less than one-half, are still mobile. Geminate chain termination can account formally for high-conversion kinetics and at the same time offers a plausible physical model in that the diffusing apart of growing geminate radicals must become severely restricted as the gel structure develops.

Integration with Ionization Detectors in Gas Chromatography

THE ionization current of the hydrogen flame ionization detector consists of a standing current and a current depending on the concentration of organic components emerging from the column. The standing current i_0 is constant when carrier gas velocity and column temperature are constant throughout the experiment. The ionization current due to organic compounds separated on the chromatographic column is a variable and will be denoted by $i(t)$.

The ionization current may, to some extent, depend on constructional parameters, but the voltage

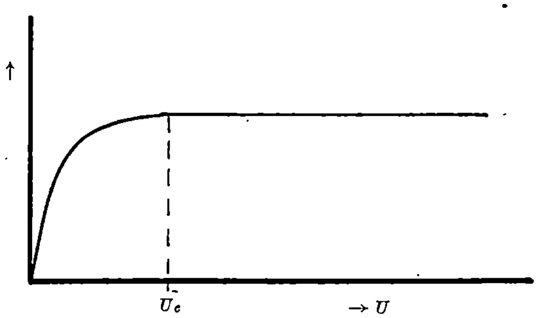

Fig. 1. Voltage-current characteristic of an ionization detector

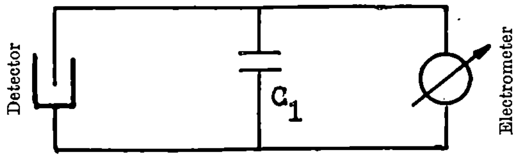

Fig. 2. Principle of the integrator

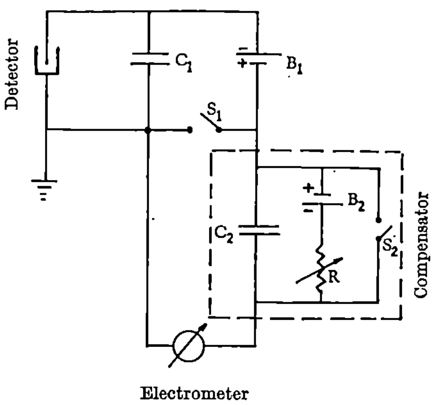

Fig. 3. Integrator with compensation. The values of the batteries, capacities and resistance given are approximate and may be varied with the operating conditions. C_1, 1,000 pF.; C_2, 100 μF.; B_1 and B_2, 90 V.; R, 100 $M\Omega$

across the electrodes has very little influence on the ionization current so long as the potential difference exceeds the value U_c in Fig. 1[1,2]. Therefore the usual constant-voltage source may be replaced by a condenser C_1 (Fig. 2).

During the experiment this condenser will be discharged and its potential drop over the time interval t_1–t_2 will be given by:

$$\Delta U = -\frac{1}{C_1}\int_{t_1}^{t_2}(i_0 + i(t))\,dt \tag{1}$$

where C_1 is the capacity of the condenser.

When the detector response is linear with concentration, $-\frac{1}{C_1}\int_{t_1}^{t_2} i(t)\,dt$ will be proportional to the amount of an organic compound leaving the chromatographic column, while $-\frac{1}{C_1}\int_{t_1}^{t_2} i_0\,dt$ will be equal to $-\frac{i_0}{C_1}\cdot(t_2 - t_1)$ if the standing current can be considered as a constant.

Leakage of detector and condenser due to imperfect insulation will cause a current which is dependent on the voltage. This leakage, however, can be made small and almost independent of the voltage if ΔU is kept small as compared with U and very good insulation is being used. The leakage is then to be considered as part of i_0.

As one is only interested in $-\frac{1}{C_1}\int_{t_1}^{t_2} i(t)\,dt$, it is essential to separate the two parts of the ionization current. This can be done by using the arrangement shown in Fig. 3, where the standing current is compensated by charging a second condenser C_2 at a rate corresponding to that at which the voltage across C_1 decreases due to the standing current.

If the signal of the electrometer is registered on a potentiometric recorder, the initial conditions can be established again by operating the switches S_1 and S_2 simultaneously through the end contact of the recorder.

The integrator may be used, in principle, with any other ionization detector having a current-voltage characteristic as shown in Fig. 1, such as the argon detector[3].

BIOCHEMISTRY

Non-Random Occurrence of Amino-Acid Replacements

One approach to elucidating the genetic code is to study its manifestations in the primary structure of proteins. Of particular interest in this respect are amino-acid replacement regions, that is, those few positions in a protein chain where 'identical' proteins isolated from different species differ in amino-acid composition, differences presumably arising from mutations in the underlying genetic apparatus[1]. For example, insulin *A* chains isolated from beef, rabbit, whale, etc., have identical amino-acid sequences except at positions 8–10, where certain differences in amino-acid composition occur[2].

Sufficient data are now available so that we can begin to characterize amino-acid replacements to some degree, and hopefully then begin to understand more about the nature of the underlying genetic coding. The first characteristic of amino-acid replacements to note is that replacements resemble burst errors; that is, given that one replacement (error) has occurred, there is a greatly increased probability that another replacement (error) will occur at an adjacent position in the protein chain. Examples of this are the 8–10 positions in the insulin chain already referred to and the 32–39 positions in the adrenocorticotropin molecule[3]. It is not possible to say whether the replacements in such a region all occurred simultaneously, but this seems a possibility. Recent experiments on chemically induced mutants in tobacco mosaic virus could help to elucidate this point[4]. A second characteristic of amino-acid replacements is shown in Table 1. Here amino-acids are listed in order of their abundance in the proteins which contain known replacements. From columns *A* and *B* it is evident that there is no striking tendency for certain amino-acids to be preferred over others, either immediately following replacement regions or actually involved in them. (The terms 'following' and 'preceding' are defined so that a given amino-acid 'precedes' amino-acid further than itself from the amino end of the molecule. A 'replacement region' is any contiguous section of a protein chain, one or more amino-acids in length, where replacements have been recorded at all positions within the region.) In contrast, there is a strong tendency for amino-acid replacement regions to be preceded by one of the four amino-acids glycine, proline, tyrosine, or cysteine. None of these four amino-acids is in the top 30 per cent in abundance, and only glycine is in the top 50 per cent in abundance. One would expect, on a

Table 1. Frequency of occurrence of amino-acids (*A*) in, (*B*) immediately following, and (*C*) immediately preceding replacement regions; data are those collected by Ycas (ref. 8). Amino-acids are listed according to order of abundance in the proteins which contain replacement regions. Only those replacements which do not occur at either terminal position of a protein chain are tabulated

Amino-acids in order of abundance	*A* Involved in replacement region	*B* Immediately following replacement region	*C* Immediately preceding replacement region	$\frac{C}{A+B}$
1. glu	11	3	1	0·07
2. ala	9	3	0	< 0·1
3. asp	5	1	1	0·2
4. ser	10	0	0	< 0·1
5. val	4	1	1	0·2
6. lys	7	1	0	< 0·2
7. gly	3	2	5	*1·0*
8. leu	5	1	0	< 0·2
9. thr	3	0	1	0·3
10. cys	0	2	2	*1·0*
11. pro	3	1	5	*1·3*
12. arg	3	1	0	< 0·3

15. his	1	1	0	< 0·5
16. ilu	3	0	0	< 0·3
17. met	0	1	0	—
18. try	0	0	0	—

random-choice basis, one of these four amino-acids to precede replacement regions in one-fifth to one-quarter of cases, but the observed frequency is four-fifths. In summary, then, amino-acid replacements are possibly burst errors and have a high probability of being preceded by one of four other amino-acids.

If one attempts to find other genetic phenomena having characteristics similar to those of amino-acid replacements, at least two are found. One is the occurrence of genetic 'hot spots' in the saturation genetic mapping studies on T_4 bacteriophage[5]. These 'hot spots' are 'points' in a T_4 genetic map where about 100 mutants are recorded. At other points in such a map only one or at most a few mutants have been found. This phenomenon recalls the likelihood of amino-acid replacements to occur at certain regions in a protein chain. (There are about ten replacements recorded in the various examples of the insulin *A* chain, all at positions 8–10 (ref. 2).)

The second genetic phenomenon in ways resembling amino-acid replacements again arises in connexion with the T_4 genetic map. Specifically, certain mutations, termed 'deletions', occupy a considerable distance on the linear genetic map[5]. There is no evidence to our knowledge that a segment of the bacteriophage genome has actually been removed in these cases. It is evident from the above discussion that some 'deletions' could also be burst errors.

In that genetic 'hot spots' and 'deletions' both have characteristics similar to those of amino-acid replacements, we should attempt a unified explanation for all three. Recently, Golomb has suggested a coding scheme which appears to account for genetic 'hot spots'[6]. On this scheme the origin of a hot spot is in the make-up of certain code words in an error-correcting, 'biorthogonal', comma-free, nucleotide sextuplate code. In that this code is comma-free (therefore, no influence of one code word on neighbouring ones), it does not explain either of the characteristics associated with amino-acid replacements (burst error aspect or high probability of following one of four amino-acids), so it is not a unified explanation of all three phenomena.

It seems difficult in the present state of our knowledge to present an explanation of these characteristics of amino-acid replacements, but attempts to do so will force us to consider many genetic coding mechanisms now given little or no serious attention. For example, the question of whether an amino-acid template includes an adjacent amino-acid residue in addition to nucleotides is raised. The possibility that an error in protein synthesis can result in a mutation is also suggested. (Stent *et al.* have been collecting evidence that replication of deoxyribonucleic acid intimately involves very specific protein synthesis[7].) Perhaps overlapping degenerate coding schemes should be investigated. These results also indicate that genetic error-correcting mechanisms may exist in the cell.

Recent attempts by me to develop a nucleotide triplet code based on the composition of the RNA viruses have given a suggestion as to how an explanation of these phenomena might be developed, and, at the same time, become reconciled in part with existing concepts of genetic coding[9,10]. When such a nucleotide triplet code was devised, it turned out that most of the triplets could be included in a comma-free system. However, a few of them could not fit such a system; notable among the exceptions were the triplets corresponding to the amino-acids proline, tyrosine, and cysteine (that is, three of the four amino-acids which precede replacement regions with a high probability). The cardinal characteristic of a comma-free code is that 'displaced words', words formed from adjacent letters in two adjacent coding words (for example, if *ABC* and *DAB* were two adjacent coding words, then *BCD* and *CDA* are displaced words), are never coding words also. This suggests that associated with the amino-acids having a high probability of preceding replacement regions are nucleotide coding words capable of producing some displaced words which themselves are coding words. For example, overlap between *CCC* and *CXX* produces the displaced word *CCC*, which is also a coding word. Now, where the displaced words, like that in the example, are the same as one of the code words producing them, we might have a mechanism whereby displaced words used mistakenly by the cell as code words initiate burst errors, resulting in replacement regions which have a high probability of being preceded by certain amino-acids. Such a mechanism as briefly sketched here would, of course, necessitate postulating also cellular mechanisms which cope with, eventually terminate, such a burst error without interrupting synthesis of a protein chain, and a feedback mechanism whereby an error in certain protein synthesis eventually produces a genetic error (mutation). (The previously cited work of Stent *et al.* makes this suggestion not too improbable.) Though these concomitant postulates appear somewhat extreme at present, it seems as though an explanation of errors producing amino-acid replacements may force us to think in now unfamiliar terms.

A Simplified Method for separating Amino-acid Mixtures from Protein Hydrolysates on One Ion-Exchange Column during Preparation

MOST of the methods used for the separation of mixtures of amino-acids are based on the work of Moore *et al.*[1–3]. Separation is achieved either on two columns, acidic amino-acids being separated on a 'Dowex' 1 anion-exchange column and the basic and neutral amino-acids on a 'Dowex' 50 cation-exchange column or by chromatography on one column on 'Dowex' 50 in the H-cycle, elution being carried out with citrate phosphate buffer solutions. Hamilton and Anderson[4] recently described a semi-automatic method for these separations containing several improvements of the original process. These methods ensure good separation of amino-acids; the eluates, however, contain either the hydrochlorides of the amino-acid and hydrochloric acid or considerable amounts of salts, which are difficult to remove. An efficient method for the separation of amino-acids should permit separation in a small volume of the elution reagent in a short time; the buffers used should be removable by a simple method. Wilcox *et al.*[5] used volatile buffers for the separation of aspartic and glutamic acid on an anion-exchange column. Vaněček *et al.*[6] and Tomášek[7], used volatile buffers successfully for the separation of peptides on 'Dowex' 50.

In connexion with our work[8,9] on the preparation of amino-acids-^{14}C from proteins containing carbon-14 obtained from a photosynthesizing organism, we elaborated a method fulfilling the requirements mentioned here.

Separation of the amino-acids from the protein hydrolysate was carried out on one 'Dowex' 50 4 × 200–400 mesh column. A column of 2·0 × 150 cm. was operated at 37° C. Amounts of amino-acids of 600 mgm. were separated on this column. The ion-exchange column was prepared according to Tomášek[7], that is, from the H-cycle transferred to the pyridine cycle and equilibrated with a 0·1 *M* pyridine formate buffer solution of *p*H 3·1. Elution was carried out by the gradient system. The buffers used are listed in Table 1. The effluent was collected by an automatic fraction collector in 5–20 min. intervals and at an effluent-rate of 7·5 ml./10 min. The fractions were identified by chromatography and autoradiography and the radioactivity of the suitably combined fractions determined. A typical result of the separation is given in Fig. 1. The amino-acids were obtained in about 1,200 ml. of the eluate, the total volume being 2·5–3 l. All the amino-acids were obtained in pure form except serine–proline and alanine–glycine, which were eluted in pairs and have to be separated chromatographically. The pure amino-acids were isolated in the free form by repeated evaporation of the aqueous solution *in vacuo*. The yield of pure amino-acids amounted to 75 per cent of the radioactivity of the hydrolysate. The method is easily reproducible.

Table 1. COMPOSITION OF THE BUFFER SOLUTION

Buffer	Pyridine (mole)	*p*H	*p*H adjusted with
1	0·1	3·1	formic acid
2	0·2	3·1	formic acid
3	0·2	4·4	acetic acid
4	1·0	5·1	acetic acid
5	2·0	5·1	acetic acid

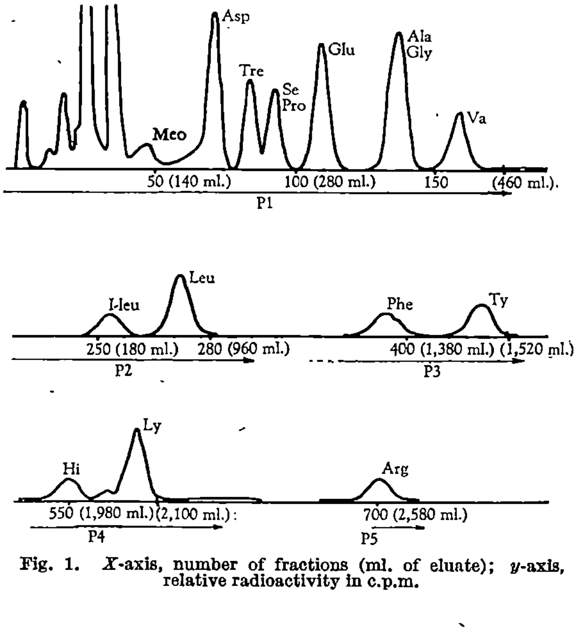

Fig. 1. *X*-axis, number of fractions (ml. of eluate); *y*-axis, relative radioactivity in c.p.m.

As this method is simple to perform and gives good separation results, it should be generally applicable to the separation of amino-acids from protein hydrolysates.

Oxidative Demethylation and Carcinogenicity of 4-N-Dimethylaminoazobenzene Derivatives

RECENT work on the hepatocarcinogenic amino-azo compounds has shown that the presence of at least one N-methyl group and the formation of a firmly bound compound between metabolites of the azo compound and rat-liver proteins are probably necessary for the strong activity[1]. The biochemical behaviour of N-methyl groups with respect to the protein-bound polar dye formation has not yet been elucidated satisfactorily, because of the structural complexity and very little amounts of polar dye obtained. We showed that the N-^{14}C-methyl group of 4-N-^{14}C-methylaminoazobenzene was incorporated almost quantitatively into the polar dye[2]. The N-methyl group of 4-N-methylaminoazobenzene (MAB), being one of the most reactive sites and rapidly demethylated to split formaldehyde, appears to be responsible for the polar dye formation in an active metabolic intermediate.

N-Demethylation, which is one of the major metabolic pathways of 4-N-dimethylaminoazobenzene

(DAB), MAB and their derivatives[3], is carried out by liver microsomes and requires both reduced triphosphopyridine nucleotide and free oxygen[4], though a clear picture of its precise mechanism is not yet established. Unpublished investigations in this laboratory have shown that the system consisting of the iron chelate of ethylenediaminetetraacetic acid (EDTA), ascorbic acid and free oxygen, which was established as a hydroxylase model by Udenfriend[5], is also suitable for the demethylase model. The present communication demonstrates that this system demethylates ring-methylated derivatives of DAB to their MAB analogues, and the rate of reaction is correlated with the π electron density[6] at N-dimethylamino nitrogen.

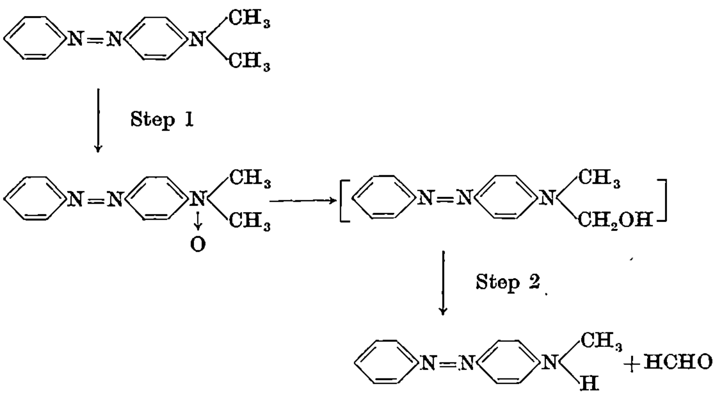

Fig. 2. Proposed mechanism of oxidative demethylation of DAB

The reaction system given in Table 1 was incubated in the metabolic shaker, designed for the purpose, for 4 hr. at 40° in an atmosphere of oxygen (Po_2 = 785 mm. mercury). The reaction was terminated by adding 50 ml. of 0·5 per cent sodium bicarbonate solution and the dyes were extracted three times with chloroform. Chloroform was evaporated under reduced pressure, and the residue dissolved in light petroleum (boiling point 60°–80°) was subjected to chromatography using an alumina column, in order to separate the demethylated products from the substrate. Demethylation, as measured by the amounts of MAB derivatives produced, depended on pH and temperature. As the reaction did not occur in the absence of oxygen, the system may function as an oxygenase.

Table 1. DEMETHYLATION OF DAB DERIVATIVES

Compound	Rate of demethylation (10^{-6} moles/4 hr.)	Carcinogenicity (ref. 3)
4′-Me-DAB	1·42 ± 0·11	1
3′-Me-DAB	1·12 ± 0·08	10 ~ 12
2′-Me-DAB	1·41 ± 0·08	2 ~ 3
DAB	1·18 ± 0·08	6
2-Me-DAB	1·36 ± 0·04	0
3-Me-DAB	0·843 ± 0·043	0

The system contained $1·5 \times 10^{-5}$ moles of azo dyes, $1·5 \times 10^{-6}$ moles ferrous ion as ferrous ammonium sulphate, $3·0 \times 10^{-5}$ moles EDTA, $3·0 \times 10^{-4}$ moles ascorbic acid, and $10 \times 1·0^{-3}$ moles phosphate buffer, pH 7·3, in a total volume of 50 ml. (30 per cent acetone solution).

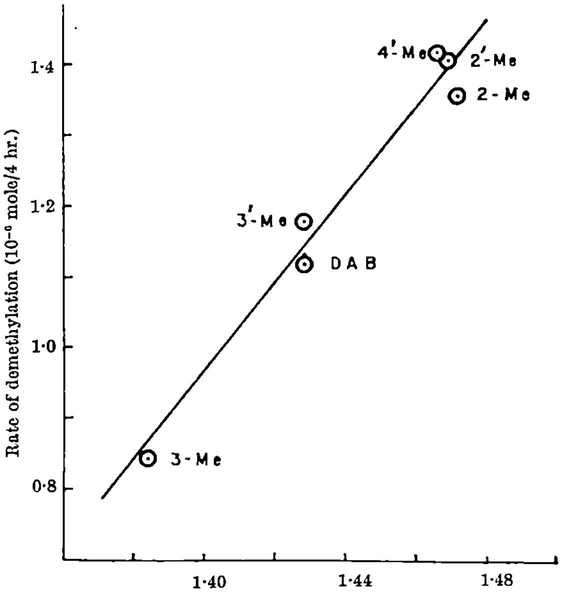

Fig. 1. Relation between the rate of demethylation and total π electron density at the dimethylamino nitrogen of DAB derivatives

The rate of demethylation was shown to be satisfactorily correlated with the π electron density at N-dimethylamino nitrogen, but not with the carcinogenicity (Fig. 1 and Table 1). However, it is interesting to see that strong carcinogens such as DAB and 3′-methyl DAB show moderate values of the reaction-rate. 4-N-Dimethylaminoazoxybenzene amino-oxide, which was assumed to be an analogue of the active intermediate, could be demethylated quickly to MAB in the presence of ferrous ion alone, and formaldehyde was detected. With the same conditions, 4-N-dimethylaminoazoxybenzene was resistant to the oxidative demethylation. The active oxygen thus appears to attack first the nitrogen atom of the dimethylamino group (electronegative centre), and forms the unstable amino-oxide, which seems to be rearranged in turn to split off formaldehyde (Fig. 2). According to the relation shown in Fig. 1, step 1 in Fig. 2 may determine the rate.

Chromatographic Fractionation of Hog Thyroglobulin

DERRIEN *et al.*[1,2] have purified thyroglobulin, the main protein component of thyroid, in a native state, and stated that their preparation was ultracentrifugally as well as electrophoretically homogeneous. However, since the iodine content of thyroglobulin varies with preparations, especially with

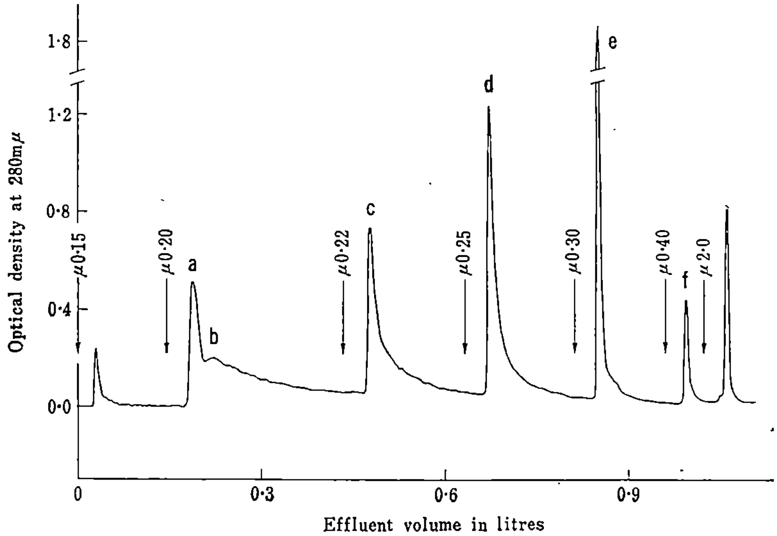

Fig. 1. Chromatographic diagram of hog thyroglobulin on *DEAE*-cellulose. Vertical arrows indicate the point of application of eluants. 1/*N* for the peaks are: *a*, 25; *b*, 27; *c*, 30,; *d*, 34; *e*, 39; *f*, 35

different physiological states of animals from which it is prepared, it is reasonable to assume that thyroglobulin is not a single protein, but consists of proteins iodinated to different degrees.

The following evidence, obtained in our laboratory (Ui, N., and Tarutani, O., work to be published), also indicates inhomogeneity of thyroglobulin. Ultracentrifugal analyses showed, in agreement with the findings of other investigators[3], the presence of a greater or lesser amount of a faster sedimenting component ($S^0_{20,w}$ = 28 S.) in the preparations. This component, tentatively named *F*-component, could not be distinguished from the main component ($S^0_{20,w}$ = 19 S.) with respect to solubility characteristics. In moving-boundary electrophoresis, although the preparation always showed a single boundary, the heterogeneity was indicated by the 'reversible boundary-spreading' technique[4], even with a preparation essentially free from the *F*-component which was occasionally obtained.

In view of these findings, we have attempted to fractionate thyroglobulin. The present communication describes the result of cellulose ion-exchange chromatography and some properties of the fractions obtained.

Thyroglobulin used in this work was prepared from hog thyroid glands according to a modified method of Derrien *et al.*[1], in which fractional salting-out between 1·55 and 1·75 *M* ammonium sulphate was performed at a low temperature instead of the 20° C. in the original method.

In Fig. 1 is shown a typical chromatographic diagram. In this experiment, about 130 mgm. of thyroglobulin dissolved in a phosphate-sodium chloride buffer (NaCl: 0·05 *M*) of *p*H 6·5 at ionic strength (μ) of 0·15 was applied to a column of *DEAE*-cellulose[5] (1·5 cm. × 30 cm.) equilibrated with the same buffer. The column was operated at a rate of approximately 20 ml./hr. The effluent was collected in 3-ml. fractions; and the optical density at 280 mμ was determined.

When stepwise elution was carried out according to the elution schedule indicated by arrows in Fig. 1, there appeared several thyroglobulin peaks (fractions $a - f$) with an increase in the concentration of sodium chloride in the buffer. Other small peaks, one which emerged on washing the column and one with elution at ionic strength 2·0, were due to minor impurities; the latter component was found by means of its ultra-violet absorption spectrum and chemical analysis to be ribonucleic acid. The total apparent recovery was 87 per cent as determined by ultra-violet absorption at 280 mμ. Re-chromatography was almost satisfactory, but fractions eluted in lower ionic strengths had a tendency to emerge on re-chromatography at a higher ionic strength than in the initial chromatography if the ratio of the load of protein to the amount of *DEAE*-cellulose was lower on re-chromatography. In a gradient elution experiment, too, heterogeneity of thyrogobulin was indicated, but the separation was poorer, as reported by Ingbar *et al.*[6].

Chemical analyses of these chromatographic fractions showed that the ratio of iodine to nitrogen increased steadily from fraction *a* to fraction *e* with an increase in the ionic strength of the eluant. The ratio expressed as μgm. iodine/mgm. nitrogen for each peak is given in the legend of Fig. 1. In an ultracentrifuge (Fig. 2), fractions *a*, *b* and *c* showed a single boundary corresponding to the main component of the original preparation, while *F*-component was found to be concentrated in fractions *d*, *e* and *f*, especially in fraction *e* (about 30 per cent). Fraction *e* contained, besides ordinary *F*-component (F_α), an additional component with a higher sedimentation coefficient (F_β).

Attempts to obtain pure *F*-component have been, so far, unsuccessful, the purity being no more than 62 per cent after repeated chromatography. However, it was considered from iodine analysis of these preparations that *F*-component would be iodo-protein(s). Further work is necessary to confirm this.

Although these experiments were carried out on a preparation derived from a number of thyroid glands, a similar chromatographic diagram was obtained with a preparation obtained from a single gland.

On the basis of these observations it is suggested that hog thyroid contains a large number of iodoproteins, which differ in the degree of iodination

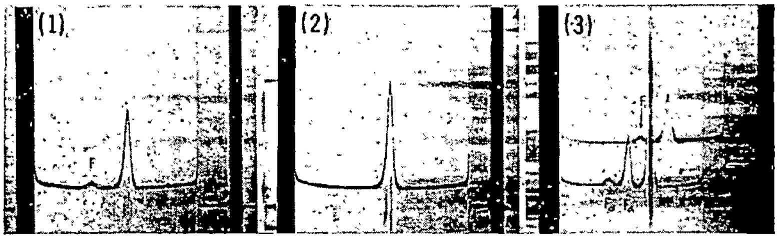

Fig. 2. Ultracentrifugal patterns of thyroglobulin fractions. (1) Original thyroglobulin preparation; (2) fraction *a*; (3) upper, fraction *d*; lower, fraction *e*. Sedimentation proceeds from right to left

and in other properties. It should also be noted that, in spite of this heterogeneity, no iodine-free component was found in thyroglobulin.

Further work is now in progress, and the results will be published elsewhere together with details of the present experiments.

Selenomethionine as an Antioxidant

EVIDENCE has accumulated indicating that: (1) vitamin E functions, at least in part, as a lipid antioxidant; (2) unrelated substances having antioxidant activity can alleviate or prevent some of the symptoms of vitamin E deficiency[1]; (3) selenium compounds also can alleviate or prevent some of the symptoms of vitamin E deficiency[2]; (4) the ingestion of selenium oxide renders tissues less susceptible to oxidative attack[3]; (5) some seleno-amino-acids have antioxidant activity in aqueous lipid emulsions[4]. The experiments reported here were undertaken to determine whether seleno-amino-acids could act as antioxidants in anhydrous fats and oils.

Denison and Condit[5] had first shown that organic selenium compounds were powerful antioxidants in lubricating oils. Woodbridge[6] has summarized the literature dealing with selenium compounds as anti-oxidants in rubber and lubricating oils and contributed information on their effectiveness in squalene.

Most of the experiments were run with selenomethionine, one sample of which was obtained from E. Painter[7], and a second from Y. Natori. The latter sample was pure by paper chromatography. Similar results were observed for both samples. Triolein was obtained from the Hormel Foundation. Lard was a commercial sample containing no added antioxidants. Menhaden oil was a purified sample obtained from the Bureau of Commercial Fisheries.

Antioxidant activity was estimated by the gain-in-weight method described previously[8]. Covered beakers containing the oil samples were incubated in constant-temperature draught ovens. Once daily they were removed from the oven, tested for rancidity by odour, allowed to cool to room temperature, weighed and returned to the oven. The end of the induction period was indicated by a gain in weight and also by the development of rancidity.

Peroxides were determined by iodimetry, essentially according to the A.O.C.S. method Cd 8-53 but adapted for a sample size of 200 mgm. The containers were kept filled with nitrogen during the one minute reaction period with potassium iodide.

Table 1. EFFECT OF SELENOMETHIONINE ON INDUCTION PERIOD OF TRIOLEIN, LARD, MENHADEN OIL*

Additive	Amount (μM/gm.)	Induction period (days)
Triolein (60°):		
None	—	5, 5
Selenomethionine	1	5
	2·5	9
	5	57
	10	31
	25	> 355
Methionine	10	8
	25	9
Lard (60°):		
None	—	1, 2
Selenomethionine	10	6, 6
	25	> 240, > 240
	50	> 240, > 240
Methionine	10	1, 1
	25	1, 1
Menhaden oil (50°):		
None	—	1, 1
Selenomethionine	10	1, 1
	25	1
	50	1

* Fat samples which were held for months at 60° without becoming rancid did, however, develop a garlic odour, and gradually became more viscous.

As shown in Table 1, selenomethionine was ineffective in the various substrates at levels below 5 μM/gm.; at higher concentrations it gave remarkable stabilizing effects with lard and triolein, but was ineffective in menhaden oil (a highly unsaturated fish oil, iodine value 160). The protection afforded the more saturated fats was not uniformly demonstrable, and it was noted in most instances that oxidation, as measured by gain in weight, proceeded for a few days to 0·25–0·75 per cent of the total weight, and then came to an abrupt stop. No changes then occurred for several months. Parallel runs with methionine did not show similar behaviour. Other seleno-amino-acids, namely, selenocysteine, phenyl selenoglycine, selenohomocysteine, and phenyl selenomethionine, also acted as antioxidants when added in relatively large amounts, but they were not as exten-

Table 2. PEROXIDE CHANGES IN LARD INCUBATED AT 60° WITH AND WITHOUT ADDED SELENOMETHIONINE AND HYDROPEROXIDE

	Additive	Amount (μM/gm.)	Original peroxide value	Time (hr.)	Final peroxide value

* Hydroperoxide added as oxidized safflower oil methyl esters.

† Hydroperoxide added as menthane hydroperoxide.

sively studied. Quantitation with the selenoamino-acids was rendered difficult by the heterogeneity of the system; none was completely in solution in the substrates used.

Changes in peroxide value were followed in lard samples with and without added selenomethionine and also with and without added peroxides. The results, shown in Table 2, indicate that in the presence of selenomethionine the peroxide values did not rise so high and tended to decrease with time, more so than when either methionine or no additional additive was present. In this sense selenomethionine appeared to be able to decompose peroxides.

The results with selenomethionine differed from those observed with other antioxidants in: (1) they appeared to have no effectiveness in low concentrations; (2) the protection even in large amounts could not be uniformly demonstrated; (3) no protection was afforded to a highly unsaturated oil; (4) some oxidation appeared to occur before the antioxidant effect appeared. These observations may tentatively be explained by assuming that selenomethionine is not itself an antioxidant but that it is oxidized to a derivative which is. Such systems have been described for thio- and dithio-compounds by Barnard *et al.*[9], and for seleno-compounds by Woodbridge[6]. In the former case the active antioxidants are thought to be the derived sulphoxides, and thiosulphinates.

It is reasonable to suppose that the reactions which lead to the formation of a sufficient amount of a powerful antioxidant so that oxidation stops would be of a complexity such that only at times could this consummation be reached. Thus, if a highly unsaturated oil formed peroxides rapidly, the intermediate antioxidant might be further oxidized before it could stabilize the reaction.

These results give further suggestive evidence that some of the tocopherol-like physiological properties of selenium compounds may be mediated through an antioxidant action[4]. Perhaps the lack of parallelism in their physiological effects is due not only to the differences of availability to different cells of tocopherols compared with seleno-compounds but also to the requirement that specific selenium derivatives, which occur or are synthesized in ways not yet understood, are required to achieve the antioxidant state.

Occurrence of Mevalonic Acid in Carrots

Although tracer studies in a number of carotenogenic systems[1,2] have conclusively proved that mevalonic acid is an effective precursor of carotenes, the presence of mevalonic acid has not been demonstrated in any of such systems. In this laboratory an attempt has been made to isolate mevalonic acid from carrots. Previous work[3,4] has shown that cell-free extracts of carrots can synthesize carotenes from acetate and mevalonic acid.

100 gm. (wet weight) of freshly collected carrots were minced and placed in 100 ml. phosphate buffer (0·1 *M*, *p*H 5·8) for about 2 min. in a Waring blender to prepare the homogenate. From the filtered homogenate the proteins were removed by treatment with trichloracetic acid and the supernatant, after neutralization, was concentrated *in vacuo* to about 60 ml. For isolation of mevalonic acid the concentrated material was acidified with 8 ml. of 10 *N* sulphuric acid, then extracted with ethyl ether for 8 hr. and the extract treated according to the method of Lynen and Grassl[5]; finally mevalonic acid was determined by reaction with hydroxylamine at *p*H 7·0 and subsequent colorimetric measurement of the resultant hydroxamic acid by formation of a complex with ferric salts. The quantitative range of mevalonic acid present in carrots varied from 2 to 4 μmoles/100 gm. of carrots (wet).

The dibenzylethylenediamine (DBED) salt of isolated mevalonic acid was prepared according to the procedure described by Hoffman *et al.*[6]; a crystalline salt was obtained which melted at 115° (114–119°).

For further confirmation the mevalonic acid DBED salt was dissolved in minimum amount of water, the *p*H was adjusted to 10 and the free amine was extracted with ethyl ether. The alkaline solution was readjusted to *p*H 6·5–7, and then, after concentration, portions were chromatographed according to the method of Yokoyama *et al.*[2] and the spot of mevalonic acid was identified by spraying with bromophenol blue.

The compound isolated was also confirmed as mevalonic acid by identifying the hydroxamate derivative which was chromatographed by using butanol saturated with water as the solvent system as reported by Knauss *et al.*[7]. The spots were made visible by spraying with 5 per cent $FeCl_3.6H_2O$ in 90 per cent ethanol and 0·1 *N* hydrochloric acid.

In view of the recent findings of Braithwaite and Goodwin[8] that mevalonate is more efficiently incorporated than acetate into carotenes of carrots, the occurrence of mevalonic acid in carrots makes the carrot system a valuable tool for further work.

HISTOCHEMISTRY

Tissue Dilution Artefact; a Re-interpretation of Variations in Levels of Succinic Dehydrogenase during Chemical Carcinogenesis

RECENT biochemical studies on succinic dehydrogenase in livers of rats fed with the liver carcinogen *p*-dimethylaminoazobenzene (DAB) for periods of up to 150 days have confirmed the well-established phenomenon that the level of this enzyme generally falls as feeding progresses (Table 1). Samples of tissue from each liver lobe were taken for histological and histochemical investigations, and the remainder was homogenized. Succinic dehydrogenase was estimated to within an accuracy of ± 10 per cent by the anaerobic methylene blue technique, basing the Q_{MB} values on dry weight. For histochemical purposes the tissue was frozen[1], stored for not longer than a week, and cut at $-20°$ C. in a refrigerated microtome. Succinic dehydrogenase was detected histochemically by incubating frozen sections in a neotetrazolium–succinate buffer system[2]; in addition, the periodic acid–Schiff method[3] was used to stain glycogen, while phospholipid was stained by the acid hæmatin method[4].

The histochemical results indicated that the succinic dehydrogenase activity of the liver cells was high in liver from rats fed on a complete diet or on a low-protein methionine-supplemented diet[5] with or without DAB, and that in the course of feeding this activity per cell did not alter detectably. In contrast, normal bile duct epithelium had a low activity, while connective tissue gave no apparent reaction ; as the period of feeding increased, the proportion of these less or non-reactive components became greater, and the gradual fall in Q_{MB} was qualitatively matched by a reduction in the proportion of liver cells, which histochemically still reacted in a manner comparable with normal liver cells. Sections have also been stained with hæmatoxylin and eosin, while the periodic acid–Schiff and acid hæmatin stains have provided useful information in distinguishing cell types. The latter, in particular, differentiates the weakly staining cells of bile duct and connective tissue in contrast to the strong reaction of liver cells.

When rats were allowed to remain on diet for 200 days, the Q_{MB} values, even of tissue samples selected from the same lobe, showed considerable variation. High Q_{MB} values, about 75–90 per cent of control values, were given by areas containing a high proportion of liver cells, though this proportion was not as high as in normal liver. Low values of Q_{MB}, 20–50 per cent of control values, were obtained from areas of liver composed principally of bile duct cells and fibrous tissue.

Daoust and Cantero[6], who studied the livers of Wistar rats, showed that as the period of feeding the carcinogen DAB was extended, so the relative proportion of liver cells decreased, while the proportions of connective tissue and bile duct cells increased. In these studies, rats of the August strain have been used, but the histology of these livers was qualitatively similar to that reported by Daoust and Cantero. Thus the proportion of liver cells containing a high level of succinic dehydrogenase fell, while the amount of much less active bile duct cells and inactive connective tissue increased ; the overall fall in succinic dehydrogenase was due, not to any change, malignant or otherwise, in any particular cell type, but rather to an alteration in the relative proportions of cell types. It is suggested that the term 'tissue dilution artefact' be used to describe this phenomenon.

Table 1. VARIATIONS IN VALUES OF Q_{MB} IN THE RIGHT ANTERIOR LOBES OF MALE RATS (AUGUST STRAIN) FED WITH THE LIVER CARCINOGEN DAB ON A LOW PROTEIN DIET

Period of feeding	Q_{MB} in right lobe (DAB)	Q_{MB} in right lobe (control)	DAB Q_{MB} as percentage of control values
No DAB		25 ± 4	
30 days	23	25	92
60 days	20	24	83
90 days	13	22	59
120 days	15	29	52
150 days	10	22	45

It is claimed then that this artefact may occur generally in biochemical studies of a tissue containing two or more cell types which may vary in proportion during the course of the experiment. A notable example of such investigations is that on livers of animals treated with liver carcinogens. In this kind of work the onus lies with the experimenter to demonstrate that biochemical comparisons reflect a true alteration in cell metabolism, and are not due to a change in the proportion of cell types of different metabolic activities. Rigid histochemical and histological checks become of the utmost importance in interpreting such biochemical results if invalid conclusions based solely on such data are to be avoided.

PHYSIOLOGY

Sub-fractionation of Human Serum Leucine Aminopeptidase

OUR earlier starch-gel electrophoretic zymograms[1], obtained with 1-leucyl-β-naphthylamide (LBNA) substrate, revealed a single leucine aminopeptidase (LAP) zone for human serum. The substitution of alanyl-β-naphthylamide (ABNA) substrate now consistently reveals, within the diffuse trail behind the primary zone, an additional less-intense zone (Fig. 1*a*), detectable also for some sera by LBNA. Occasional sera give three or more zones; and one chronic pancreatitis serum has given a remarkable zymogram with five zones which, when observed through a suitable blue filter (Dupont No. 9 plastic 'Varigam' filter), can be distinguished as eight zones (Fig. 1*b*).

Whereas some zymograms are distinctive because of this multiplicity of zones, others are distinctive because of a single zone. In 21 determinations, ABNA substrate on 18 serum samples from 8 varied patients (run on 4 different days over a 3½-month period), the usual two zones were resolved in every instance. Conversely, in each of 5 determinations on 5 serum samples from one other patient (run on 3 different days along with the other patients' samples), only the one primary zone could be found. Although no correlation with diagnosis is at present justified in this case, the serum of this particular patient seems clearly characterized by a marked deficiency or absence of at least one common peptidase sub-fraction.

The electrophoretic sub-fractionation is accomplished (as previously described[1,2]) in 15 per cent starch gel, prepared in 0·03 M, pH 9·0, borate buffer (final gel pH 8·5); and a 6 V./cm. gradient for 6 hr. The gel strip (2·0 × 0·65 × 25 cm.) is then cut horizontally into two thin slices and incubated at room temperature in a substrate solution[3], prepared by mixing and dissolving: (*a*) 8·0 ml. of a 1 per cent solution of ABNA (or LBNA) in water; (*b*) 40·0 ml. of 0·2 M *tris*(hydroxymethyl)aminomethane buffer that has been adjusted to pH 7·1 with hydrochloric acid; (*c*) 160 ml. of water; (*d*) 120 mgm. of diazotized *o*-aminoazotoluene. The zymogram of orange red zones against an orange yellow background usually begins to develop within 15 min., although 2 hr. are allowed for full development. The gels are finally rinsed thoroughly with water and saturated overnight with glycerol, which prevents drying and preserves the zymograms.

Special clinical interest attaches to this new evidence that LAP is heterogeneous. An early optimism that increased LAP activity in serum may be diagnostic of pancreatic cancer[4] has been questioned by similar findings for non-malignant diseases[5,6]. (Similarly, while Burstone[7] has associated abnormal LAP increases in certain tissues with invasive cancer, Monis *et al.*[8] attribute such increases to non-specific inflammatory and proliferative processes.) But beyond the controversial significance of total serum LAP activity, it is now apparent that a zymogram or distribution pattern of this activity among several different LAP sub-fractions can be much more informative, perhaps because each sub-fraction independently reflects the condition of its own particular source tissues. This situation has been demonstrated for other enzymes, tissues and diseases, most recently by Wroblewski[9] for heart lactic dehydrogenase, which selectively increases in serum after myocardial infarct. On this background our present work on LAP zymograms will be extended with emphasis on pancreatic cancer, other pancreatic and liver diseases, pregnancy and other conditions showing unusual serum LAP activity.

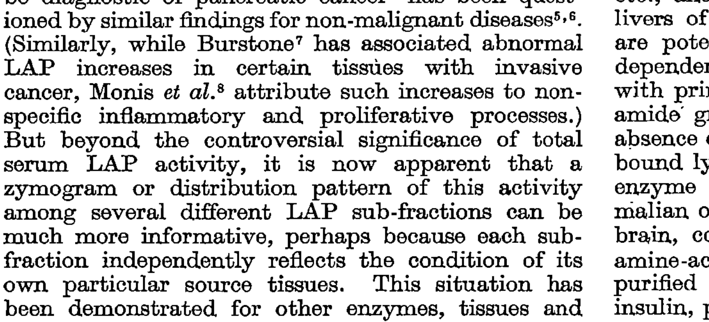

Fig. 1. Leucine aminopeptidase zymograms (ABNA substrate) of human serum (schematic). *a*, Typical pattern; *b*, a chronic pancreatitis pattern (observed through blue filter). The relative locations of the major protein zones (Smithies nomenclature) are noted below the zymograms

This work was aided by grant No. *T*-77 from the American Cancer Society and by a gift from Mollie E. Swinney. We also wish to acknowledge laboratory facilities and other valuable support provided by Dr. Samuel H. Bassett.

Working independently of us, Sanford H. Lawrence, Perry J. Melnick and Harry E. Weiner (private communication) have also found two or more LAP zones for human serum.

Incorporation of Histamine into Liver Protein *in vivo*

RECENTLY we have described an enzyme system which catalyses the exchange of the amide group of protein-bound glutamine with primary amines, such as methylamine, putrescine, histamine, serotonin, etc., and also hydroxylamine and ammonia[1]. The livers of rodents, and in particular of guinea pigs, are potent sources of the enzyme. This calcium-dependent enzyme not only catalyses the exchange with primary amines but also the hydrolysis of the amide group of protein-bound glutamine[2]. In the absence of added amine the ε-amino group of protein-bound lysine may act as the replacing agent[3]. The enzyme was named 'transglutaminase'. All mammalian organs examined, and in particular liver and brain, contain proteins which may act *in vitro* as amine-accepting substrates, as are also a number of purified proteins, such as casein, lactoglobulin, insulin, pepsin, etc.

Whereas there is no difficulty in demonstrating transglutaminase action *in vitro*, in early experiments, attempts to show fixation of administered amines in the liver proteins of mice were unsuccessful even after experimental liver damage (carbon tetrachloride) or after nephrectomy. The possibility was considered that proteins modified by incorporated amines may have antigenic properties and could be involved in auto-immune reactions. Since *H. pertussis* vaccine enhances anaphylactic sensitization its effect and that of a lipopolysaccharide from *S. typhosa* on liver transglutaminase[4] and histamine incorporation into liver proteins was studied. In mice, 16 hr. after a single injection of lipopolysaccharide, the transglutaminase-level in liver was increased up to three-fold. The enzyme was assayed in the 100,000g supernatant fluid of 0·25 molar sucrose liver homogenates with a tryptic digest of casein as substrate and hydroxylamine as replacing amine[2]. *H. pertussis*

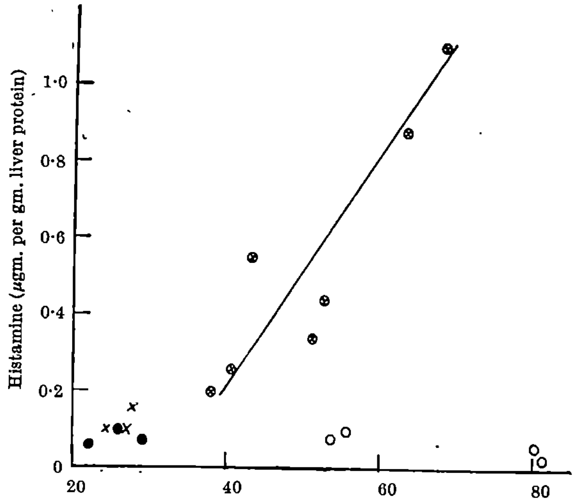

Fig. 1. Transglutamine activity and concentration of protein-bound histamine in mouse livers. Transglutaminase unit = optical density (525 mμ) × 1,000 of the Fe^{+++} complex of hydroxamic acid formed after 10 min. incubation at 37° C. Normal mice (●); normal mice + 37·5 mgm./kgm. of histamine (×); mice treated with 5 mgm./kgm. of *S. typhosa* lipopolysaccharide (○); mice treated with lipopolysaccharide, and 37·5 mgm./kgm. of histamine (⊗)

vaccine acted similarly, but was less effective in raising the enzyme-level. Histamine (37·5 mgm./kgm.) was administered intraperitoneally to groups (6–10) of normal and lipopolysaccharide-treated mice which were killed 30 min. later. Small portions of each liver were homogenized together for enzyme determination; the pooled remainder of the livers was precipitated by trichloracetic acid, the protein purified and traces of adsorbed histamine removed by thioglycollate treatment. Histamine was extracted from the ammonia-freed acid hydrolysates of the purified liver proteins using a modification of the method described by Shore *et al.*[5] and assayed on the superfused guinea pig ileum. The results of enzyme and histamine determinations are shown in Fig. 1. The histamine content of the liver proteins from normal or lipopolysaccharide-treated mice with or without histamine injection was less than could be detected and the points shown indicate the limits of the sensitivity of the assay. The liver proteins of lipopolysaccharide-treated animals after histamine injection contain significant amounts of histamine, the quantity of which correlated with the transglutaminase-level ($r = 0·9$; $P < 0·001$). The validity of the above results was further confirmed in experiments in which histamine labelled with carbon-14 was administered.

It should be emphasized that the increase of enzyme activity and protein-bound histamine does not necessarily represent a causal relationship, nor do the results permit the conclusion that the histamine is incorporated by exchange with the amide group of glutamine bound in liver protein. In order to demonstrate increased histamine fixation in liver protein of lipopolysaccharide-treated mice, it was necessary to administer large doses of histamine. This raises the question whether histamine is the natural replacing amine and experiments are now in progress to study the conditions of *in vivo* incorporation of other amines. Experiments testing the antigenic properties of proteins into which histamine was incorporated *in vitro* by transglutaminase have up to now given equivocal results.

This work was supported in part by grants from the National Institute of Neurological Diseases and Blindness (grant *B*–226), from the Ford Foundation, and by a contract between the Air Force Office of Scientific Research and the Research Foundation for Mental Hygiene, Inc. One of us (M. G.) is indebted to the Wellcome Trust for a travel grant. We are grateful to Miss Ethel Danielson for the performance of most of the enzyme assays and to Mrs. Paula Mela for her assistance.

Comparison of Short-Circuit Current and Net Water Movement in Single Perfused Proximal Tubules of Rat Kidneys

THE major portion of renal salt and water reabsorption occurs within the proximal convoluted tubule, amounting in mammalian kidneys to about 80 per cent of the quantities present in the glomerular filtrate. Based on indirect evidence, proximal sodium transport has been postulated to be active. Recently, however, results obtained in stop-flow experiments were interpreted in such a way as to indicate passive bulk movement of tubular fluid as the predominant mode of proximal tubular salt transfer. Micropuncture work on rats has demonstrated unequivocally the existence of active sodium transport across proximal epithelium[1], but did not provide information as to the relative contribution of active sodium transport to the overall net movement of this ion species. The present work represents an attempt to clarify this point by correlating active transport of ions as measured by the short-circuit method with measurements of net movement of water under comparable conditions. Assuming that proximal fluid reabsorption is isosmotic—an assumption in agreement with all known measurements of osmotic pressure of proximal tubular fluid—net water movement can be used as an index of net transport of sodium. Thus short-circuit current can be correlated with net movement of sodium.

Experiments were performed on rat kidneys *in vivo*. Short-circuit current was measured by means of the original short-circuit method as described by Ussing and Zerahn[2], using double-barrelled electrodes[3], or by a modification as described by Karger *et al.*[4]. By definition, short-circuit conditions occur when the trans-membrane potential difference is reduced to zero. Under such conditions the current generated by the epithelium passes through an outer circuit of zero effective resistance. Applied to the renal tubule, the short-circuit current is that current which, applied from an external battery, renders the electrical resistance of a probing micro-electrode within the tubular lumen identical to that of the same electrode when it is outside the lumen. Thus the resistance of the membrane is effectively reduced to zero. Since electrolyte concentrations are nearly identical in proximal tubular fluid and interstitial fluid, the current measured under these conditions must be generated by active ion transport.

All measurements of short-circuit current were performed on tubular fluid segments one diameter in length, isolated from the rest of the tubular fluid by means of columns of mineral oil. The reason for this choice of distance between the bordering oil droplets arises from conclusions derived by cable analysis. In this type of analysis the renal tubule is treated as an electrically leaky cable, and a quantitative measure of its resistance to passive ion flow can be obtained. Use was made of equations derived by Hodgkin and Rushton for the giant axon of the squid[5]. Assessment of the length constant was made possible by passing a known current through one micro-electrode into the tubular lumen and recording voltage displacements at known varying distances within the same tubule by means of a second micro-electrode. With anodic stimulating currents of 10^{-6} amp., voltage amounted to 14 mV. (2 observations, range 8–17 mV.) at 15μ, 9·6 mV. (6 obs., range 6–14 mV.) at 30μ, 5 mV. (2 obs., range 4–6 mV.) at 60μ, and 3·3 mV. (2 obs., range 2·5–4·0 mV.) at an interelectrode distance of 90μ. These results indicate that a current applied through the stimulating micro-electrode leads to a decline in voltage amounting to 63 per cent of its original value at a distance of about 55μ. An identical decline of current intensity can be predicted provided that the tubular epithelium behaves as an ohmic resistance. Therefore, experiments were performed in which the voltage-current relationship was directly examined. With varying anodic and cathodic d.c. currents (up to 3×10^{-6} amp.), proportional displacements of voltage were recorded. Thus proximal tubular epithelium behaves as a linear, non-rectifying circuit element, and the decline of a locally applied current can be predicted from the value of 55μ obtained for the length constant. From these findings it can be concluded that a distance of one tubular diameter (30μ) between the isolating oil droplets is adequate to assure constancy of current density and effective short-circuiting. The average short-circuit current, as measured in a series of 10 experiments by means of the method of Karger *et al.*[4], amounted to 100×10^{-10} amp./$2{\cdot}8 \times 10^{-5}$ cm.^{2} (*S.E.* ± 20 per cent). Using the approach of Ussing and Zerahn[2], in which double-barrelled electrodes were applied, the average short-circuit current obtained in 6 experiments amounted to 101×10^{-10} amp./$2{\cdot}8 \times 10^{-5}$ cm.^{2} (*S.E.* ± 7 per cent). The pooled data of these two series of short-circuit current measurements correspond to a net ion transport of 34×10^{-10} equiv./cm.^{2}/sec.

The measurements of short-circuit current were compared with the net movement of sodium ions as calculated from water movement observed in perfusion experiments on single proximal tubules of the rat kidney. In this technique coloured mineral oil is injected into the tubular lumen and split by a small amount of perfusion fluid. The position of the isolated column of perfusion fluid is then secured by injecting mineral oil through a second pipette into the most distal surface loop of the proximal tubule. The perfusion fluid is left within the lumen for a short period, usually about 30 sec., and is then collected through the second, distally located pipette, while mineral oil is injected through the proximal micropipette.

Tubules were perfused with fluid containing 145, 100, and 10 m.equiv./l. of sodium. All perfusion fluids were kept isosmotic to plasma by addition of adequate amounts of mannitol. ^{14}C-inulin concentration ratios of collected and injected perfusion fluid were taken as an index of net water movement. At an intratubular sodium concentration of 145 m.equiv./l., water movement amounted to an average value of 59 per cent of the injected volume (4 obs., range 50–67 per cent), at 100 m.equiv./l., to 31 per cent (2 obs., 30 and 31 per cent), whereas at 10 m.equiv./l. the direction of net water movement was reversed and intratubular fluid volume increased by 46 per cent (3 obs., range 41–50 per cent). It should be noted that water reabsorption was reduced to a mean of 5 per cent of the injected volume (4 obs., range −6 to +17 per cent) when sodium cyanide at a concentration of 4×10^{-3} *M*/l. was added to the perfusion fluid containing 145 m.equiv./l. of sodium. It may be concluded from these results that a decrease in intratubular sodium concentration results in a decrease in water reabsorption. However, the net water movement may not be ascribed solely to the effect of the intratubular concentration of sodium chloride, since mannitol also was present in the perfusion fluid. To correct the above results for water movement secondary to mannitol flux, a second series of 9 experiments was performed under the same experimental conditions, except that ^{14}C-mannitol was measured rather than ^{14}C-inulin. The ratios of concentrations of ^{14}C-mannitol between collected perfusate and injected perfusion fluid averaged 0·31 (4 obs., range 0·17–0·49) at 10 m.equiv./l. intratubular sodium, and 0·84 (5 obs., range 0·63–0·94) with perfusion fluid containing sodium at a concentration of 100 m.equiv./l. Calculation of the net water movement which may be ascribed to transport of sodium chloride, after correction for mannitol-induced transfer[6], shows that net movement of sodium chloride out of the tubule can take place against a considerable concentration gradient. Water movement ceases between a solution containing 88 m.equiv./l. sodium and one containing sodium at a concentration of 145 m.equiv./l. When the concentration gradient exceeds 57 m.equiv./l., the direction of water movement, ascribed to sodium transfer, is reversed and water enters the tubule. The magnitude of this critical gradient is somewhat greater than that found during free flow conditions in micropuncture studies on rats during osmotic diuresis[1].

Net movement of water observed in experiments in which tubules were perfused with fluid containing 145 m.equiv./l. of sodium could be expressed as net movement of sodium without correction for mannitol flux. In this calculation a mean tubular radius of 15μ was used in estimating the exposed tubular surface area. Furthermore, the assumption was made that proximal fluid absorption is isosmotic and that tubular fluid volume changes as a linear function of time. The calculated mean trans-tubular net flux of sodium, thus obtained, amounts to 30×10^{-10} equiv./cm.^{2}/sec.

The results obtained in this work indicate that the critical sodium concentration gradient at which net movement of sodium across proximal tubular epithelium stops is 57 m.equiv./l. Comparison of measurements of short-circuit current and calculated sodium reabsorption obtained from data on perfusion experiments indicates that the major portion, possibly all, the proximal sodium reabsorption in the rat kidney is active in nature.

CYTOLOGY

Cytology of Some Genera of Polypodiaceae in Eastern India

POLYPODIACEAE (*sensu* Copeland[1]), a part of the once comprehensive family Polypodiaceae (*sensu lato*), comprises 65 genera, occurring mostly as epiphytes in the tropical and subtropical evergreen and semi-evergreen forests. The genera are characterized by simple, pinnatifid or rarely pinnate fronds with round and rarely linear or acrostichoid typically exindusiate sori. A thorough analysis of the literature together with the study of herbarium specimens available in the Central National Herbarium, Sibpore, West Bengal, and Eastern Regional Herbarium of the Botanical Survey of India, Shillong, Assam, suggests that the family is represented in India by 26 genera and 104 species[2], of which 91 species are distributed in various parts of eastern India, which incidentally appears to be richest in the fern flora in the whole country.

Although Manton[3] has worked out the cytology of 40 species, mostly from Ceylon and Malaya, none of the Indian plants belonging to the family Polypodiaceae (*sensu* Copeland, 1947) has yet been studied cytologically (the first report of the basic number in *Paraleptochilus decurrens* (Bl.) Copel. from Darjeeling has been published only recently by S. S. Bir in *The Nucleus*, **3**, 121; 1960) despite much work on the cytotaxonomy of the other families of ferns. As a part of the larger scheme of undertaking a cytotaxonomic revision of the predominantly epiphytic family Polypodiaceae, the East Indian species are being investigated. The present communication records the chromosome numbers unequivocally established for the species listed in Table 1.

14. *Pyrrosia flocculosa* (Don) Ching	Jowai	$n=36$	,,
15. *Pyrrosia mannii* (Gies.) Ching	Shillong	$n=37$	,,
16. *Pyrrosia subfurfuracea* (Hk.) Ching	Assam	$n=37$	,,
17. *Lepisorus pseudonudus* Ching	,,	$2n=39$	Auto-triploid
18. *Lepisorus* sp. nov.	Jowai	$n=22$	Diploid

While the present findings confirm the basic chromosome numbers for the genera *Lepisorus*, *Pyrrosia*, *Microsorium*, and *Crypsinus* reported earlier by Manton and Sledge[3], new records of basic chromosome numbers for four genera are now established, namely, *Arthromeris* with $n = 37$ (Fig. 1), *Colysis* with $n = 36$ (Fig. 2), *Loxogramme* with $x = n = 35$ (Figs. 3 and 4), and *Pseudodrynaria* with $n = 36$ (Fig. 5). Although Manton reported three different basic numbers, namely, $x = 35$, 36 and 37, in three species of *Lepisorus* from Ceylon, two species studied by us from eastern India each show $n = 35$ only, whereas two other species show the lowest basic chromosome numbers, namely, $x = 11$ and 13, discovered so far in the family. While the genus *Pyrrosia* appears to be characterized by $n = 37$,

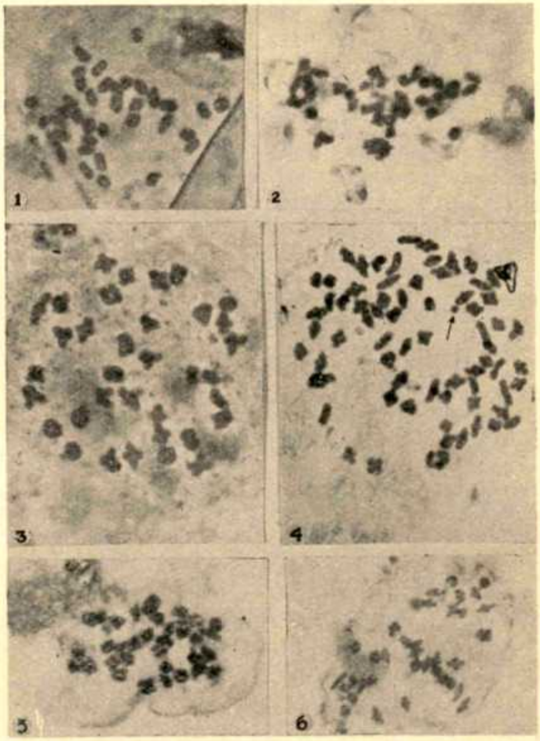

Fig. 1. Samples of meiotic behaviour in wild plants of Polypodiaceae of eastern India (all × 575) from permanent acetocarmine squashes prepared by S. N. Patnaik and photographed by C. C. Mukerjee: (1) *Arthromeris wallichiana*, a diploid ($n=37$); (2) *Colysis elliptica* var. *pothifolia*, a diploid ($n=36$); (3) *Loxogramme lanceolata*, a diploid ($n=35$); (4) *Loxogramme involuta*, a tetraploid ($n=70$, arrow indicating an extremely small bivalent); (5) *Pseudodrynaria coronans*, a diploid ($n=36$); (6) *Pyrrosia flocculosa*, a diploid ($n=36$)

Pyrrosia flocculosa alone shows a deviation with $n = 36$ (Fig. 6). The finding of $n = 36$ in *Pseudodrynaria coronans* (Wall.) Ching as distinct from $n = 37$ in three other species of *Drynaria* studied (Manton and Sledge[3]) lends support to the separation of *Drynaria coronans* (Wall.) J. Sm. for the construction of the monotypic genus *Pseudodrynaria* C. Chr. Of the four species of *Loxogramme* cytologically investigated, three species are diploids each with $n = 35$, whereas *L. involuta* is a tetraploid species showing unmistakably $n = 70$, with a single conspicuously small bivalent at diakinesis. Thus *Loxogramme* is characterized by the basic number $x = 35$ and not 36 (ref. 4). Hence, Manton's report of the chromosome number of *L. involuta* from Ceylon as $n = 70$ to 72 at meiosis and as "probably of the order of 140 in root tip" and her suspicion of the basic number as "probably 36" need revision in view of the unequivocal finding of $x = 35$ in four species of *Loxogramme* in eastern India. Manton (personal communication, 1961) agrees with this finding on the basis of her recent studies of *L. avenia* from Asian tropics.

Copeland's suggestion for merging *Arthromeris* with its parent genus *Crypsinus* to form a natural group is discounted by our discovery of $n = 37$ in *A. wallichiana* from Shillong as against $n = 36, 35, 33$ in *Crypsinus* reported from Eastern India, Ceylon and Malaya. On the other hand, the cytological findings of discordant basic numbers in *Crypsinus* corroborate Copeland's observations regarding the unnaturalness of the genus.

The discovery of the same basic chromosome number, namely, $n = 36$, in the genera *Microsorium*, *Colysis*, and *Leptochilus*, shows close affinity between them and may afford cytological evidence in favour of Holttum's contention of the origin of *Leptochilus* from *Microsorium* through *Colysis*-like ancestors.

Our thanks are due to Dr. J. C. Sen Gupta, chief botanist, Botanical Survey of India, Calcutta, for encouragement, and to the authorities of the Council of Scientific and Industrial Research, New Delhi, for the award of a research fellowship to the junior author and other financial assistance.

HÆMATOLOGY

Association of Hæmoglobin *N* and Microcythæmia in a Sardinian Family

IN the course of a survey of the frequency of microcythæmic syndromes conducted in the summer of 1960 in Sardinia[1], we encountered a family in which were present both an abnormal hæmoglobin, faster than Hb *A*, and the microcythæmic (or thalassæmic) character.

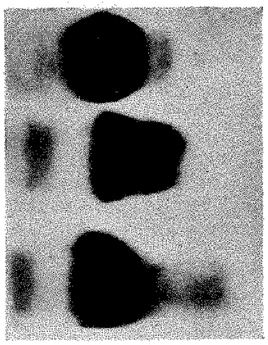

Fig. 1. Paper electrophoresis of Hb Bart's in cord blood (above), Hb *N* (at centre) and Hb *H* (below). Glycine buffer *p*H 8·8, ionic strength 0·04. Staining with bromophenol blue. Mobility of Hb *N* is similar with that of Hb Bart's; but less than that of Hb *H in toto*

The father (Table 1) was found to be a carrier of abnormal hæmoglobin; the mother was a carrier of microcythæmia; the first son, Gaet., was completely normal; the other two sons, Aless. and Franc., twins, were those that brought the family under our observation, because it was thought that they were affected by Cooley's disease. Indeed, both showed paleness of the skin and of the mucous membranes, skull slightly increased in volume, spleen enlarged to three fingerbreadths below the costal margin, and liver palpable 2 cm. below the right costal margin.

It has not been possible to conduct a hæmatological examination of Aless.: the blood smears, however, showed very intense erythrocytic alterations, quite similar to those of Cooley's disease. The other twin brother, Franc., presented an evident anæmia with hæmatological characters of microcythæmia (hypochromia, microcytosis, diminished cell fragility) and intense alterations of the morphology. Furthermore, both twins were carriers of fast hæmoglobin, while the proportion of Hb A_2 was less than the normal. The abnormal hæmoglobin presented the following characters: (1) on paper and starch electrophoresis at alkaline *p*H (Fig. 1) the hæmoglobin had a mobility identical with that of Hb Bart's, but lower than that of Hb *H in toto*; (2) on electrophoresis at acid *p*H (Fig. 2), the abnormal hæmoglobin tends to separate from Hb *A*, forming a thicker hæmoglobinic spot; (3) on agar-gel electrophoresis at acid *p*H, this abnormal hæmoglobin cannot be distinguished from Hb *A*; (4) on 'Amberlite *IRC*-50' chromatography at acid *p*H, the abnormal hæmoglobin precedes Hb *A* and separates from it (Fig. 3), but it is slower than Hb *F*.

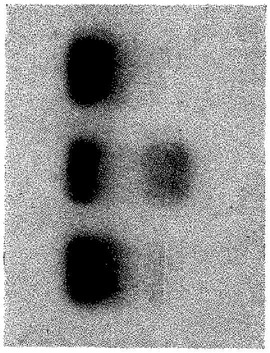

Fig. 2. Starch-gel electrophoresis of Hb *N* (above and below) and Hb *H* (centre). Phosphate buffer *p*H 6, ionic strength 0·12. Staining with amidoschwarz. The Hb *N* tends to separate from Hb *A* and forms a thicker spot than Hb *H*

Table 1. HÆMATOLOGICAL AND HÆMOGLOBINIC FINDINGS

Name and age (yr.)	Hb (gm./100 ml.)	Red blood cells (millions per c.mm.)	Mean corpuscular volume (μ^3)	Mean concentration of corpuscular hæmoglobin (per cent)	Hæmolysis in 0·4 sol. of Simmel's method	Blood film	Hæmoglobin types*			Percentage alkali-resistant Hb of total Hb
							Hb A_2	Hb A_1	Hb *N*	
Father, 36	15·2	4·7	95	33·7	97·9	Normal	1·35	62·2	36·4	1·06
Mother, 39	11·5	6·0	65	29·3	88·4	Anisocytosis, poikilocytosis, target cells, oval cells, moderate hypochromia	4·58	95·4	abs.	2·05
Gaet., 4	13·2	4·2	91	34·3	97·7	Normal	2·61	97·4	abs.	1·25
Aless., 1½						Marked anisocytosis and poikilocytosis, numerous target cells, oval cells and microcytes, marked hypochromia	1·14	62·0	36·9	1·98
Franc., 1½	6·8	3·6	67	27·8	94·5	Marked anisocytosis, poikilocytosis, microcytosis, numerous target cells and oval cells, marked hypochromia	0·78	63·5	35·7	2·36

* Percentages by starch-block electrophoresis, according to Kunkel *et al.*

In all the subjects (Table 1), the proportion of fast hæmoglobin was about 36 per cent, and that of Hb *a-r* was normal. In the ultra-violet region, the fast fraction isolated has a normal absorption spectrum; the resistance to alkali of this fraction is normal.

It is evident that the above characters correspond to those of Hb Liberia I of Robinson *et al.*[2] or Hb *N* of Ager and Lehmann[3]. Therefore, the present hæmoglobin may be classified as Hb *N*. The behaviour of Hb *N* on agar-gel electrophoresis at acid *p*H is not different from that of Hb *A*.

The present observation is, so far as we know, the first of Hb *N* identified in the Italian population. Association with the microcythæmic trait is not surprising, as the family is Sardinian and microcythæmia has an average frequency of 23 per cent on the Island[1]. It is interesting to visualize the presence of an anæmic-splenomegalic syndrome in the twin brothers, who are carriers of abnormal hæmoglobin. True Cooley's disease cannot be involved, since the microcythæmia is absent in the father, and illegitimacy is ruled out by the presence of the abnormal hæmoglobin in the father and sons. However, it is quite probable that both sons are carriers of the microcythæmia inherited from the mother, and that their illness is due to the association of microcythæmia and Hb *N*. Therefore, this would be another example of illness due to the association of two different hæmatological anomalies, the first example of which is the microdrepanocytic disease which we have identified[4-5].

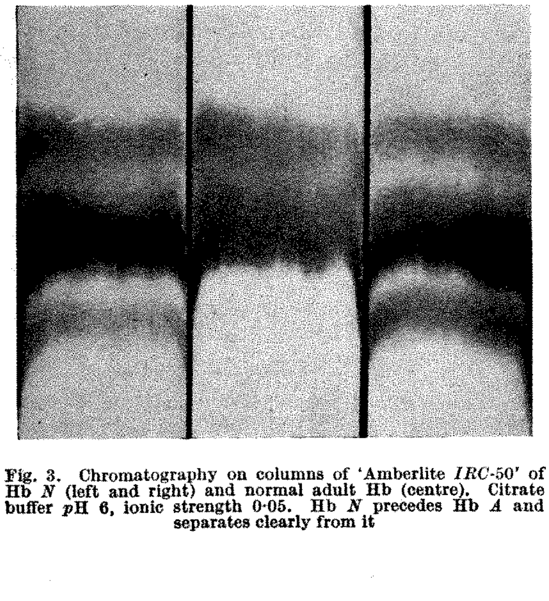

Fig. 3. Chromatography on columns of 'Amberlite *IRC*-50' of Hb *N* (left and right) and normal adult Hb (centre). Citrate buffer *p*H 6, ionic strength 0·05. Hb *N* precedes Hb *A* and separates clearly from it

The proportion of Hb A_2, which is strangely low in the twins, suggests the consideration that the presence of an abnormal hæmoglobin, faster than Hb *A*, may represent the determining factor for the reduced proportion of Hb A_2, as we see also in the carriers of Hb *H*.

This investigation was supported by a grant from the Department of Public Health.

Anti-Leucocyte Cytoplasm, Anti-Leucocyte Nuclei and Anti-Platelets in Disseminated Lupus Erythematosis

THE indirect antiglobulin consumption test[1,2] has been carried out on human leucocyte cytoplasm, leucocyte nuclei and platelets, using sera containing anti-leucocyte and/or platelet antibodies from non-transfused or minimally transfused patients: six disseminated lupus erythematosis (DLE), five idiopathic leuco-thrombopenias (ILT), four idiopathic thrombocytopenic purpuras (ITP). The auto-antibody nature of these substances was confirmed by the positive direct antiglobulin consumption test performed on the patients' own leucocytes and/or platelets. Three sera containing iso-leucocyte and platelet antibodies from three multiple transfused patients were also tested.

Leucocyte nuclei were isolated from liquefied cytoplasm[3]. Cytoplasmic proteins were obtained from the supernatant by ethanol precipitation (Colombani, J., unpublished work). Four absorptions were performed systematically and total absorption was always controlled. Elution was performed by heating the sensitized deposit for 30 min. at 56° C. in hypertonic saline. Sera, before and after absorption, and eluates were respectively tested against the three antigens (Table 1).

L, Leucocytes; *C*, leucocyte cytoplasm; *N*, leucocyte nucleus; *P*, platelet.

* The figures are the number of geometric dilution lost by the antiglobulin titre (titrated against *O* Rh + RBC sensitized by incomplete anti-*D*) after contact with the antigens sensitized by the auto- or iso-antibody.

DLE sera contained three distinct antibodies against cytoplasm, nuclei and platelets. ILT sera contained two antibodies against cytoplasm and platelets. ITP sera contained only one antibody against platelets. The sera of patients with multiple transfusions behave like ILT sera.

Table 2. DIFFERENTIATION BETWEEN THE ANTI-LEUCOCYTE AND ANTI-PLATELET ANTIBODIES DETECTED BY THE INDIRECT ANTI-GLOBULIN CONSUMPTION TEST

	Action on animal leuco-cyte or platelet	Agglutinating power on leuco-cyte and/or platelet	Antibodies not detected by some antiglobulin sera
Anti-leucocyte antibodies			
DLE	+ +	±	−
ILT	−	−	−
Iso-antibody	−	+ +	−
Anti-platelet			
DLE	+ +	±	−
ILT	−	−	−
ITP	−	−	+ +
Iso-antibody	−	+ +	−

The three anti-cytoplasm antibodies are not identical. DLE anti-cytoplasm reacts with the leucocyte cytoplasm of animal origin (ox, sheep, pig, horse), though the others do not react. ILT sera are not leuco-agglutinating, though iso-leuco-antibodies used in this work are strongly agglutinating.

The four anti-platelet antibodies are not identical. DLE anti-platelet reacts with animal platelets, though the others do not. ILT and ITP sera are not thrombo-agglutinating, though iso-thrombo-antibodies used in this work are agglutinating.

ITP antiplatelet antibodies react with a component of the antiglobulin sera which is different from the component reacting with the three other anti-platelet antibodies[4] (Tables 2 and 3).

These findings show that DLE sera possess an anti-cytoplasm factor at least as strong as the anti-nucleus factor when using the antiglobulin consumption test, although with fluorescent antiglobulin only the nucleus seems to be sensitized. Anti-cytoplasm antibodies in DLE were already suspected[5,6] but had not been directly demonstrated in human material.

IMMUNOLOGY

Elimination of Bovine Serum Albumin in Acute Experimental Uræmia

In patients suffering from acute or chronic uræmia the production of classical antibodies has been shown to be within normal limits[1-4]. The Mantoux test may be positive in chronically uræmic humans, implying that the formation of certain intra-cellular antibodies is also maintained. However, skin homografts survive for prolonged periods in the uræmic human[1,2], indicating that the onset of transplantation immunity is delayed. Medawar[5] has stated that the instruments of transplantation immunity are antibodies bound to cells of the lymphoid series and not serum antibodies. Skin homografts also survive for extended periods in uræmic rabbits[6], and this has been shown to be due to a delay in the onset of the immune responses in the draining lymph nodes (ref. 6 and unpublished work by Barwell, R. G., *et al.*). Having demonstrated the effect of uræmia on the production of the cell-bound antibodies of transplantation immunity, we decided to investigate (*a*) the elimination of a hetero-

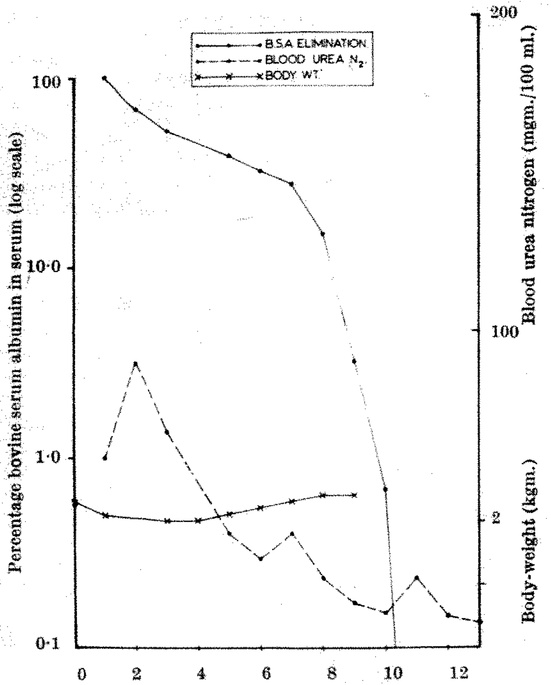

Fig. 1. Graph to show elimination of bovine serum albumin, levels of blood urea nitrogen and body-weight in a mildly uræmic rabbit

logous serum protein and (*b*) the production of serum antibodies in the uræmic rabbit.

Rabbits of Flemish giant strain each weighing 2·5–3·5 kgm. were used. The animals were anæsthetized by intravenous sodium pentobarbitone. The left kidney was removed from each animal and the right renal vascular pedicle occluded for 1 hr. by a non-crushing arterial clamp. After release of the clamp, the kidney was seen to flush and was then replaced within the abdominal cavity and the wound closed. Immediately after removal of the clamp, each rabbit received 5 ml. of a 5 per cent solution of bovine serum albumin (Armour) intravenously. Specimens of blood were taken for immunological examination, and blood urea nitrogen was determined at 24 hr. after the injection of bovine serum albumin and at daily intervals for a further twelve days. The blood urea nitrogen was estimated by the method of Archibald[7] and each animal was weighed daily.

The samples of blood obtained for immunological analysis were allowed to clot, and serum separated by centrifugation and stored in sterile rubber-stoppered glass tubes at 4° C. for at least 7 days to allow precipitation to occur. The sera were then recentrifuged and the bovine serum albumin contents were determined by the constant-antibody precipitation technique. The level of serum bovine serum albumin 24 hr. after injection was taken as 100 per cent, and readings obtained thereafter for each animal were expressed as a percentage of the first reading.

The effect of mild uræmia on the elimination of bovine serum albumin and on the body-weight is shown in Fig. 1. In this animal the blood urea nitrogen rose to 90 mgm. per 100 ml. 48 hr. after operation and then fell, at first rapidly, and then more slowly towards normal levels. Loss of weight occurred but only during the first three days of observation. The elimination of bovine serum albumin in this animal proceeded in a manner which could not be distinguished from normal. After equilibration, a logarithmic phase of elimination occurred lasting four days, followed by a period of rapid 'immune' elimination for the next two or three days before the bovine serum albumin became undetectable. This pattern of response was found in four rabbits.

The results obtained from an animal with severe uræmia are shown in Fig. 2. By the fifth day, the blood urea nitrogen had risen to 190 mgm. per 100 ml. and, after a transient fall, it again rose before death occurred in severe uræmia on the thirteenth post-operative day. A progressive loss of weight occurred during the course of the experiment. After the equilibration phase, the bovine serum albumin was eliminated logarithmically from the blood over the remaining period of observation. Its half-life during the logarithmic phase was 4 days, which is similar to the half-life in the logarithmic phase of normal rabbits. The half-life of endogenous albumin in normal rabbits is 6–8 days; hence despite the absence of the immune phase of elimination in the severely uræmic rabbit, the bovine serum albumin is still recognized as a foreign protein. Two of the three severely uræmic rabbits which showed this pattern of response and survived the experiment had formed serum antibodies when tested on the thirty-fourth post-operative day.

These experiments demonstrate a marked delay in the elimination of bovine serum albumin from the sera of severely uræmic rabbits. It seems likely that the persistence of detectable antigen for longer periods than in the mildly uræmic or normal animal is associated with the impaired production of serum antibodies, but how this occurs is unknown. It has been shown that the elimination of heterologous proteins from the blood stream is also prolonged after

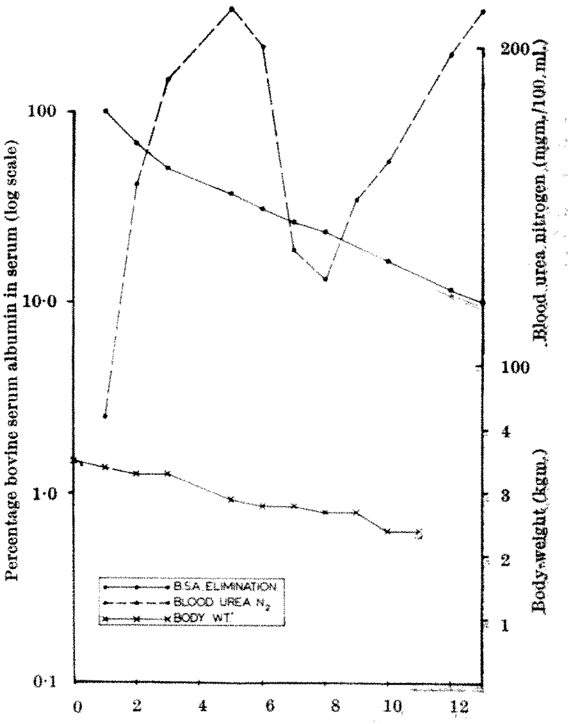

Fig. 2. Graph to show elimination of bovine serum albumin, levels of blood urea nitrogen and body-weight in a severely uræmic rabbit

the administration of the purine metabolic analogue, 6-mercaptopurine[8]. This drug also prolongs the survival of skin homografts in rabbits[10] and renal homotransplants in dogs[9].

A more detailed account of our findings, together with further work on the effect of experimental uræmia on classical immunological responses, will be published later.

Demonstration by Paper Electrophoresis of an Auto-immunological Precipitin possibly due to Fibrinolysins

WE have examined recently blood containing fibrinolysins in high titre. The blood was taken from a man who was later diagnosed as suffering from prostatic malignancy. The presence of high-titre fibrinolysins, raised formal acid phosphatase, and greatly reduced fibrinogen content, were all carried out by routine, accepted biochemical methods, and were fully diagnostic. It was then considered that there could be present a circulating auto-immunological factor which we might be able to demonstrate.

The method chosen was what we have called joint paper electrophoresis, and is essentially that of Flynn and Mayo[1], the only addition being that we offer a suitable source of fibrinogen to the serum containing fibrinolysins. We do this by applying plasma from another subject a short distance behind the serum start line, the result being, naturally, two protein separations, one behind the other. Our findings show that it is possible to produce a thin band typical of auto-immunological precipitins. This band appears in the region of the serum γ-globulin separation and we believe it to be an auto-immunological fibrinolysate.

Procedures taken to discover the optimal source of fibrinogen and to qualify our belief have been fully embodied in a paper which we hope to publish in the near future.

PATHOLOGY

Immunological Observations in Experimental Silicosis

EVIDENCE which suggests that an immunological mechanism may participate in the pathogenesis of human silicosis has been summarized by Vigliani and Pernis[1]. We have attempted to identify such a mechanism in the experimental disease by applying the fluorescent antibody technique of Coons and Kaplan to rats with silicosis at different stages of development, while observing at the same time the γ-globulin- and conglutinin-levels in their sera.

Silicosis was induced in rats by the intratracheal injection of a quartz suspension under ether anæsthesia, the rats being killed approximately 1–12 months later. Serum was obtained from the rats by cardiac puncture just before death and analysed for protein composition (paper electrophoresis) and for conglutinin titre[2]. Sera were prepared in rabbits against rat whole-serum and against rat γ-globulin obtained by ethanol fractionation[3]. Antibody protein was conjugated with lissamine rhodamine *B* 200[4] and applied to sections fixed in ethanol after preparation from freshly frozen silicotic lung in a cryostat. The customary control procedures were employed.

The serum globulin and conglutinin (Table 1) tended to show changes similar in type to those found by Ceppellini and Pernis[5] in human silicosis. In rats with silicosis more than 6 months the serum globulin was sometimes raised, but there was no elevation in three long survivors. When an increase occurred it mainly affected γ-globulin, though in some animals there was also a slight elevation of β-globulin. Silicotic rats often had a considerable augmentation of conglutinating activity in their sera, but this rise was related neither to the duration of their disease nor to the occurrence of hyperglobulinæmia.

Table 1. SERUM FINDINGS IN EXPERIMENTAL SILICOSIS

Duration of disease (months)	Conglutinin titre	Hyper-globulinæmia
1	1 in 32	Absent
1	8	Absent
1	64	Absent
3½	8	Absent
3½	256	Absent
6½	8	Present
6½	128	Present
6½	4	Present
11	64	Present
11	32	Absent
11	128	Absent
12	4	Absent
12	32	Present

By immuno-electrophoresis[6], it was established that the rabbit antiserum to rat whole-serum produced precipitin bands to all components of rat serum proteins, whereas the rabbit antiserum to rat γ-globulin showed the characteristic bands in the appropriate zone with only very slight β-globulin activity. Although many of the rat silicotic nodules showed hyalinization, no fluorescence of their connective tissue was observed in any of the sections treated with conjugated antibody to rat whole-serum or to rat γ-globulin. Some fluorescence did, however, occur within the larger blood vessels and in exudate lining alveoli, and was, presumably, a reflexion of the presence of serum proteins. In view of this negative finding in the fibrous tissue of the nodules it was necessary to provide a positive control to our technique. Sections from a human rheumatoid nodule were therefore treated with a conjugated antiserum to human globulin. Vivid specific fluorescence of the central hyaline material was obtained, thereby confirming the findings of Vazquez and Dixon[7].

Chemical analysis of the hyalinized connective tissue from human silicotic nodules showed that it consisted of 80 per cent protein, but only about 40 per cent of this was thought to be collagen, the remainder resembling serum β- and γ-globulins[1]. The immunological work of Ceppellini and Pernis[5] supported this view. Using a different technique and experimentally induced silicosis, we have been unable in mature nodules to provide evidence of the presence of globulins similar to those of the serum. Moreover, the conglutinin titre and the occurrence of hyperglobulinæmia bore no consistent relationship to the stage of maturity of the lesions. Our essentially negative results may mean that the induced lesions did not contain globulins or that, if present, our technique was not sufficiently sensitive to detect them. Further chemical and immunological investigations are evidently needed to decide whether or not the pathogenesis of the experimental disease is essentially different from that of human silicosis.

Dr. Nagelschmidt kindly provided the sized quartz dust.

Transplantation of Murine Leukæmia by Unconventional Routes

A LYMPHOCYTIC type of leukæmia which arose spontaneously in a mouse of strain *CBA* has already been described[1]. Investigation of transmission of this leukæmia between mice of the strain of origin revealed the following features: transmission could not be effected by the injection of cell-free homogenates of leukæmic organs into mice either before or after birth; transplantation bioassays of single-cell suspensions of morphologically intact leukæmic cells showed that an average intraperitoneal inoculum of only two cells would consistently achieve successful transplantation to 50 per cent of injected mice (that is, $TD_{50} = 2$ cells); similar very low TD_{50} values were obtained from assays performed by the subcutaneous or intravenous routes; no solid tumours appeared at sites of subcutaneous injection, and no trace of ascites appeared after intraperitoneal injection of the cells.

With the foregoing features of this strain of leukæmia in mind, I was encouraged to attempt transplantation of the cells by several unconventional routes: pervaginally, pernasally, via the conjunctival sac, percutaneously, and by limited surgical incision of the skin using instruments contaminated with viable cells. In each case, the inoculum consisted of a single-cell suspension of viable leukæmia cells in Tyrode solution containing 5 per cent of *CBA* mouse serum; the total number of cells available in each inoculum was within the range 10^4–10^5.

For pervaginal transplantation, a drop of suspension was placed in the vagina with a smooth-tipped Pasteur pipette; pernasal transplantation was effected by placing a drop of suspension on the noses of inverted lightly anæsthetized mice; application to the eyes was made simply by depositing a drop of suspension on the globe of each eye of anæsthetized mice. All the above applications were made with meticulous avoidance of trauma to the mucosal surfaces. For percutaneous transplantation, the fur was plucked from one flank and the skin was scarified with a needle sufficiently lightly to penetrate the keratin layer without drawing blood; a drop of suspension was rubbed into the scarified surface with a glass rod. To test for transplantation of cells from contaminated instruments, scissors which had been dipped in cell suspension were used to remove a small V-shaped segment from the periphery of the auricles of mice, a minor surgical procedure commonly employed to differentiate mice that are to be caged together.

The incidence of successful transplantation by these various routes, together with the survival-times of affected mice following treatment with cells, are given in Table 1.

Table 1. INCIDENCE OF LEUKÆMIA, AND SURVIVAL TIME OF AFFECTED MICE, FOLLOWING IMPLANTATION OF LEUKÆMIA CELLS AT UNUSUAL SITES

Site	Proportion of treated mice developing leukæmia	Survival-times (days)
Vagina	1/4	20
Nasal cavity	11/12	15–17
Conjunctiva	0/22	—
Scarified skin	4/4	24–27
Incised skin	6/6	18–37

It is probable that the success of intravaginal transplantation is influenced by œstrus; an effect of œstrus at the time of painting the cervix with benzopyrene has been demonstrated for the chemical induction of cervical neoplasia[2].

Since most of the cells deposited on the globe of the eye are likely to accompany the tear stream into the naso-lacrymal duct, it may appear surprising that this transplantation route was far less effective than the direct instillation of cells into the nose. On the other hand, the method used to introduce cells into the nose would be expected to result in cells reaching the ethmoid region or being inhaled into the bronchi, where they would come to lie on non-stratified epithelium; cells entering the nasal cavity from the naso-lacrymal duct would be unlikely to reach these regions.

About ten days after application of cells to the scarified skin, temporary enlargement of the regional lymph nodes was observed, suggesting that leukæmia cells may have entered the lymphatics of the skin.

In no case was a local tumour seen at any of the sites of implantation used.

The results of these experiments seem to justify use of the term 'contagion' to describe the means of cellular transplantation reported, and it is clear that a strictly 'aseptic' routine must be followed if mixing of cell strains is to be confidently avoided in laboratories where several different leukæmia strains indigenous to the same mouse strain are maintained by serial transplantation. It is not inconceivable that occasional accidental transplantation could occur from cannibalization of dead leukæmic mice by isologous cage-mates.

Although a considerably longer latent period usually distinguishes the development of virus-induced leukæmia from that of transplanted leukæmia, the present findings indicate that stringent criteria for cell exclusion must be observed in all experiments which purport to demonstrate subcellular transmission of leukæmia.

All mice dying of leukæmia following the introduction of cells by the unusual routes described showed the typical pattern of generalized visceral infiltration, with no signs referable to the point of entry of the cells. This finding seems to emphasize that evidence for a multifocal origin of spontaneous leukæmia, commonly mooted in text-books of general pathology, cannot be got from histopathological or morbid anatomical study of the leukæmic individual.

BIOLOGY

Effect of Thyroxine Plus Thiourea on the Early Development of the Chum Salmon (*Oncorhynchus keta*)

Available evidence indicates that the effect of the thyroid hormone in fishes is morphogenetic rather than metabolic. Thyroid treatment stimulates growth differentially during development, so that proportions of fins, body-wall, weight and length are altered. Deposition of guanine in the skin of the salmonids[2] and the rate of formation of scales in sturgeons (genus *Acipenser*) are accelerated[3]. Working with the chum salmon, Dales and Hoar[4] found that thiourea slowed down growth and morphogenetic processes. They found that, while the body-wall started growing over the yolk sac very early in the case of alevins treated with thyroxine, this process was considerably retarded in the forms treated with thiourea. The experiment, the results of which are presented here, was undertaken in order to ascertain the effect of a mixture of thyroxine and thiourea on the early development of the chum salmon. It was of interest to find out whether, in a mixture, the effect of thyroxine would be dominant over that of thiourea or vice versa.

Chum salmon eggs were collected by stripping fish migrating into Cultus Lake, B.C., on November 6, 1954. They were fertilized immediately and brought to the University hatchery. The eggs were transferred to 4 troughs (5,000 in each). The capacity of each trough was 10 litres. They were placed in a running tap-water bath; the first trough was the control and contained tap water; the second contained a thyroxine solution (1 : 12,000,000); the third one contained thiourea (0·05 per cent) and the fourth contained a mixture of thyroxine (1: 12,000,000) and thiourea (0·05 per cent). The solutions were aerated at all times, and their temperatures ranged from 5° to 11° C. during the 92 days of the experiment. Temperature was recorded daily and the solutions changed weekly. Dead eggs were removed once a week.

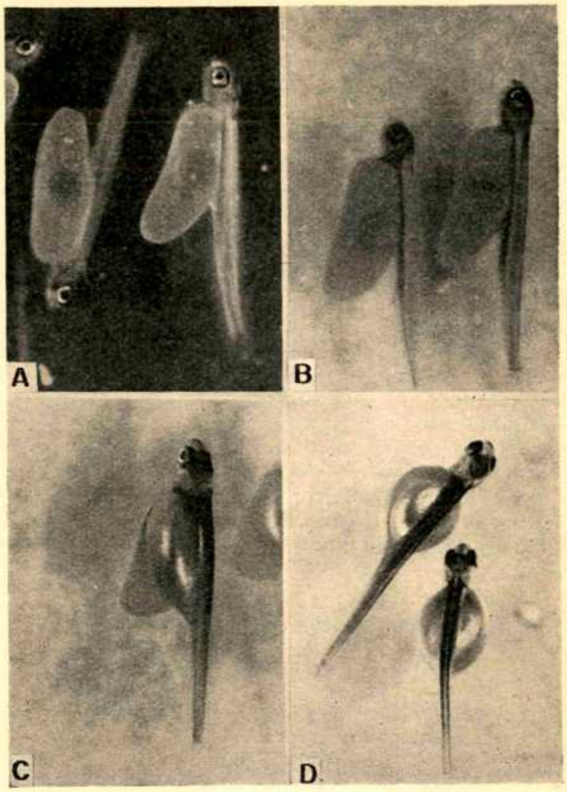

Fig. 1. Alevins soon after hatching. *A*, Control; *B*, treated with thiourea; *C*, treated with thyroxine; *D*, treated with thyroxine + thiourea. Sizes range from 20 to 26 mm. Note the growth of the body-wall and deposition of guanine in *C* and *D*

As a result of heavy mortalities from fungal infection, the experiment was terminated 92 days after it commenced. It is of interest to point out that, while the eggs in the other three tanks suffered heavy fungal attack, none of the eggs in the thiourea tank was infected. Since the eggs in the thyroxine and thiourea mixtures were infected, it may be speculated that the infecting organisms found it possible to thrive in the presence of thyroxine even though thiourea was also present, although they did not survive in a pure thiourea solution.

Eggs in the thyroxine and thiourea mixture hatched first (56 days after fertilization), followed by those treated with thyroxine (60 days), control (64 days) and those treated with thiourea (67 days).

The early development of the chum salmon has already been studied[5]. Development of the embryos prior to hatching, their morphological characteristics before and after hatching, rate of yolk absorption, pigmentation, guanine deposition, rate of heart-beats and mouth and gill movements were investigated. Observations made in the case of control, thyroxine and thiourea groups were similar to those made by Dales and Hoar[4] and will not be repeated here.

Careful examination showed that the development of eggs incubated in a mixture of thyroxine and thiourea solutions is very similar to that of eggs treated with thyroxine alone and the observations of Dales and Hoar[4]. Small variations do occur but are not of any significance. The accompanying photographs (Fig. 1) show the alevins from the four tanks soon after hatching. In these photographs, the similarity between the alevins treated with thyroxine and those treated with thyroxine + thiourea, and the dissimilarity between the alevins treated with the mixture and those treated with thiourea as well as the control alevins are obvious.

From these results it would appear that during the early development of the chum salmon the influence of thyroxine prevails over that of thiourea. While thiourea exerts some influence in the absence of thyroxine, in a mixed solution the effects of thyroxine are dominant and completely suppress the effect of thiourea, even though the former is present only in a much more dilute form than the latter.

Oocyte Numbers as a Diagnostic Character for the Identification of Ammocœte Species

THE nature of the relationship between the European brook lamprey *L. planeri* and the closely related parasitic form, *L. fluviatilis*, has been the subject of considerable discussion, especially since the classical studies of Weissenberg[1-3] showed that differences between these species are based on biological rather than morphological criteria. The difficulty of finding taxonomic characters for the identification of their larval stages has been a matter of great inconvenience to workers in this field, especially since the two species often occur together in the same river system.

In view of the great difference in fecundity between the adult brook and river lampreys which produce about 1,000–2,000 and 4,000–40,000 eggs respectively[4-6], the suggestion was made by Weissenberg[3] that there would be corresponding differences in the number of oocytes at the ammocoete stage. This point has now been examined, using ammocoetes from the R. Yeo (Somerset) and R. Nevern (Pembrokeshire), which are known to consist of *L. planeri* only, and others from the Rivers Teifi and Usk, where both species occur.

Although the larval ovary extends almost throughout the entire length of the body cavity, the oocytes tend to occur in greatest number in the region of the mesonephric kidney anterior to the first dorsal fin. Counts have been made of the number of oocytes in random transverse sections of this part of the body for a large number of animals and the results plotted as a frequency histogram (Fig. 1). Since practically all male ammocoetes develop a few oocytes during the earlier stages of larval life, all the groups examined show a fairly high proportion with small oocyte numbers (less than 20). In *planeri* ammocoetes from the R. Yeo only one case has been recorded of more than 45 oocytes per section, but for both the Teifi and the Usk no less than 32 per cent have exceeded this figure, and at the upper limit numbers of more than 100 have occurred. The frequency distributions for the Teifi and Usk also appear to indicate the presence of two groups with smaller and larger oocyte numbers, the latter with a frequency peak at 50–55 oocytes/section. As it seemed probable that the animals with the larger oocyte numbers represented *fluviatilis* ammocoetes, estimates were made of the total numbers of oocytes in the whole ovary in animals selected from the upper and lower ranges of oocyte numbers (Table 1). This was done by the laborious method of taking sample serial sections through the whole ovary at intervals of 1–2 mm. using the microtome to measure these intervals. Measurements of the average oocyte diameters for each animal enable the total number of oocytes to be estimated. For *planeri* ammocoetes (R. Yeo and R. Nevern) these estimates have varied from 4,900 to 10,600 for animals with 25–50 oocytes/section. For material from the Teifi and Usk, ammocoetes with 60 or more oocytes/section have given total counts of 8,300–26,000. Bearing in mind the reported range of egg production in *L. fluviatilis*, it seems safe to refer the higher counts to this form, and, while there may be some overlapping of oocyte numbers in the two species, counts in excess of 14,000 or 65/section may be taken as indicating river lamprey ammocoetes. Although *P, marinus* is known to spawn in the Usk, the possi-

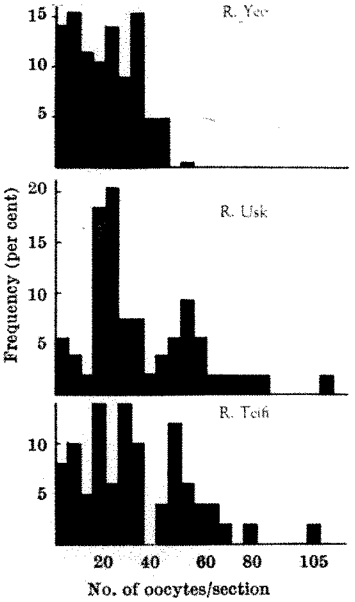

Fig. 1. Frequency histograms for oocyte numbers in ammocoetes from three different rivers

	99	70	18,000	81
	99	81	22,800	70

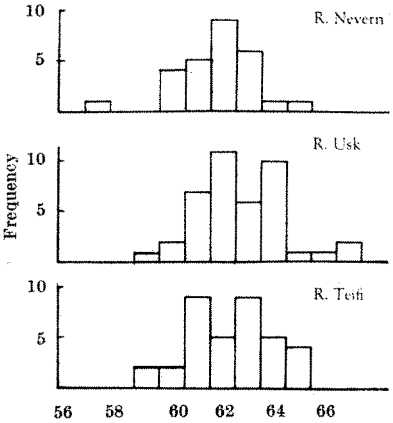

Fig. 2. Frequency distribution of myotome numbers in ammocoetes from three Welsh rivers

bility that ammocoetes with the largest oocyte counts might belong to this species can be excluded, as a number of sea lamprey larvæ which have been examined have given total counts of more than 100,000.

Myotome counts have been made on 104 ammocoetes from the Rivers Nevern, Teifi and Usk and, while the Nevern population gave a unimodal distribution with the maximum frequency at 62, histograms for the Teifi and Usk were bimodal with frequency maxima at 61, 63 and 62, 64 respectively (Fig. 2). Although previous workers have reported no significant differences in myotome numbers for the adults of *L. planeri* and *L. fluviatilis*[7-10], it was thought possible that the bimodal distributions might be due to small differences in the myotome numbers of the ammocoetes. An examination was therefore made of the gonads in two groups of ammocoetes from the Teifi and Usk, falling within the upper and lower ranges of myotome numbers. Of eleven female ammocoetes with 64–66 trunk myotomes three were of the *fluviatilis* type with more than 65 oocytes/section; the other group of twelve animals with 59–63 myotomes contained one ammocoete of this species with 110 oocytes/section. Since *planeri* ammocoetes were found over the whole range of myotome numbers (59–66) there is no evidence for differences in the distribution of myotome numbers in the two species.

Although the method of identification based on oocyte numbers has obvious limitations, it is quite possible that in older ammocoetes the males also could be differentiated by the number of spermatogonial follicles and the relative size of the testis. In any event the ability to identify at least the female ammocoetes provides the necessary basis for further attempts to discover other more convenient diagnostic characters.

Warm-water Species in the Plankton off Newfoundland during Winter Months

SINCE September 1959 plankton samples have been taken, at monthly intervals whenever possible, with the Continuous Plankton Recorder[1] between Iceland and Newfoundland. The Recorder is towed by commercial ships and obtains a continuous sample of plankton from a depth of 10 m. This sampling is part of a regular survey of the plankton of the North Atlantic Ocean and North Sea conducted from this Laboratory.

The western portions of the Newfoundland Recorder routes during the winter months of 1959–60 are shown in Fig. 1. In this sea area, boreal species, particularly the copepod *Calanus finmarchicus* and the euphausiid *Thysanoessa longicaudata*, usually constitute almost the whole of the zooplankton sampled by the Recorder. During December 1959, however, many *Calanus* present in the region off the Belle Isle Strait agreed with the description by Jaschnov[2] of the stage V copepodites of *Calanus glacialis*, an arctic form. In February 1960, the sampling followed a course towards Cape Race, and a clearly defined patch of warm-water species was found off the north-eastern slope of the Grand Banks. These included the copepods *Nannocalanus minor*, *Clausocalanus arcuicornis*, *Lucicutia flavicornis*, *Pleuromamma gracilis*, *Pleuromamma borealis* and *Heterorhabdus spinifrons*, together with the euphausiids *Thysanoessa gregaria* and *Euphausia krohnii*. The record for March followed closely a similar course to that taken during February; no warm-water species were observed but two species normally associated with cold-water conditions, the copepod *Metridia longa* and the chætognath *Sagitta maxima*, appeared in the same area. In April the Recorder was towed along a more southerly course and again no more warm-water species were encountered, but two patches of cold-water copepods, *Metridia longa* and *Calanus hyperboreus*, were found.

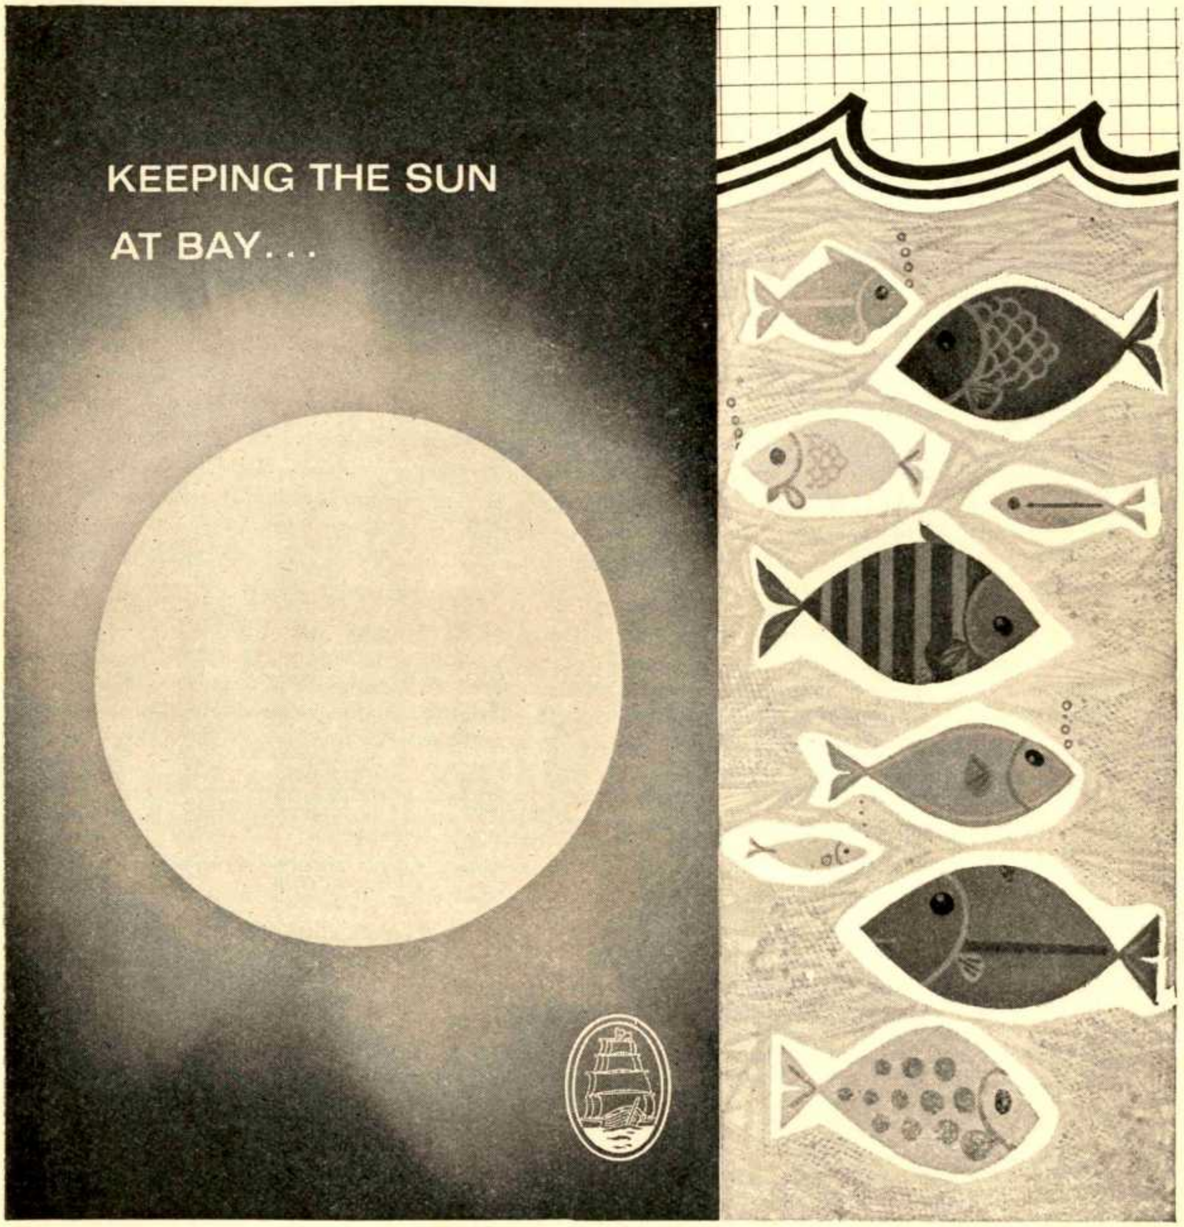
During early March 1961, a patch of warm-water species was again found, on this occasion between 52° 00′ N., 42° 25′ W. and 50° 20′ N., 43° 25′ W., that is, between 90 and 140 miles east of the patch observed during February 1960.

The occurrence of warm-water species in February and March, when surface temperatures in the region are usually close to the annual minimum[3], is related presumably to the changing pattern of water movement.

The area east of Newfoundland is influenced, from the north, by the cold water of the Labrador Current and, from the south, by the warmer waters of the North Atlantic Current, once thought to be formed by a branching of the Gulf Stream System[4]. Fuglister[5,6] has suggested that there is no real branching; but that the Gulf Stream System in this region consists of a number of disconnected filaments of current the pattern of which is variable.

The presence of warm-water species to the north-east of the Grand Banks, therefore, may indicate a temporary extension of the Gulf Stream System. It is not known whether such events occur at regular or irregular intervals, but it is interesting to note that Kielhorn[7] found several warm-water species of zooplankton in January and February at Weather Station *B* in the Labrador Sea during a survey throughout 1950.

Stommel[8] has directed attention to the lack of knowledge about fluctuations in ocean currents,



THE SUN'S THIRST is remorseless and insatiable. In the world's arid spaces, loss of water by evaporation puts both life and industry in jeopardy. Techniques developed by Price's for spreading a monomolecular film of Cetyl Alcohol blends on the water surface have successfully reduced evaporative loss by as much as 35%. Government departments and divisions of industry concerned with the conservation of water are employing Price's materials and techniques throughout the world.

A PRICE'S TECHNICAL PUBLICATION, "Fatty Alcohols for Water Conservation", tells the whole story—and may well show how our resources, and resourcefulness, can be of service to you. You are invited to take full advantage of Price's wide experience and unique facilities at our Bromborough Pool plant for creative oleochemical research, pilot-scale development, and our specialist technical sales service.

Comparative Neuropathology

By J. R. M. Innes, *Brookhaven National Laboratory, and* L. Z. Saunders, *Smith, Kline & French Laboratories, and University of Pennsylvania*

With contributions by
Ludo van Bogaert, *Institut Bunge, Antwerp*
R. Fankhauser, *University of Berne*
W. J. Hadlow, *U.S. Department of Agriculture and Agricultural Research Council Field Station, Compton, Berks, England*
K. V. Jubb, *Ontario Veterinary College, Guelph*

October, 1961, about 825 pp. (8 in. × 10 in.), approximately 215s.

COMPARATIVE NEUROPATHOLOGY is a combination atlas, text, and reference work. The coverage of neurological diseases is world-wide in scope, with a correspondingly international bibliography of approximately four thousand references. Of the about six hundred selected illustrations, a substantial majority are photographs, including two colour plates. The unusually large format of the book was chosen to permit the reproduction of the photographs in complete detail; many full-page plates are included. All aspects of cerebrospinal fluid examination are discussed comprehensively. Wherever possible the authors have made analogies between animal and human neuropathology.

Effect of Ferric Dimethyldithiocarbamate on the Rooting of Cuttings of *Hevea brasiliensis*

A METHOD involving the technique of mist-propagation which has led to the successful rooting of leafy clonal cuttings of the Para rubber tree, *Hevea brasiliensis*, has been reported earlier[1,2]. A routine application of 'Fermate' dust (ferric dimethyldithiocarbamate, kindly supplied by Messrs. E. I. Dupont de Nemours and Co., Inc.) to the base of the cuttings was mentioned in these publications and elsewhere by Levandowsky[3] also working with *Hevea* cuttings.

This compound was used as a fungicide to protect the trimmed base of the cutting which might be subject to fungal attack; but later observations showed that rotting of the stem was not usually severe, even on untreated cuttings under mist-propagation conditions, and poor rooting was often due to the deterioration of the leaves, which resulted from a long period under the spray. Improved rooting where this compound was used could not therefore be attributed entirely to its fungicidal effect and recent work has established its importance in stimulating initiation of roots in *Hevea* cuttings. Some of the evidence is presented here.

After trimming, the cuttings were stood in water for a few minutes to coagulate the latex, which is then peeled off; the bases were then dipped into the dithiocarbamate powder (diluted in talc to give 35 per cent of active ingredient) to a depth of 1 in. and immediately planted into the rooting beds containing a 1 : 1 mixture of sawdust and sand. Talc was used as the control and treatments replicated at least three times. After forty days under mist, periodical inspections for rooting were made; dead cuttings or those in poor condition due to deterioration of the leaves were discarded. Table 1 shows the rooting records from some of these experiments.

Table 1 shows that clones *RRIM* 501, 605 and 632, *AVROS* 157 and *PB* 5/63 show little or no success where untreated, but application of 'Fermate' improves rooting significantly at all stages. With *GT* 1 (two experiments) and *PB* 86 there is good final success with both treatments, but rooting is markedly accelerated where 'Fermate' is applied.

Three concentrations of 'Fermate' and the talc control were compared in two experiments with clones *PB* 86 and *RRIM* 501; the rooting records are shown graphically in Figs. 1 and 2.

Fig. 1 shows that all three concentrations of 'Fermate' accelerated the rate of rooting of *PB* 86 cuttings relative to the talc control. This is most marked with the 75 per cent powder treatment, which achieves 100 per cent success after 75 days. After 98 days, this treatment is significantly better than the control, and the 17·5 per cent concentration.

Fig. 2 illustrates the rooting of *RRIM* 501 cuttings treated similarly. Again, the 75 per cent concentration results in greatest final success and induces earlier rooting. After 114 days, all three levels of 'Fermate' show significantly greater success than the control, which has given only 10 per cent final success.

'Manzate', 'Zerlate' and 'Parzate', manganese ethylenebisdithiocarbamate, zinc dimethyldithiocarbamate and zinc ethylenebisdithiocarbamate respectively, all at 40 per cent concentration, were used in comparison with 40 per cent 'Fermate' and talc in one experiment. All four compounds led to significant increases in rooting success relative to the talc control. In final success the superiority of 'Fermate' over 'Manzate' and 'Parzate' was not established, although it was significantly better than 'Zerlate'.

Preliminary experiments using growth substances including indole-3-butyric acid and naphthalene acetic acid have proved unsuccessful in promoting root initiation in leafy clonal *Hevea* cuttings, but more experiments with these compounds and with other dithiocarbamates are in progress and will be reported in detail elsewhere.

Van der Kerk *et al.*[5] first reported that the compound *S*-carboxy-methyl dimethyldithiocarbamate showed growth-regulating activity. Ng and Carr[4] also showed that this compound at an optimal concen-

tration of 20 mgm./l. effected a stimulation of growth of wheat coleoptile segments and had an activity of the same order as indole-3-acetic acid.

In our experiments, related dithiocarbamate compounds have been used at extremely high concentrations and have shown a marked effect on root initiation which cannot be completely explained by their fungicidal action.

Possibilities of Vegetative Propagation in the Coconut (*Cocos nucifera* L.)

The coconut is a perennial palm which takes 6–8 years to begin bearing, but later continues to bear right through the year and all through its life, extending during a period of 60 years or more depending on local conditions. It is highly cross-pollinated in Nature, particularly the tall variety, and is propagated only through seed. These features, namely, the long interval between generations and the highly heterogeneous nature of the plant population, are proving to be great handicaps in making quick headway in coconut breeding. The perennial nature of the palm, on the other hand, is of advantage, in that the benefit from any improvement can be enjoyed over a very long period.

Vegetative propagation is the one sure method of propagating lines true to type, and it could be very valuable in coconut research, as has been recently pointed out (refs. 1–3). In the coconut, which is a monocotyledonous plant devoid of cambium, the prospect of vegetative propagation is at present remote, but there are indications that the problem is worth following up. In Nature, tendencies on the part of the palm to produce aerial roots under adverse conditions in the environment and/or diseased conditions of the palms have been noticed[4]. Rare cases of the palms producing suckers have also been reported[5,6]. If these could be produced at will, some definite progress in vegetative propagation of coconut

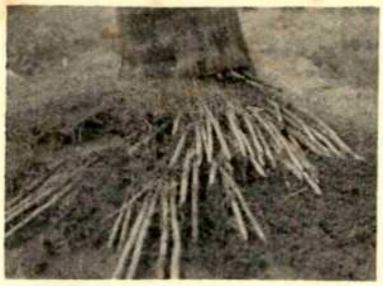

Fig. 1. Roots formed at the girdled portion on the coconut stem above ground-level where the growth substances were applied

would have been made. That rooting can be artificially induced in the stem of the coconut palm above ground-level through marcottage, has been reported[4]. After the formation of large numbers of roots, the crown can be separated by severing the palm just below the rooted region and planting elsewhere. This procedure, of course, does not permit the multiplication of desirable palms, but may help to rejuvenate and to maintain them for a much longer period than otherwise.

It is now well established that use of appropriate growth regulators in optimum concentrations can induce rooting and other meristematic activity in a variety of plants. In order to investigate how far their use in coconut will be helpful in inducing meristematic activity leading to rooting and probably suckering too, trials were carried out at this Research Station with mixtures of selected growth regulators, namely, α-naphthalene acetic acid, indole-3-butyric acid and certain purine compounds such as adenine, adenosine, alloxanthine and uric acid, in different concentrations and proportions. The growth regulators were applied as an aqueous spray or in lanolin paste after girdling or debarking the stem near ground-level. The points of application were then covered with soil which was kept moist during the rainless period by artificial watering. Initiation of roots was observed in about 1 yr. in the case of the following formulations only and roots were profuse (Fig. 1) in about eighteen months: 1 per cent indole-3-butyric acid in lanolin; 0·05 per cent naphthalene acetic acid in lanolin; and a mixture of 20 ml. of 80 p.p.m. adenosine, 5 ml. of 20 p.p.m. naphthalene acetic acid and 15 ml. of water applied as spray. There was no sign of suckering seen in any of the treatments so far.

These results thus indicate that inducing meristematic activity in the coconut is possible. Further systematic trials with a larger number of important growth regulators alone and in combinations and mixed in different proportions are under way to assess their relative merits.

Our thanks are due to Mr. A. K. Kamalakaran for his assistance.

Effect of Red and Far-red Irradiation on the Germination Process in Seeds of *Pinus sylvestris* L.

SINCE the first work on the red – far-red reversible mechanism controlling the germination of lettuce seeds[1], many investigations have shown the same type of light-controlled germination in seeds of herbaceous plants as well as in tree seeds[2]. In the genus *Pinus* it has been reported for *P. virginiana* Mill.[3], *P. taeda* L.[4] and earlier by me for *P. sylvestris* L.[5]. Results from further work on the red – far-red controlled germination in seeds of *Pinus sylvestris* L. are described here.

The germination experiments were carried out in Jacobsen apparatuses at +25° C. during 20 days. For the irradiations the following equipment was used: red irradiation from red fluorescent tubes (Philips *TL*/15, emission range between 5800 and 7200 Å. with a sharp maximum at 6600 Å.), far-red irradiation from a 500-W. incandescent lamp with a 10-cm. water filter and double layers of blue and red 'Cellophane' (transmission from 6800 Å. and upwards together with some transmission in blue). The intensity of both sources was $3\cdot5 \times 10^3$ ergs/cm.^{2} sec. The time of irradiation, the same for all the experiments here reported, was 30 min. The irradiations were started after 6 hr. imbibition. The respiration measurements were made by the Warburg direct method. Cell divisions in the seeds were examined by aceto-orcein staining of embryo smears[6]. All handling of the seed materials was performed in green safe-light[7].

As in lettuce seeds, the light-requirement for germination can be satisfied by a single irradiation. Maximum sensitivity is obtained after 6–12 hr. imbibition. As reported earlier[5,8], seeds which have not imbibed water can also be influenced by irradiation. From the action spectrum it is evident that red light around 6600 Å. is most effective in stimulating germination. Stimulation can be nullified by far-red irradiation immediately afterwards (see Fig. 1). With a time-lapse of 48 hr. between a red and a far-red irradiation, the latter became completely ineffective. At that time, all seed embryos investigated showed mitoses. The seed temperature between the red and far-red light impulses was of importance, but not the temperature during the irradiations. The light-requirement of the seeds for germination depends on seed coat being intact. After a small puncture or complete removal of the seed coats, germination in the dark became high. It was then impossible to inhibit germination by far-red irradiation. The same results were obtained after stratification of the intact seeds (storage on wet cotton pads in Petri dishes at +2–4° C. in the dark for 2 weeks).

In order to establish whether the red – far-red irradiations influence any phases of the germination process earlier than the visible germination, work on seed respiration and on the occurrence of mitoses in seed embryos was carried out during the first three days of the germination period. Some of the results are presented in Fig. 1.

The respiration measurements shown in Fig. 1 were started after 48 hr. imbibition, that is, 42 hr. after the start of irradiation, and similarly for the work on mitoses. The values for respiration are based on 3 × 50 seeds per experiment and expressed in μlitres oxygen/50 seeds and ¼ hr. The values for mitoses are the percentages of embryos investigated with mitoses determined on 2 × 10 embryos per

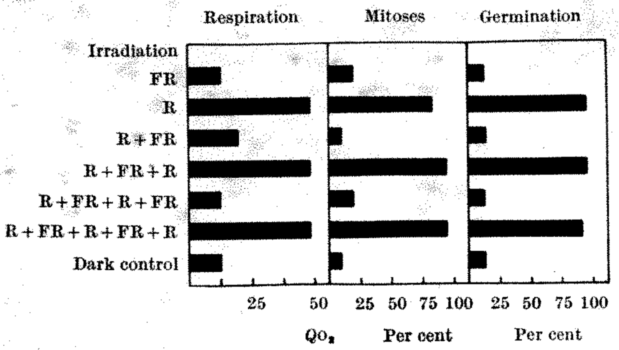

Fig. 1. Reversible effects of red (R) and far-red (FR) irradiations on the respiration-rate, the occurrence of mitoses in embryos and the percentage of germination in seeds of *Pinus sylvestris* L.

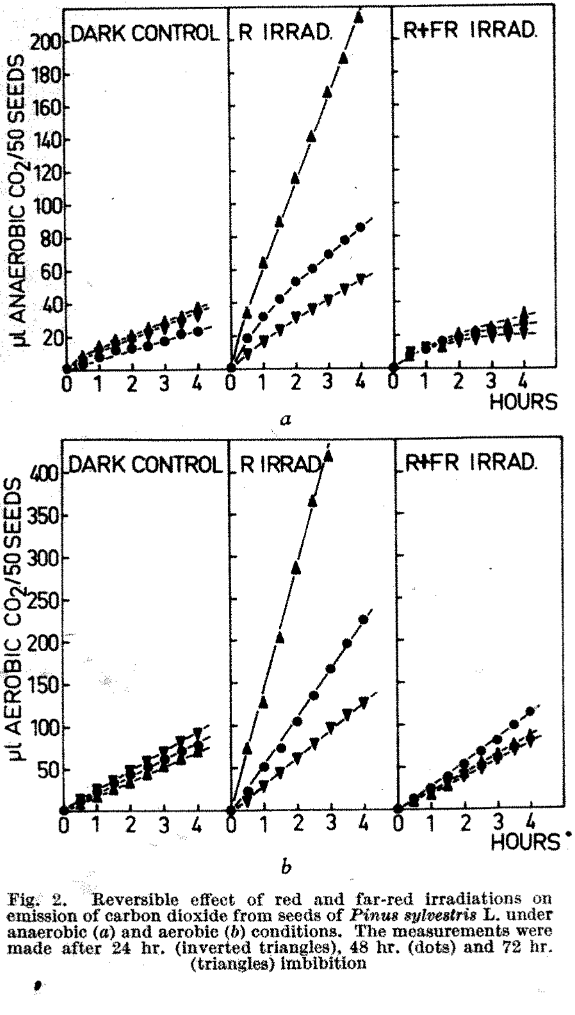
experiment. The germination values are based on 2 × (100–10) seeds per experiment (after 20 days). The stimulating effect of red irradiation is significant (0·001 > P) in all the three groups of experiments. From these results it is evident that the effect of red and far-red irradiations on the germination can be traced quite early in the germination process. Red light stimulates, and far-red light inhibits, respiration as well as mitotic activity in the embryos. A significant increase in respiratory activity induced by red light can be observed after imbibition for 24 hr. and stimulation of mitotic activity after 36 hr. The visible signs of germination (protruding rootlets) appear first after more than 48 hr. imbibition. In seed samples irradiated with red + far-red the inhibited visible germination can be traced in an inhibition of respiration and mitotic activity. In recently published work on lettuce seeds[9] it has been stressed that the occurrence of mitoses in the embryos is independent of the red – far-red irradiation, as is also the respiration of the seeds before the appearance of the first visible signs of germination. This is evidently not the case for the seeds investigated here, which in many other respects show the same responses as lettuce seeds.



a

b

Fig. 2. Reversible effect of red and far-red irradiations on emission of carbon dioxide from seeds of *Pinus sylvestris* L. under anaerobic (*a*) and aerobic (*b*) conditions. The measurements were made after 24 hr. (inverted triangles), 48 hr. (dots) and 72 hr. (triangles) imbibition

In other respiration measurements the effects of red and far-red irradiations on the emission of carbon dioxide under aerobic and anaerobic conditions have been investigated after different times of imbibition. The results are given in Fig. 2.

For both aerobic and anaerobic conditions, the rate of emission of carbon dioxide is already higher after 24 hr. in the red-irradiated seeds as compared with the dark control and the red + far-red irradiated seeds (0·001 > P). There is thus an effect of irradiation, not only on the aerobic but also on the anaerobic phase of the seed respiration. The effect on the anaerobic phase can perhaps be combined with the red – far-red effect in the synthesis of the TPN-linked triosephosphate dehydrogenase[10].

The results will be published in detail elsewhere. This work has been supported by a grant from the Swedish Forest Research Foundation.

MICROBIOLOGY

Numbers and Types of Bacteria from the Rhizosphere of Pasture Plants : Possible Occurrence of *L*-forms

During work on micro-organisms in meadow and pasture soils[1] large numbers and high activity were found in the surface soil layer of 0–5 cm. I decided to investigate the plant roots which form a dense mat in this zone since these might influence micro-organisms. Microscopical counts and estimations of the quantity of fungal and actinomycete mycelia in the soil between the roots and in soil washed from the roots were carried out using stained agar films as Jones and Mollison did, but with phase-contrast observation[2,3]. Agar plate counts were used as a second method, yielding various results, and an attempt to explain this is the purpose of this communication.

Table 1. NUMBERS OF BACTERIA IN THE RHIZOSPHERE OF *Holcus lanatus* AND SURFACE SOIL

		No. $\times 10^9$			
		Sandy loam, dry		Clay, moist	
Date	Log dilution	*Holcus lanatus*	soil	*Holcus lanatus*	soil
12.11.1957	7	170	1·50	156	1·25
	8	—	—	616	
20.1.1958	7	565	0·25	190	0·37
	8	4,430		1,260	
23.4.1958	7	367	1·24	155	0·99
	8	2,810		866	
3.6.1958	7	1,980	1·09	420	0·68
	8	2,610		2,490	
16.9.1958	7	563	1·22	1,080	1·36
	8	1,490		8,360	

Samples were collected from two locations. The suspensions from 0–5 cm. surface soil and roots obtained by vigorous shaking for 5 min. with sterilized tap-water were diluted by successive steps of 1:10 to 1:10^7 or 1:10^8 and plated with soil extract agar cooled to 45° C. When collected the day before, the samples were kept at $+2$–4° C. in a refrigerator to avoid multiplication of the bacteria.

Table 1 shows the numbers of bacteria (average values from five replicate plates) in the rhizosphere of *Holcus lanatus* on five dates as an example for twelve species of plants investigated. These were: *Dactylis glomerata, Helictotrichon pubescens, Poa pratensis, Trifolium repens, Plantago lanceolata, Achillea millefolium, Galium mollugo, Rumex acetosa*, in a meadow on sandy loam, and *Alopecurus pratensis. Festuca pratensis*, and *Ranunculus acris* in a moister meadow on clay soil. *Holcus lanatus* was collected from both locations. The magnitude of bacterial numbers is surprising and has not been reported before. It reached 8×10^{12}/gm. and depended largely on the logarithm of the dilution. In contrast the values for the soils are much lower, between 1 and 2×10^9/gm. The maximum number of rhizospheres in sandy loam soil occurred in winter when the soil population was a minimum whereas in the clay soil rhizosphere maximum was observed in early autumn when soil bacteria also reached their greatest number.

These results exclude the assumption of normally developed bacteria occurring in such large numbers. Assuming a minimum size for a small coccoid soil form of $0{\cdot}125\mu^3$, 8×10^{12} of these would fill completely 1 cm.^{3} without leaving any space between them. Even if the sample consisted entirely of bacteria of this size it could contain only about 4×10^{12}/gm. Experimental error, on the other hand, could be excluded because the control plates showed no colony growth in any case. Plates inoculated with diluted rhizosphere suspension showed even with logarithm of dilution 8 up to 2,000 colonies per plate, which could be counted with reasonable precision using a binocular microscope. Agar films gave maximal numbers between 300 and 400×10^9/gm. in the rhizosphere of *Holcus lanatus*, which had the highest numbers among all plants investigated. This is in any event considerably lower than the plate counts, which normally yield lower numbers than direct counts.

Table 2. PERCENTAGE COMPOSITION OF BACTERIAL POPULATION ISOLATED FROM SOIL AND RHIZOSPHERE DILUTION PLATES

Date	Source	No. of isolates	*Arthrobacter*	*Mycobacterium*	Gram-positive rods	Gram-negative rods	Cocci	Motile bacteria
12.11.1957	*Trifolium repens*	100	74	17	—	1	8	
12.11.1957	*Ranunculus acris*	40	91	6	2	1	—	
12.11.1957	*Alopecurus pratensis*	50	88	—	4	2	6	
3.6.1958	Sandy loam, dry	51	48	4	16	32	—	18
3.6.1958	*Trifolium repens*	59	35	3	5	57	—	33
3.6.1958	Clay, moist	53	57	2	8	24	9	11
3.6.1958	*Ranunculus acris*	54	48	5	15	32	—	37
3.6.1958	*Alopecurus pratensis*	52	75	—	12	13	—	19

These high numbers could only be caused by very small propagation units known as '*L*-forms' of 0·1–0·2μ diameter. Küster[4] obtained them from soil bacteria after treatment with penicillin or glycine and Vilas[5] identified such *L*-forms in soil. The occurrence of filterable *L*-forms in the rhizosphere of the plants investigated may be postulated. It may be favoured by effects originating from the dense population of microbes occurring in a naturally grown grass sward.

The main group of bacteria obtained belonged to *Arthrobacter*, a genus of Conn and Dimmick, 1931, autochthonous coryneform soil bacteria. They are Gram-positive to Gram-variable rods of different length, which form either smaller ovoid cells of 0·5–0·8μ diameter or larger cells in terminal swellings of 1·0–1·2μ diameter, the so-called cystites, within their cell walls. These may grow and form rods again[6,7]. Their proportion in soil and rhizosphere decreases more or less during the summer in favour of Gram-positive and Gram-negative rods. The latter are pseudomonas-like, motile short rods, some of them fluorescent and long, thin rods of 10–20μ length, which usually show a slowly creeping movement. These long rods reached the high proportion of 26 per cent only in the rhizosphere of *Trifolium repens*. In accordance with the results of Lochhead[8], the rhizosphere generally contained relatively more motile and Gram-negative bacteria than the soil. This selective rhizosphere effect was most marked with *Trifolium repens* and least with *Alopecurus pratensis*. Probably the most numerous *Arthrobacter* forms and the Gram-negative rods would provide the *L*-forms causing the high counts.

Morphological Variation in *Ferrobacillus ferrooxidans* related to the Rate of Iron Oxidation

WHILE investigating the removal of pyritic sulphur from coal by a microbiological method, we propagated large numbers of the chemoautotrophic iron-oxidizing bacterium *Ferrobacillus ferrooxidans*. During mass culture of the bacterium in an inorganic iron salts medium (9*K*)[1], it was observed that alterations in cellular morphology occurred in response to excessively vigorous aeration. Normal cells measure 1·0–1·7μ by 0·5μ (Fig. 1*A*), while the abnormal (morphologically altered) cells differed by having a diameter of 1·0μ, so that many enlarged, coccoidal forms were present (Fig. 1*B*). The abnormal strain, on large-scale sub-culture using less vigorous aeration, or in shake-culture flasks, showed virtually complete reversion to the normal morphology after the second transfer (Fig. 1*C*, *D*).

Normal (Fig. 1*A*), abnormal (Fig. 1*B*) and reverted (Fig. 1*D*) cells were collected as previously described[1] and the rates at which they oxidized ferrous to ferric iron were determined by standard manometric techniques. Each Warburg vessel contained a total of 1·7 ml. liquid consisting of 500 μ*M* Fe^{++} (as $FeSO_4.7H_2O$ dissolved in distilled water acidified to *p*H 2·6 with sulphuric acid) in the main compartment, 0·5 ml. of cell suspension in the side arm, and 0·2 ml. of 20 per cent potassium hydroxide in the centre well. The gas phase was air. All suspensions were tipped in at zero time and the uptake of oxygen at 30° C. was measured at 10-min. intervals over a period of 70–120 min. Cellular nitrogen was determined by a micro-Kjeldahl procedure.

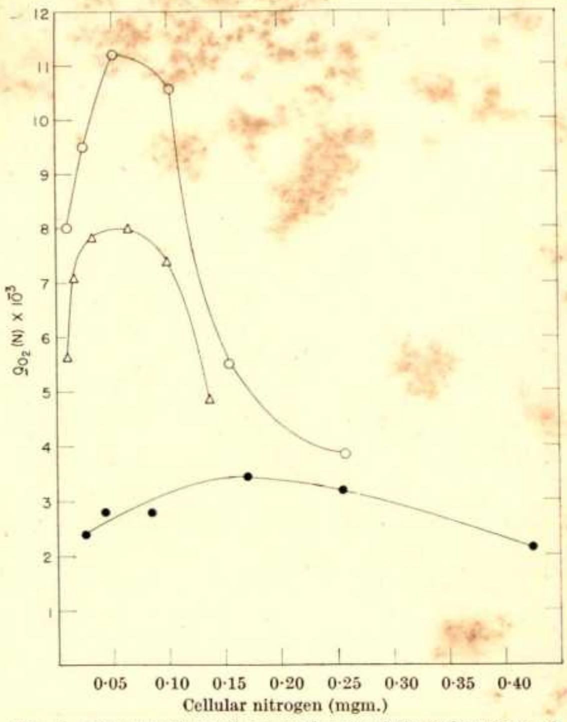

Fig. 2. Rate of uptake of oxygen by morphological variants of *F. ferrooxidans* as a function of cellular nitrogen. ○, Reverted cells; △, normal cells; ●, abnormal cells

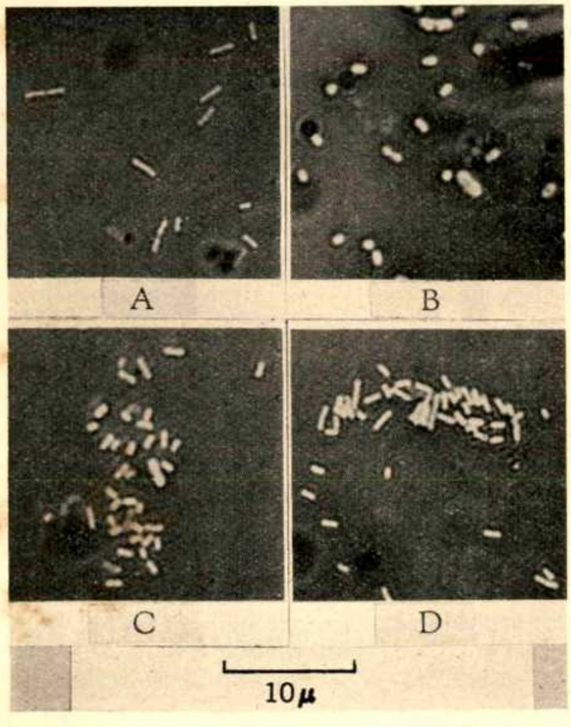

Fig. 1. Different morphological variants of *Ferrobacillus ferrooxidans*. *A*, Normal cells; *B*, abnormal cells; *C*, intermediate stage in reversion to normal morphology; *D*, reverted cells (final stage in reversion to normal morphology). Negative stain with congo red. (*c*. × 1,800)

The results indicated that abnormal cells were consistently less active than their normal or reverted counterparts. However, Qo_2(N) values (μl. oxygen uptake/mgm. cellular nitrogen/hr.) varied considerably with cell concentration within each of the resting cell suspensions. A more systematic investigation was undertaken where the rate of iron oxidation by normal, abnormal and reverted cells was examined as a function of cellular nitrogen. The results are shown in Fig. 2. The rate of oxidation of the three cell suspensions for any given concentration of cellular nitrogen followed the order—reverted > normal > abnormal. Maximum and minimum Qo_2(N) values ranged from 11,209 (0·051 mgm. nitrogen) to 3,840 (0·257 mgm. nitrogen) for reverted cells, 8,012 (0·065 mgm. nitrogen) to 4,784 (0·162 mgm. nitrogen) for normal cells, and 3,480 (0·170 mgm. nitrogen) to 1,932 (0·425 mgm. nitrogen) for abnormal cells.

Beck[2] reported that an iron-oxidizing bacterium, isolated from the acid water of Bingham Canyon, Utah, exhibited Qo_2(N) values that decreased with increasing concentrations of cells. He attributed this to the possible failure of oxygen equilibrium between the fluid and gaseous phases during rapid oxygen uptake. Our findings might be explained on this assumption up to the maximum Qo_2(N) values, but the decrease in Qo_2(N), on further dilution of the cells, argues against oxygen solubility as the sole factor in determining the curves illustrated in Fig. 2.

On the assumption that the nitrogenous constituents of the larger, more spherical, abnormal cells increased in proportion to the increased cell volume, it is interesting to speculate as to the site(s) of iron oxidation in this bacterium. The smaller surface-to-volume ratio of abnormal cells, coupled with the lower rate of oxidation, seems to imply that the cell surface may play an active part in the oxidation of iron, and that at least one, and possibly more, of the unknown steps in the transfer of electrons from ferrous iron to oxygen may occur at this site.

Simple, Quick Methods for Detection of 6-Amino-penicillanic Acid

ONE of the greatest discoveries of the past years in penicillin research was the discovery, isolation[1] and preparation of 6-amino-penicillanic acid (6-APA) forming the common 'nucleus' of natural penicillins[2,3], and the successful introduction into therapy of semi-synthetic penicillins produced from it[4,5]. The new semi-synthetic penicillin preparations have already made great progress in the fight against resistant bacteria. The possibility is now laid open for the preparation of penicillins possessing novel effectiveness[6]. The basis for efforts of this kind is 6-APA research, and its quick identification in fermentation liquor and other reaction mixtures.

The biological methods hitherto used (such as paper-chromatography; the chemical transformation of 6-APA into some familiar natural penicillin, or bioassay) even if not complicated, are comparatively lengthy. The following two simple methods have been devised for quick detection of 6-APA:

(1) The essence of the paper-slice method is the cutting of 1 cm.-wide slices from Whatman No. 1 filter-paper in appropriate lengths and washing them first in a solution of 3 per cent sodium bicarbonate, then, after drying, in a solution of 1 per cent phenylacetylchloride in acetone. After drying in air, a solution containing 6-APA is added, drop-wise, to the impregnated paper. If there is 6-APA in the solution, it will be converted to *G*-penicillin on the paper and yield an inhibition zone. This method is appropriate for qualitative determination.

(2) The 6-APA content of fermentation liquid or other solutions is demonstrable also by means of the hole plate method. 6-APA is transformed directly into a natural penicillin within holes in an agar plate inoculated with *B. subtilis* spores. In this manner, the time and effort needed to perform this reaction in a separate test-tube are saved. Fig. 1 illustrates such a demonstration. Each fermentation liquid is measured into two holes. Into one hole (upper row in the figure) a single drop of 3 per cent $NaHCO_3$ solution is added, while into the other hole (lower row in the figure) one drop of 1 per cent phenylacetylchloride in acetone is also added. The plate is then incubated for 5 hr. at 37° C. If there is 6-APA in the fermentation liquid, it is converted to *G*-penicillin and yields an inhibition zone, as can be seen around the holes 1–4 of the lower row in the figure. Around the holes of the upper row is the inhibition zone due to the penicillin remaining in the fermentation fluid after extraction. The fifth hole, where distilled water was introduced, the reagents in the quantity applied do not produce an inhibition zone. This method is applicable for the quantitative, quick detection even of a tenth unit of 6-APA.

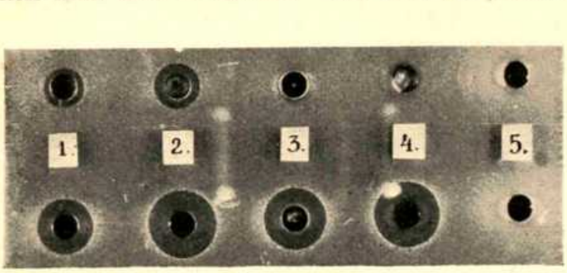

Fig. 1. Detection of 6-APA content of fermentation liquids by use of the hole plate method.

Test micro-organism: *B. subtilis*, 0·1 ml. of the liquid containing 6-APA (1, 0·04 unit; 2, 0·2 unit; 3, 0·06 unit; 4, 0·2 unit; 5, dist.H_2O) measured into holes. One drop of 3 per cent $NaHCO_3$, and, on the lower row, an additional drop of 1 per cent phenylacetylchloride in acetone is measured. In the upper row: inhibition zone of remaining natural penicillins. In the lower one: inhibition zone of *G*-penicillin deriving from 6-APA

ENTOMOLOGY

Exchanges of Sodium Ions in the Central Nervous System of an Insect (*Periplaneta americana* L.)

IN earlier work it was shown that the exchanges of sodium and potassium ions between the hæmolymph and the central nervous system of the cockroach occurred relatively rapidly[1]. It was concluded from these results that the connective tissue layer surrounding the nervous system did not function as a significant diffusion barrier and that in such a dynamic system any selective permeability must be attributed to the underlying cellular layer of the nerve sheath or some associated elements.

An attempt has recently been made to throw some further light on these processes by studying the efflux of sodium ions from isolated abdominal nerve cords and single connectives and ganglia of *Periplaneta americana* L. In these experiments the rate of loss of sodium-24 was measured by determining the decline in radioactivity of isolated preparations maintained in a flowing physiological solution. The greater part of the efflux of sodium-24 measured in this way was found to approximate to a simple exponential function, both for the whole nerve cord and for the isolated fragments. The presence of 2:4-dinitrophenol and cyanide in low concentrations was found to reduce substantially the rate of efflux of sodium measured in these experiments (Fig. 1). Similarly, an absence of potassium ions from the external solution resulted in a slowing down of loss of sodium, although sodium-free solutions appeared to have no appreciable effects on the measured efflux from the nerve cord. Thus it seems that, as for some other cells and tissues[2], sodium ions are extruded from the central nervous system by a metabolically maintained secretory mechanism which is also associated with the uptake of potassium ions.

In another group of experiments the effect of removing the cellular and fibrous nerve sheath on the rate of sodium extrusion was investigated. It was found that the rate of efflux of sodium-24 from the terminal abdominal ganglion was not appreciably affected by the removal of substantial portions of the perilemma (Fig. 2). It must be concluded, then, that the rate-limiting process measured in these experiments was not the transfer of the ions across

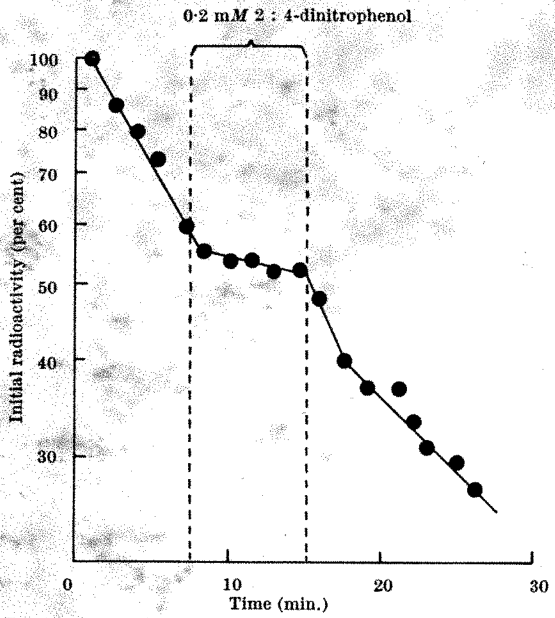

Fig. 1. Effect of 0·2 mM 2 : 4-dinitrophenol on the rate of loss of sodium-24 from a single, ligatured, terminal abdominal ganglion washed in inactive physiological solution

the cellular perineurium, but the exchanges associated with some underlying cellular components of the central nervous system. The relatively rapid effects of the poison molecules and the potassium-free solutions on the measured effluxes from the intact abdominal nerve cord thus imply that the changes in the chemical composition of the external solution were quickly transmitted to the deeper layers of the central nervous system.

The ionic fluxes calculated in the previous account[1], using conventional equations, involved the assumption that the rate-limiting process was the transfer across the superficial boundary of the central nervous system and that the movements within the underlying tissues occurred relatively rapidly so that the labelled ions were effectively well mixed. The results here show that this represents an over-simplification, and consequently the calculated values have little significance. It is hoped that in a future investigation, in which any relatively rapid movements can be measured, a quantitative analysis can be given for this more complex system.

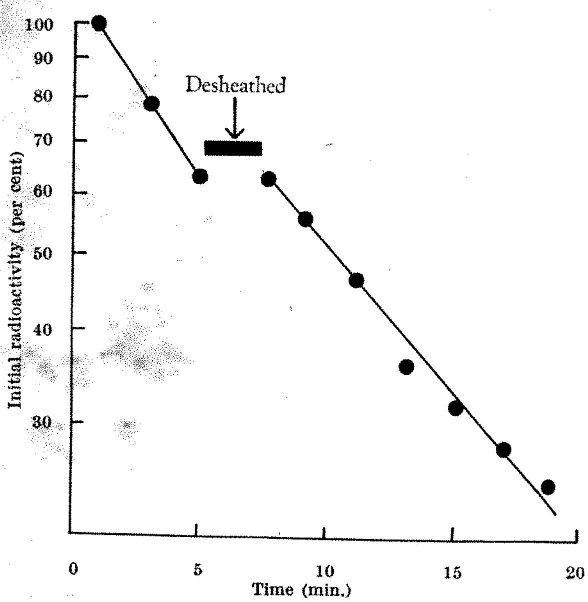

Fig. 2. The effect of removing the nerve sheath from the dorsal surface of the ganglion on the rate of loss of sodium-24

An Acid Mucopolysaccharide in Cockroach Ganglia

IN a recent histochemical investigation of the neurones and connective tissues of the meso- and meta-thoracic ganglia of the cockroach, *Periplaneta americana*[1], it was noticed that an area surrounding the central mass of nerve fibres stained metachromatically with toluidine blue. The region separates the neurones and connective tissue sheath from the main mass of nerve fibres. There is no comparable region in the interganglionic connectives or peripheral nerves. This seems at present to be a structure peculiar to *Periplaneta* and other cockroaches; a similar region has been seen after staining with toluidine blue in *Blaberus craniifer*, *Blatta orientalis*, *Blattella germanica* and *Diploptera punctata*. No such region is found in insects of other orders which have been studied histochemically, for example, *Ephestia kühniella* (Richards, A. G., personal communication), *Locusta migratoria* (unpublished observations) and sucking lice[2].

The metachromatic substance in *Periplaneta* has no apparent structure and appears to be extra-cellular; the inner and outer borders are delimited by the glial cells which send slender processes across it, and, in addition, occasional glial cell bodies are seen. This is the appearance in sections of ganglia fixed in Zenker's fluid (Fig. 1). If, however, a section from a ganglion fixed in formalin is stained with toluidine blue, the metachromatic substance is displaced inwards; the region is seen to be disrupted and the substance now lies on the surface of the broken glial processes around the central nerve fibre mass. This appearance is described by Hess[3], who stained sections of these ganglia with cresyl violet, after fixation in either Bodian's or Bouin's fluids. He describes the metachromatic cytoplasm as forming a 'reticulated net' and identifies it as glial cell cytoplasm. A similar appearance is described by Pipa, Cook and Richards[4] in Bodian's protargol preparations of these ganglia. In preparations made by the osmium and ethyl gallate technique, Wigglesworth[5] describes a "glial lacunar system", in which the glial cells lie in extensive cavities, the contents of which are not stained in the preparations. He finds that comparable regions are found in all the thoracic and abdominal ganglia of *Periplaneta*. It appears, then, that this region in the ganglia is very sensitive to the action of fixatives.

The only group of substances which can be identified histochemically in this area are acid mucopolysaccharides. The reactions for proteins (coupling reaction, mercury nitrite and Sakaguchi tests) and lipids (sudan black) give negative results, and so does the periodic acid–Schiff test. This latter result is in agreement with the finding of Leblond, Glegg and Eidinger[6] that acid mucopolysaccharides are negative

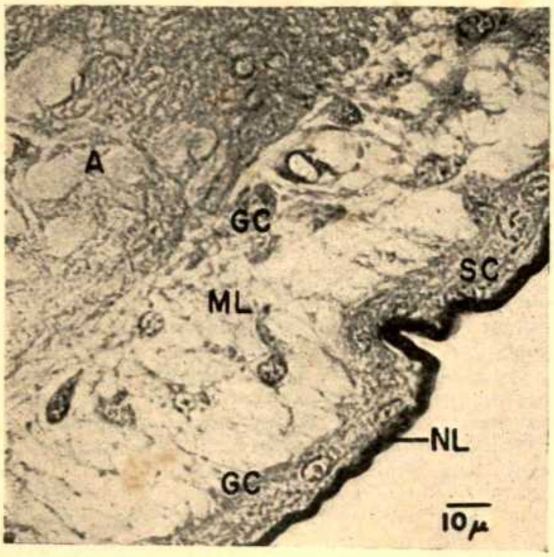

Fig. 1. Section through a thoracic ganglion of *Periplaneta americana* to show the region containing acid mucopolysaccharides. *A*, axons; *GC*, glial cells; *ML*, metachromatic layer; *NL*, neural lamella; *SC*, sheath cells

to the periodic acid–Schiff test. The metachromasy with toluidine blue is removed by incubation of the sections in hyaluronidase ('Hyalase'), but as this enzyme is not specific for hyaluronic acid, this does not give any information as to the nature of the acid mucopolysaccharide. An attempt is being made to characterize it biochemically.

The acid mucopolysaccharide forms a ground substance which resembles that of vertebrate connective tissue in its histochemical reactions, but the degree of chemical similarity remains to be determined. The function of this layer of acid mucopolysaccharide is not apparent. There are suggestions that acid mucopolysaccharides can act as ionic barriers allowing cations to pass through, but restricting the passage of anions[7]. But it seems unlikely that this acid mucopolysaccharide forms an ionic barrier, both because it is restricted to the ganglia and because removal of the connective tissue sheath from either the ganglia or connectives results in the blockage of nerve conduction[8]. Wigglesworth[5] suggests that the region might serve as a pool for nutrients, or as a means of maintaining the outer shape of the ganglion as changes in the state of nutrition alter the size of the cellular components of the ganglion. But, until more is known of the chemistry of this substance, it will be difficult to ascertain its function.

I am very grateful to Dr. A. G. Richards for his criticism of this communication.

Experimental Transmission of *Borrelia anserina* (Sakharoff 1891) by *Aedes aegypti*

THE causal organism of spirochætosis, *Borrelia anserina*, was first reported from geese in the Caucasus, and has since been isolated from the blood of infected geese, turkeys, ducks, fowls, partridges, crows and sparrows from all parts of Africa, Australia, Austria, Bulgaria, Brazil, Egypt, East Indies, Germany, Greece, Hungary, India, the U.S.S.R., Rumania and Turkey.

The known common vectors of spirochætosis are various species of *Argas* and *Ornithodoros*.

Recent outbreaks in the Kaduna area of Northern Nigeria gave indications that the disease could be transmitted by other blood-sucking insects, and it was therefore decided to attempt experimental transmission of spirochætosis with *Aedes aegypti* as this was readily available and was known to feed well on experimental birds. Laboratory-bred females were placed in plastic tubes with mosquito netting fixed at each end. This tube was held firmly on a bird (Rhode Island Red) that showed spirochætes in a stained thin blood film. After approximately 45 min. the tube was removed and the fully fed *A. aegypti* were separated from the unfed. After starving for several days they were then fed on clean birds. These birds were transferred to separate cages and thin blood films were taken daily. Control birds of the same age and breed were maintained under the same conditions and thin blood films were also taken daily from these birds.

The birds on which the *A. aegypti* had been fed developed a fever, became anæmic and showed spirochætes in their blood.

The control birds were normal throughout the experiment. Similar experiments are being carried out with *Culex fatigans*.

PSYCHOLOGY

Cross-modal Transfer in Man

LITTLE is known about transfer between different sensory systems during learning of complex material. Positive cross-modal transfer implies that learning to discriminate between a pair of stimuli in one modality leads to accelerated discrimination between the same stimuli presented in a second modality. Previous experiments showed no evidence for transfer between visual and tactile[1], or visual and auditory[2], discrimination habits in monkeys, although one investigation has been reported recently in which transfer between auditory and visual habits was obtained[3]. In certain conditions, human subjects are able to match geometrically equivalent contours successively presented for visual and tactile comparison[4]. Auditory 'flutter' can similarly be matched with visual 'flicker' by subjects specifically instructed to equate rates of intermittance of sounds and lights[5]. Such cross-modal comparisons, however, are performed more poorly than intra-modal comparisons. A general theoretical argument against the immediate equivalence of perception in differing sense modalities has been presented by Hebb[6].

followed by	followed by		
auditory ● – – vs. – – ● (+) (–)	VISUAL ● – – vs. – – ● (+) (–)		

In the rhythm discriminations temporal parameters were as follows: Duration of short components, 148 msec.; duration of long components, 504 msec.; duration of intervals between components, 110 msec.; duration of intervals between rhythm cycles, 990 msec. In the rate discrimination, the sound was interrupted 10 times per sec. for the positive stimulus, and 4 times per sec. for the negative stimulus.

In the present work cross-modal transfer of rhythm discrimination by human subjects was investigated. We wished to determine, first, whether learning of a rhythm discrimination in one modality (audition) leads to more rapid learning of the same rhythm discrimination in the second modality (vision); secondly, we investigated the ability to match auditory and visual rhythms.

The subject sat facing a pair of boxes, each of which contained a filament lamp and loudspeaker. Luminance of the lamp was 230 ft. lamberts. The basic sound source was a 400-c.p.s. tone with a small component at 2,500 c.p.s. Its intensity was judged to be about 60 db. An electro-mechanical timing device interrupted the lights and sounds to produce the rates and rhythms described in Table 1. On each trial, stimuli were successively presented on the left and right; two cycles of the rhythms were always presented, whereas the intermittent stimuli were presented for 5 sec. The position of the positive stimulus, to left or right, was determined by reference to the Gellerman schedule. Testing continued, in all conditions, until the subject made no errors in 10 consecutive trials. By convention, the final 10 trials are not included in the scores reported here.

Thirty-six adult subjects were divided into four groups and tested according to the design shown in Table 1. A pilot experiment indicated that the rhythm discrimination was more difficult in the visual than in the auditory form. For this reason it was decided to study cross-modal transfer only from audition to vision. Group 1 (*N* = 6) received no auditory training and group II (*N* = 6) learned an irrelevant discrimination of the auditory rate before both groups learned the visual rhythm discrimination. Group III (*N* = 12) learned the auditory and visual forms of the rhythm discrimination concurrently, the same pair of rhythms being given in auditory and visual form on alternate trials. None of the subjects in the first three groups was informed of the relationship between the auditory and visual rhythms. By contrast, the subjects in group IV (*N* = 12) were specifically instructed to determine, on each trial, whether a visual rhythm was identical with an auditory rhythm which immediately preceded it.

The scores of subjects in groups I and II for the visual rhythm discrimination were combined (*N* = 12) and then compared with the scores for the same discrimination of subjects in group III and also with the auditory-visual matching performance of subjects in group IV. Subjects in the first two groups required an average of 13·5 trials (range 0–57 trials) to learn the visual rhythm discrimination in the absence of associated auditory learning. Subjects in group III required an average of 20·4 trials to reach criterion on the visual rhythm discrimination (range 1–120 trials). Half the trials for these subjects, it must be noted, consisted of presentation of the auditory form of the rhythm discrimination. If these auditory trials are excluded, the average for group III becomes 10·3 trials (range 0–60 trials). Comparison of these test scores by means of the Mann-Whitney '*U*' test failed to yield any significant differences between the groups, regardless of whether the auditory trials of group III were combined with the visual trials or not. Further analysis, using a less stringent performance criterion (90 per cent, instead of 100 per cent of 10 trials), again failed to reveal significant differences between the various groups. Finally, successful matching of the auditory and visual rhythms by subjects in group IV required an average of 8·4 trials (range 0–34 trials). This value does not differ significantly from the learning scores of the first three groups.

Another measure of the degree to which learning of one form of the discrimination influences learning of the other may be obtained by determining the difference in number of trials required by subjects in group III to learn the two forms of the discrimination. The average difference between auditory and visual learning scores of these subjects was 7·3 trials (range 1–56 trials). Three subjects showed such rapid learning of both auditory and visual forms of the discrimination (that is, fewer than five trials of each) that we would attribute these low difference scores to equally rapid concurrent learning in the two modalities. The visual learning scores given by 3 of the remaining 4 subjects with low difference scores, when calculated on the basis of combined auditory and visual trials, exceed the average visual learning score of control subjects. The other five subjects in group III showed large difference scores, suggesting little, if any, transfer between modalities.

With our conditions of testing, therefore, we have found no evidence for transfer from auditory to visual learning of rhythms in man. This result agrees with the finding of relatively poor cross-modal matching performance in human subjects[5]. If confirmed and extended, results such as ours might imply that discrimination learning of complex material is largely modality-specific.

The apparatus used in this experiment was designed and constructed by Mr. H. B. Morton.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Mycologist (with an honours degree in botany, with specialization in plant pathology) at the States' Experimental Station (Department of Agriculture)—The Establishment Officer, States' Greffe, Jersey, C.I. (September 23).

Research Demonstrator (graduate in botany) to engage in research, preferably in plant physiology and biochemistry, plant pathology and ecology; and a Research Assistant (graduate in botany or graduating this year), to assist the Professor in the establishment and maintenance of a collection of plant organ and tissue cultures and in research involving these cultures—The Registrar, University College, Singleton Park, Swansea (September 23).

Lecturer in the Department of Electrical Engineering—The Registrar, The University, Leeds (September 25).

Professors of Crop Husbandry and Horticulture; Animal Husbandry and Health; and Agricultural Economy at the University of Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (September 25).

Scientific Officer or Senior Scientific Officer (physicist, chemical or mechanical engineer), to join a group studying the growth and spread of fire in and between buildings—The Director, Fire Research Station (D.S.I.R.), Borehamwood, Elstree, Herts (September 25).

Lecturer (with at least an honours degree in geology, together with special qualifications to teach geomorphology to the fourth year (honours) level in the Department of Geography) in Geography and Geology at the University of Natal, Pietermaritzburg—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, September 30).

Research Assistant (graduate or postdoctoral), to work on rapid high temperature reaction kinetics, fundamental flame properties, flame spectroscopy and allied subjects—Dr. G. Dixon-Lewis, Houldsworth School of Applied Science, The University, Leeds 2 (September 30).

Research Assistant (with a degree in botany or equivalent qualifications) in the Department of Botany—Dr. A. G. Smith, Department of Botany, The Queen's University of Belfast, Belfast 7 (September 30).

Scientific Officer or Senior Scientific Officer (with research experience in enzymology and/or protein chemistry, and some knowledge of, and interest in, fundamental genetic problems), initially to assist in current research on the effects of mutation on the structure of specific proteins in the mould *Neurospora crassa*—The Secretary, John Innes Institute, Bayfordbury, Hertford, Herts (September 30).

Vice-Principal (with a good university degree and preferably higher qualifications and Associate Membership of one of the engineering institutions, and a sound technical background and experience in a similar capacity) of the Khartoum Technical Institute, Sudan—The Appointments Section, Sudan Embassy, 3 Cleveland Row, St. James's, London, S.W.1 (September 30).

Vokes Research Fellow (preferably with a special interest in fluids or elastic theory) in the Department of Mechanical Engineering—The Secretary and Registrar, The University, Southampton (September 30).

Lecturer or Assistant Lecturer (preferably with special qualifications and interests in cytology and genetics, or in protozoology, or in the ecology of terrestrial animals) in the Department of Zoology, University of Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (October 2).

Lecturer in Botany and Assistant Curator of the Bolus Herbarium, University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, October 4).

Lecturer in Philosophy; and a Lecturer in Psychology at the University of Kong Hong—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, October 13).

Chair of Chemistry in the Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 15).

Lecturer (with a science degree specializing in geology and research experience to Ph.D. or comparable level, and well trained in modern mineralogical techniques) in Geology at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 15).

Reader in Human Genetics in the Department of Zoology, University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 15).

Lecturer (with a veterinary qualification) in Animal Husbandry in the School of Veterinary Medicine—The Registrar, Trinity College, Dublin, Republic of Ireland (October 16).

Reader in Microbiology at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, October 16).

Senior Lecturer in Physics at the Australian National University, Canberra—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 21).

Senior Lecturer (preferably with research experience in low temperature physics) in Physics at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 21).

Scientific Officer (with a first- or second-class honours degree in physics), to work on transmission of sound through panels and solid structures—The Director, Building Research Station (D.S.I.R.), Garston, near Watford, Herts, quoting Ref. BRS.32Y (October 24).

Teaching Fellows (with an appropriate honours degree) in the Department of Biochemistry (two appointments); and in the Department of Botany (one appointment), University of New South Wales, Australia—The Agent-General for New South Wales, 56 Strand, London, W.C.2, and the Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (October 31).

Lecturer in Education in the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, University of Otago (London and New Zealand, November 20).

Assistant Lecturer (graduate in chemistry or agricultural chemistry) in Soil Science—The Registrar, Massey Agricultural College (University of New Zealand), Palmerston North, New Zealand (November 22).

Lecturer or Senior Lecturer in Physiology at Monash University, Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, Monash University (Australia and London, December 4).

Agronomist (Soils) (male, between 26–40, with an honours degree in agricultural or horticultural science with agricultural chemistry as the main subject, experience in field experimental work on soil fertility, and a knowledge of tropical soils and crops) in the Department of Agriculture, Sarawak, to design and conduct field experiments with tropical crops on selected soils to assess the potentiality of the soils—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting RC.213/128/01/T.

Assistant Lecturer, Grade B (well qualified in physics and an interest in the development of some branch of applied physics) in Physics—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex.

Assistant (preferably with previous training), for work in cytogenetics—The Registrar (BX), Queen Mary College (University of London), Mile End Road, London, E.1.

Physical Chemist, Senior Scientific Officer grade (at least 26, with a degree or Dip. Tech. with first- or second-class honours degree in chemistry or equivalent qualification, and at least three years postgraduate research experience) at the Rocket Propulsion Establishment, Westcott, Bucks, to lead a small team investigating properties of materials at very high temperature with special emphasis on high temperature-resistant ceramics—The Ministry of Labour, Technical and Scientific Register (K), 28 King Street, London, S.W.1, quoting Ref. F.531/iA.

Postdoctoral Fellow in Organic Chemistry—Dr. J. I. G. Cadogan, Department of Chemistry, King's College (University of London), Strand, London, W.C.2.

Professor of Analytical Chemistry at Peshawar University—The Department of Technical Co-operation, 26/28 King Street, London, S.W.1, quoting TCS/PAK/529.

Reader in Applied Mathematics; a Senior Lecturer in Mathematical Statistics; and a Senior Lecturer or Lecturer in any branch of Pure or Applied Mathematics at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, University of Adelaide.

Research Assistant (science or engineering graduate), to work on problems related to food processing or food engineering, and to undertake some teaching—The Principal, National College of Food Technology, St. George's Avenue, Weybridge, Surrey.

Research Technician (with some experience in a biochemical research laboratory) in the Department of Chemistry and Food Technology, for work on the isolation and chemical studies of lipoproteins from cereals and oilseeds—The Secretary, Borough Polytechnic, Borough Road, London, S.E.1.

Senior Research Assistant and a Research Assistant in the Chemistry Department, to work on optical rotatory dispersion—Prof. W. Klyne, Westfield College (University of London), Hampstead, London, N.W.3.

Technicians and Junior Technicians (young men or women with an interest in synthetic organic chemistry or in biochemistry)—The Secretary (LA), Imperial Cancer Research Fund, Lincoln's Inn Fields, London, W.C.2.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Royal Observatory Bulletins. No. 34: Design and Tests of a Mirror Transit Circle Axis. By R. d'E. Atkinson. Pp. A51–A70. (London: H.M. Stationery Office, 1961.) 4*s*. net. [127

Memoirs of the Royal Astronomical Society. Vol. 68, Part 3: Classification and Radial Velocities of Bright Southern Galaxies. By Gerard de Vaucouleurs and Antoinette de Vaucouleurs. Analysis of Limb Darkening Observations. By A. Keith Pierce and John. H. Waddell. Pp. 69–112. (London: Royal Astronomical Society, 1961.) 20*s.*; 3 dollars. [127

United Kingdom Atomic Energy Authority. Seventh Annual Report for the period 1st April, 1960—31st March, 1961. Pp. viii+80+4 plates. (London: H.M. Stationery Office, 1961.) 5*s.* net. [127

Scottish Plant Breeding Station. Report, 1961. Pp. 78+1 plate. Pentlandfield, Roslin: Scottish Plant Breeding Station, 1961.) [137

General Register Office. The Registrar General's Statistical Review of England and Wales for the two years 1957–1958. Supplement on Mental Health. Pp. ix+102. (London: H.M. Stationery Office, 1961.) 7*s.* 6*d.* net. [137

The British Coke Research Association. Seventeenth Annual Report for the year 1960. Pp. 33. (Chesterfield: The British Coke Research Association, 1961.) [147

Durham University Appointments Board. Fifteenth Annual Report. Pp. 9. (Durham: Durham University Appointments Board, 1961.) [177

Food for the Chemist. By Prof. S. H. Harper. (An Inaugural Lecture given in the University College of Rhodesia and Nyasaland on 28 October 1960.) Pp. 16. (London: Oxford University Press, 1961.) 4*s.* net. [177

Regional Advisory Council for Technological Education: London and Home Counties. Regional Development Plan for Courses for the Diploma in Technology. Pp. 16. (London: Regional Advisory Council for Technological Education: London and Home Counties, 1961.) [277

Department of Scientific and Industrial Research. Report of the Warren Spring Laboratory 1960:—Report of the Warren Spring Laboratory Steering Committee and the Report of the Director of the Warren Spring Laboratory for 1960. Pp. vi+25+4 plates. (London: H.M. Stationery Office, 1961.) 3*s.* net. [277

B.B.C. Engineering Monograph No. 37: An Instrument for Measuring Television Signal-to-Noise Ratio. By S. M. Edwardson. Pp. 23. (London: H.M. Stationery Office, 1961.) 5*s.* [277

Horticultural Marketing Council. Fifth Annual Report and Statement of Accounts for the period 9th May, 1960 to 31st March, 1961. Pp. 16+4 plates. (London: Horticultural Marketing Council, 1961.) [277

Society of Chemical Industry. Proceedings of the Chemical Engineering Group, Vol. 39, 1958/9. Pp. viii+111. (London: Chemical Engineering Group, Society of Chemical Industry, 1961.) 42*s.* [277

Philosophical Transactions of the Royal Society of London. Series B: Biological Sciences. No. 705, Vol. 243 (20 July 1961): Different Types of Cirral Activity of Barnacles. By D. J. Crisp and A. J. Southward. Pp. 271–308+ plate 66. 15*s.* No. 706, Vol. 244 (27 July 1961): Studies on Triassic Fossil Plants from Argentina. 1: *Rhexoxylon* from the Ischigualasto Formation. By S. Archangelsky and D. W. Brett. Pp. 1–19+plates 1 and 2. 9*s.* 6*d.* No. 707, Vol. 244 (27 July 1961): The Layered Ultrabasic Rocks of South-West Rhum, Inner Hebrides. By W. J. Wadsworth. Pp. 21–64+plates 3–7. 22*s.* 6*d.* (London: Royal Society, 1961.) [277

Problems of Psychology, Numbers 1 and 2 (1960). Published quarterly, containing selected papers translated from *Voprosy Psikhologii*. Four issues of approximately 400 pages per annum. Annual subscription: (A) For libraries £15 (40 dollars); (B) For private subscribers £5 (15 dollars). Single issues £4 (12 dollars). (London and New York: Pergamon Press, 1961.) [277

Glamorgan Forests. Edited by H. L. Edlin. (Forestry Commission Guide.) Pp. vi+99+20 plates. (London: H.M. Stationery Office, 1961.) 5*s.* net. [277

THE HUMANITY OF MAN

"A SCIENTIST is a person, before and after becoming a scientist. Whatever your interest, your field of research—whether you are an astronomer or geologist, physicist or botanist—you cannot climb outside the humanity through which you live and have your being."

Such was the main thesis, presented and expanded by Dr. Launcelot Fleming, Bishop of Norwich, in his sermon at the Civic Service in Norwich Cathedral and attended by civic dignitaries and officers and members of the British Association for the Advancement of Science on Sunday, September 3, during the recent annual meeting of the Association.

It was a compelling address given by a man who is not only one of the leaders in the Christian Church but is also himself a trained scientist. Dr. Fleming was a member of scientific expeditions to Iceland and Spitsbergen in 1932 and 1933 and chaplain and geologist to the British Graham Land Expedition during 1934–37. Later, though still continuing to become recognized as a distinguished theologian, he was director of the Scott Polar Research Institute, Cambridge, during 1947–49. The crowded congregation in Norwich Cathedral on that day therefore had the rare privilege of listening to a sermon by an outstanding priest and a philosophical discourse by a scientist at one and the same time.

Dr. Fleming pointed out that though scientists could not be grouped, and most of them would not wish to be grouped, together as a "separate species of the human race", set apart from the rest of humanity, yet they now have almost come to be so regarded. The reasons for this are manifold. At one time, the man of science was looked upon as an individual living practically in a world of his own ; one to be kindly tolerated or merely ignored or openly feared and despised according to the attitude of the society around him. But to-day many scientists have collaborated and science has quickly developed, gradually forming laboratory teams and then spreading more widely on national and international scales to such an extent that to-day man's very existence largely depends on it. Industrialists have recognized this to their own and to the world's material advantage and, in many cases, to the benefit of science itself ; even leaders in national and world politics must now at least acknowledge that science is firmly entrenched, though it is up to them to decide to what extent it shall be used for the advancement of mankind or, on the other hand, to its detriment and possibly eventual destruction.

In this sense, scientists cannot be a race apart, for they are now welcome in industry and, willy-nilly, have become absorbed into the body politic. It is still the so-called humanitarians—men of letters and other leaders of our society—who persist in ignoring scientists or at any rate turning deaf ears and presenting sightless eyes to scientists and their work, especially in so far as results of the latter are now exerting a profound influence on society. Sir Charles Petrie has recently complained that certain leaders of society show little interest in, or sympathy with, men of letters; this protest can be echoed by the scientists.

As a member of human society, the average scientist seems a tolerant individual. Yet, instead of waiting for the time to come—as come it must if the world is to survive, let alone progress in peace and prosperity—when all members of society recognize and encourage science, it would be better if the man of science periodically paused to examine more closely the basic unit of humanity, namely, himself.

This was the wise advice offered by Dr. Fleming at Norwich. We are each urged to get to know ourselves ; to ask : Who am I ? How can I be myself ? Dr. Fleming went far in aiding us to discover the answers to these fundamental questions ; for, as he claimed, we should recognize that each of us comprises several different selves.

"If I am a scientist, there is the scientific self—student, teacher, research worker—absorbed in lab. or classroom or museum, in some particular area of knowledge—using a particular method of enquiry, empirical, analytical—selecting only such categories as will serve the purpose best. Then there is another and a different self who plans out the course of lectures or the progress of research, who signs the cheques, makes up the diary, and arranges meetings. One might call this my administrative self, and here rather different qualities come into play than those I need in the lab. And finally there is a third, the social self, involved in relationships of many kinds—relationships at work, relationships outside work, relationships at home, and here I am in so many ways a different kind of person—more emotional, though not necessarily on that account less reasonable, than the scientific or administrative self.

"And these three selves, although I know perfectly well that each of them has its own proper place, appear so often to be pulling in opposite directions. It is not only that their interests may clash. That can, of course, happen. A man may become so absorbed in his work that his home life suffers ; or so taken up with his home that his work suffers : or the ambition for administrative control, for the sake of advancement or for money, may affect his relationship with fellow scientists or even prejudice the integrity of his work."

But the tension does not end there, at least so far as one's scientific self is concerned, for new scientific facts are continually being discovered, and so some conclusions have to be modified or cast aside. Therefore, as Dr. Fleming pointed out, the scientist for the purpose of his work must be detached and dispassionate, and his conclusions provisional. All sensible scientists now recognize this and act accordingly ; but many of even the best of us might ponder Dr.

Fleming's emphasis on our social relationships, for here, as he said, the values and forms of truth which relate to this side of our lives apply very differently. As a member of society, not even the scientist can remain detached, and he cannot, indeed he must not, remain dispassionate. "He must be prepared to stand committed, for better or for worse."

"To resolve the tension between one's three selves poses the question whether there are valid conceptions of truth to which all three sides of my life can be related, and by which they can be reconciled and governed. Is there such a thing as ultimate truth—however limited my understanding of it may be—a value outside myself to which every side of my personality may be related ?

"Either we think that our lives are purposive—and sustained by a power greater than ourselves—or we believe that life is a chance arrangement in the sense that it is without purposive significance, and we are left to make what we can of the existence with which we have been landed.

"The way one lives requires an affirmation or a denial concerning the very nature of Creation. Christian teaching on this subject has been the occasion for extraordinary misrepresentations, as past records of the British Association only too clearly demonstrate—not so much as to what is believed as to the arguments which have been adduced to support belief. The trouble started, perhaps, in the non-scientific and rather static age, when scholastic proofs for the existence of God—such as the argument from Design and the argument from a First Cause were produced. This had a doubly unfortunate result. In the first place, later generations, finding these arguments unsatisfactory, tended to assume that the conclusions must also be false—a natural, but quite illogical, assumption to make. But in addition, these arguments tended to associate Christian belief about Creation with the thought of a single decisive act of initiation, on the analogy of a divine architect. If you want an analogy, it were better to think rather of the singer who both makes the song and sustains it. The trouble has largely centred around the earliest Biblical story of Creation in the first Chapter of Genesis, as if it were to be understood in historical terms, whereas its intention is different.

"It is when I have recognized within myself that I have part and place in a purposive order of Creation—and this is implied in Christian teaching—that I can use this perception to understand the way the stars are moved—and, in addition, I can see more clearly how the different strands of my life and experience can be reconciled and unified.

"The Christian belief about Creation does not involve any necessary ground of contradiction between the scientist and the Christian in regard to the observable facts. [There is] no argument, for instance, between the Christian and the Doctor as to how a baby is conceived and born. The question which remains is the interpretation that we set upon these facts : 'What is the meaning and the purpose of the life thus born ?' If the Doctor should also happen to be the father of the child, then this is precisely the kind of question he will be disposed to ask. For, as a father, he has a special interest in the child, to whose care and welfare he is committed—committed in a way which includes and transcends his scientific interest for the child's good. Furthermore, his caring for the child must be the regulating factor if the father's relationship is to be adequately exercised, and if the child's interests are to be adequately secured.

"To give precedence to caring—to maintain that other factors must be subservient to it—is, in fact, to illustrate a vital affirmation concerning the end and purpose of Creation. [Sir Wilfrid le Gros Clark, president of the British Association] . . . particularly stressed the significance of altruism in the individual and in society alike, and the necessity for co-operation in man's development."

No matter which of the world faiths one professes (if any), there can be no argument against the fact that the Mosaic Laws or Commandments do, if conscientiously practised, at least make possible the communal life of man. These Commandments enable man to live in communion with himself and also with his fellow-men. "Thou shalt not kill." "Thou shalt not bear false witness." "Thou shalt not steal."

Then much later, Jesus Christ—to the Christian, the greatest sociologist in history—extended the policy pervading the Mosaic Commandments by preaching His second Commandment : "Thou shalt love thy neighbour as thyself". This aims at making the social life of man not only possible but also more purposive, peaceful and contented. Dr. Fleming made much of this doctrine, first of all by carefully emphasizing how to-day the word 'love' has become "sentimentalized and debased".

"In the sense of caring for, and caring about the world and its life—caring in particular about other people for their own sake, love is a creative and positive force. Caring involves and even demands an openness of mind as well as of heart to the spirit of enquiry. There is repeated insistence on this in the teachings of Jesus. Love is also a unifying power within man—for once given its place, the different sides of our personality at last fit purposively together. And love is a unifying power between men, enabling them to sacrifice their personal interests for the good of others ; a requirement of which, in the face of world events to-day, we are being made acutely conscious."

Man's nature and nurture are not inherited or acquired and are not evolving solely according to the broad biological principles generally accepted to-day ; for if so the law of the jungle would still be universally prevalent. A physically healthy body governed by an acute brain is not enough. The weakest of men need not, indeed must not, go to the wall. They need the help of the strongest, and it is difficult to conceive of the latter recognizing, and acting on, such profound responsibility to his fellow-men unless he is supported by, and imbued with, a spirit of humility, righteousness and even loving-kindness which can come to him only if he acknowledges some purpose in life. Science, among other disciplines, can give him strength ; but the spirit of purpose must come from within himself. All the great world faiths teach this in some form or other ; in fact, it is the very basis of the Christian faith.

Many people associate love too closely with sex : they must have a very superficial knowledge of the biological sciences. Yet this is and has been exemplified in literature and drama throughout the ages. Then there are others who, with a smattering of psychology or a tendency to use psychological terms which they do not understand, look upon love as being purely 'emotional'—a very overworked term these days. Even now, in all the disciplines of life (and that includes science), there are those who, though they may have made brilliant contributions to knowledge, are content to let the world go by provided they themselves are not unduly disturbed. Such men are morally indolent and slovenly. Then at the other end of the scale we have those, perhaps good in their chosen profession, who are never really happy unless they are metaphorically perched on a rostrum expounding social, economic and political theories about which they usually understand very little. Such men are bores, perhaps even dangerous. If the concept of more than one 'culture' be incorporated in our future school and university education, then the former might be stirred out of their selfish apathy ; the latter can, and must, be challenged, for, despite their sometimes good academic achievements (and, maybe, arguments), beneath it all frequently lurk a meanness of spirit and self-seeking, unkind, unscrupulous attitudes. They pass from pillar to post telling others how to live, boring those who prefer to think and act for themselves, yet, alas, persuading many who are willing to let others do their thinking for them. Perhaps the best retort to such people might be : "Physician, heal thyself" ; for they are just deceiving themselves with self-satisfaction and false pride, misleading their weaker brethren with rhetoric or monotonous verbosity, yet withal unable to justify their arguments (frequently one-sided) by either precept or example—destructive criticism scarcely followed by constructive suggestion.

Here, therefore, is much food for thought, for the Bishop of Norwich has given men of science a great objective which can render their work not only of rational and practical value but also of greater social significance. The problem is to reconcile collective progress and ultimate fate with individual will. These must not be divided aims, but should be joined together having one objective—the advancement and betterment of world civilization. The connecting links are kindness and consideration for others, or, as the Bishop put it, love. Love must be construed as indicating consideration and care for all those who need it, thus getting outside oneself (selflessness) and sometimes even outside one's own family circle (avoiding nepotism). Neither sentiment nor sentimentality is involved in this philosophy. It is plain common sense, though it may involve some sacrifices which all too few seem ready to make. Moreover, the more kindly and tolerant among us might do better for society by sometimes becoming militant.

There are those among us, scientist and non-scientist alike, who have, perhaps too nonchalantly, cast aside their faiths (whatever they may have been), mainly because, in their so-called scientific reasoning, such faiths cannot be sustained by observable and measurable facts. They then risk ignoring the other selves which Dr. Fleming emphasized. Yet many facets of man's social life are intangible, though none the less real, and the scientist especially might ignore these at his peril—certainly to the detriment of social satisfaction and even world peace. Knowing and recognizing man's social history, surely we have reached a point in our evolution when there need be no more melodramatic religious revivals or insurrections ; nevertheless, caring and loving in their truest sense could be practised much more than they are to-day ; and this with the help of science, which might well go hand in hand with belief in a purpose in communal life. Thus man may find direction, purpose, integration and quality in everything he does.

There are many indications to-day that this is just what people need, and, more important, realize that they need it : otherwise, for example, can there be any valid reasons why the Cathedral Church of Norwich was packed to capacity on September 3 ? It is doubtful if any member of that congregation went there to scoff at what he imagined to be outmoded philosophies ; some have been and still are agnostics ; a few may have appeared either just to see or be seen ; but it is most likely that the majority attended that Service to listen to, and afterwards ponder, the words of one of Britain's leaders in thought —at once a sociologist, a geologist and a theologian.

PROGRESS REPORTS AND TUMOUR RESEARCH

Progress in Experimental Tumor Research

Vol. 1. Edited by F. Homburger. Pp. xv + 476. (Basel and New York: S. Karger, 1960.) 83 Swiss francs.

It is not unlikely that in a twenty-first century history of science and medicine, the second half of the twentieth century will be called a period of high fashion for reviews, advances and progress reports. The future reviewer of these reviews will say probably that there was a pressing need for these to help the student, the research worker, the team leader, and the spectator on the touch-line to digest the enormous bulk of publications ; but he will also discover that the number of specific publishers, without giving due consideration to avoiding duplication, brought out, if not identical but very similar, collections of articles almost simultaneously. These, in addition to symposia reports, congress minutes, etc., so the reviewer of reviews probably will write in A.D 2061, were rather overwhelming in numbers and a burden to the budget of libraries.

Consequently, when a new series of progress reports appear in the crowded market, they have to be very good indeed to justify their existence even in a field like cancer research, with its fronts quickly changing. Of course, if the names of the authors of subsections or chapters are identical with those of the leading workers in special branches then most authoritative accounts can be expected. This is the case with the contributions in the present volume dealing with virology, including oncolytic viruses, carcinogenesis and tumour biochemistry. However, frequently one cannot escape the impression of having read similar reports, sometimes by the same authors, in other collections. Consequently, the reader is torn between his desire to go back to the original papers and his inclination to skim superficially over the texts of the reviews. Another criticism which can be raised against this specific volume is that, under the heading "Progress in Tumour Inhibition", a review of cytotoxic agents of the purine and the steroid group is presented which refers only to compounds synthesized by Lettré and his colleagues and mainly tested on cell cultures. The article by Sokoloff on oncolytic antibiotics is fascinating from the point of view of combination therapy with reticulo-endothelial system activators, such as hæmatoporphyrin and congo red, but it deals solely with four mould products which, so far as one knows, do not belong to the same chemical family.

There is no desire to throw doubt on the value, which is considerable, of this progress report. However, and this question can be raised with a large number of others of a similar type and of high quality, are these progress reports "really necessary ?". It is suggested that the answer lies mainly with the review authors, who in future should have the strength of mind to turn down requests for reviews and only accept the task of writing a few inside a period of three to five years. It is not certain which of us would have this strength.

F. BERGEL

ILLUSTRATIONS OF HUMAN ANATOMY

Atlas of Human Anatomy

Edited by Prof. Ferenc Kiss and Prof. János Szentágothai. Contributor: István Munkácsi. Vol. 1: Osteology—Syndesmology—Myology. Pp. 297. Vol. 2: Splanchnology—Endocrine Glands—Heart. Pp. 214. Vol. 3: Nervous System—Vascular System—Lymphatic System—Sense Organs. Pp. 289. Eighth edition. (Budapest: Publishing House of the Hungarian Academy of Sciences—Publishing House Medicina; London: Collet's Holdings Ltd. 1960.) 180*s*. the three volumes.

THE pioneer work in the field of modern anatomical illustration we owe to Andreas Vesalius, who published his *De Corporis Humani Fabrica* in 1547. It is true that Leonardo da Vinci produced a considerable number of magnificent anatomical drawings —with the legend in his characteristic mirror writing —but for various reasons these never attained the wide circulation and popularity of the drawings prepared by Vesalius.

The Vesalian illustrations were in black-and-white. Aselli's work, *De Lactibus Sive Lacteis Venis*, published in Milan in 1627, contained the first anatomical illustrations in colour. It is a far cry from Aselli's few simple woodcuts to our modern profusely illustrated anatomical atlases, all of which have followed Aselli's lead in making liberal use of colour.

It is generally assumed that the art of anatomical illustration has improved greatly since the time of Vesalius; but it is questionable whether this is entirely true. One of the striking differences between the Vesalian drawings and those found in modern atlases, such as that now before us, is the way in which Vesalius repeatedly depicted the body as a whole, more especially in relation to the skeletal and muscular systems. Though to do this adequately requires plates which are too large for a volume of average size, it possesses very considerable advantages.

Again, it is not clear what purpose is served by the indiscriminate use of colour. Where the colours used resemble those in the original, the illustration will be of value in recalling the dissection which it is intended to portray. Where, however, the colours are purely conventional and bear little or no resemblance to the original, their value becomes very problematical. They may be magnificent, but they are not anatomy. It is far easier with the eye of the mind to superimpose the colours of the original on a black-and-white diagram than on a diagram with colours so greatly at variance with the original that it becomes impossible to substitute the latter for the former.

The *Atlas* now before us is on the whole well done. The illustrations frequently tend to be schematic, but that is a feature common to most modern atlases. The authors have commendably allowed the illustrations to explain themselves, and have refrained from burdening the reader with superfluous legend. Vol. 1 depicts bones, joints, muscles and fasciæ. Vol. 2 deals with viscera, endocrine glands, and heart; and Vol. 3 is devoted to the nervous, vascular and lymphatic systems, concluding with the sense organs.

It would appear from the preface that this *Atlas* has attained great popularity in countries behind the Iron Curtain, and that a Chinese edition has been prepared by Prof. Yü-Ch'üang Tsang.

J. M. YOFFEY

RUSSIAN WORK IN ORGANO-PHOSPHORUS CHEMISTRY

Soviet Research on Organo-Phosphorus Compounds, 1949–1956

In English Translation. Part 1: Pp. viii+448. 50 dollars. Part 2: Pp. vii+449–890. 50 dollars. Part 3: Pp. iv+891–1208. 30 dollars. Complete collection, 120 dollars. (Chemistry Collection Series.) (New York: Consultants Bureau, Inc., 1960.)

DURING the past two decades, there has been a great resurgence of interest in the chemistry of organo-phosphorus compounds, both on the purely scientific side and on the technical side: the academic chemist is attracted by the many novel reactions of these compounds, and the technical chemist by their potential application for a variety of purposes. This resurgence of interest has been strongly marked in chemical studies in the United States and the U.S.S.R.; but in Britain, apart from certain manufacturing processes, the interest has appeared to be very much less active, possibly because the new work has tended to be in highly specialized fields.

The Russian contributions to organo-phosphorus chemistry have naturally been published almost entirely in Russian, and consequently these contributions, although very considerable, have not been easily and rapidly available to English-speaking chemists. The latter are now deeply in debt both to Prof. Alfred Burger of the University of Virginia, who has selected about 250 of the chief Russian papers on this subject which appeared during 1949-56, and classified them in three main divisions, and to the publishers, who have arranged for complete translations of these papers to appear in these three volumes. It should be emphasized that the translations are literally complete with diagrams and full experimental sections.

This has necessarily been a costly undertaking, and as a guide to the prospective purchaser the contents of the three parts (or volumes) are briefly indicated. Part 1. "Derivatives of Organic Phosphorus Acids containing (*A*) the C-O-P Linkage, (*B*) the C-O-P-S and C-S-P Linkages ; (*C*) Effects of Inorganic Phosphorus Compounds on Organic Compounds or Reactions." Part 2. "Derivatives of Organic Phosphorus Acids containing (*A*) the C-P-O Bond, (*B*) the C-P-S Bond." Part 3. "(*A*) Inorganic Complexes of Organic Compounds of Phosphorus ; (*B*) Phosphines, Phosphine Oxides, Phosphonium Compounds and their Se, N, S and Halogen Derivatives ; (*C*) Nitrogen-containing Derivatives of Organic Phosphorus Compounds."

In the table of contents in each part, the title of each paper is accompanied by a simple code symbol which indicates the name of the journal in which the paper originally appeared, the year of publication, and the page number both in the journal and in the earlier English translations which were prepared by the present publishers and from which the papers in the present collection have been reprinted.

The papers in these three parts cover a very wide range of subjects, and will be almost indispensable to chemists who are actually working in the phosphorus field, and who therefore require greater detail than any abstracts can possibly supply. My only (and very minor) criticism of this publication is that, although the majority of the papers are printed very clearly, an occasional paper has formulæ which have become rather blurred in the printing process employed.

It is pleasant to see in this collection a number of papers by Prof. A. E. Arbuzov (who celebrated his eightieth birthday in 1957), and also by his son, Prof. B. A. Arbuzov, and their co-workers.

F G. MANN

TRANSITION-METAL CHEMISTRY

An Introduction to Transition-Metal Chemistry

Ligand-Field Theory. By Leslie E. Orgel. Pp. 180. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1960.) 25*s*. net.

An Introduction to Co-ordination Chemistry

By Dr. D. P. Graddon. (International Series of Monographs on Inorganic Chemistry, Vol. 3.) Pp. vii+111. (London and New York: Pergamon Press, 1961.) 25*s*. net.

The Theory of Transition-Metal Ions

By Prof. J. S. Griffith. Pp. x+455. (Cambridge: At the University Press, 1961.) 95*s*. net.

IT is a sign of the astonishing development of inorganic chemistry during the past fifteen years that no less than three books come to be reviewed simultaneously. Furthermore, all three are so distinct in their emphasis that not one of them is included in the others.

The briefest possible description would be to say that Dr. Orgel's book gives the most pictorial account yet provided of the reasons why transition metals form such interesting complexes; Dr. Graddon's book gives an account of the many different varieties of co-ordination compounds recently developed, and increasingly used in various industrial processes; Prof. Griffith's monumental tome lays down the basic theory in a form that is definitive and impressive.

Dr. Orgel has set out to write a book which displays the pattern of transition-metal chemistry in the simplest, and most pictorial, fashion. This aspect of chemistry is really bound up with the behaviour of atomic *d*-electrons. Orgel is able to show, with a series of most effective and elementary diagrams, how the energies of these *d*-orbitals are affected in the presence of a given set of ligands, having tetrahedral or octahedral symmetry. The one impression that stands out from reading this admirable volume is the simplicity and order that have been brought into this previously complicated field, by quite elementary notions of wave mechanics. At the elementary level to which this book aspires, it would be very difficult to improve on it. I find it hard to believe that any undergraduate reading for a degree in chemistry could not understand it, and profit greatly at the same time.

Dr. Graddon's emphasis is on the experimental results. He begins with a history of co-ordination chemistry and shows that this may be traced back as long as 1753, when Macquer obtained potassium ferrocyanide. It is good to be reminded that the famous series of cobaltammines dates back to Tassaert in 1798. Subsequent chapters deal with polymerization, stability constants, oxidation potentials, carbonyls and π-complexes, solvent extraction and sequestration. It will be clear from this that Dr. Graddon provides a good deal of experimental information not covered by Orgel. I wish I could speak equally favourably of his theoretical treatment. This, alas, is marred by several bad mistakes. To mention a few: the combination of d_{z^2} and $d_{x^2-y^2}$ atomic orbitals is not spherically symmetrical; ligand-field theory is not an electrostatic theory (though crystal-field theory much more nearly is so); two *d*-electrons do not necessarily lead to a state with angular momentum 3; the molecular orbital for ferrocene which Dr. Graddon refers to as Σ is not "analogous to an atomic *s*-orbital". These are serious errors, which much reduce the value of the book, and make it dangerous in the hands of a student.

Prof. Griffith has written a large and impressive account. It is hard going, and no one should be tempted to accept the beginning disclaimer, that scarcely any quantum theory is needed. Perhaps no one is very likely to do so, when he sees that preliminary reading includes chunks of Dirac's *Quantum Theory*, and the language of bra's and ket's is used without apology. But for those who will normally be theoretical physicists, who can cope with the mathematics, this is a book with no rival in its field. In the earlier chapters Griffith revises the theory of atomic structure, and recapitulates much of the corresponding work in Condon and Shortley's well-known monograph in the same "Cambridge-Blue" series. This is followed by a valuable account of group theory, including spinors, and the application in one-electron and many-electron ions. The Jahn–Teller effect, paramagnetic effects, optical spectra, the relation between holes in nearly filled shells and a similar number of particles, the effective Spin–Hamiltonian, electron-spin-resonance are all dealt with. The account is clear, and—if it were not for a few silly footnotes in praise of discussions around a coffee table—set-out with dignity, precision and completeness. My only comment of an unfavourable kind concerns the distinction between crystal-field theory and ligand-field theory. Here Orgel seems to be more explicit and helpful. It is true that the distinction (without which one cannot adequately deal with the successes and failures of Pauling's early theory of hybrids) is implicit in Chapter 7. But it would have helped very much to have had it developed more explicitly. Then the role of the linear combination of atomic orbitals approximation would have become more apparent, and it would not have been relegated to an appendix. It would also have been easier to relate nuclear hyperfine and electron-spin measurements to the degree of delocalization of the various molecular orbitals. I could also have wished that the author had distinguished more clearly between what chemists call orbitals and spin-orbitals.

But these are small points. This is a really important book, and will at once take its pride of place as the most definitive full-scale study of this field.

Inorganic chemistry has moved a long way from the situation in which the poor unhappy chemist had to learn long lists of formulæ and reactions by heart. It now has a shape and a coherence. Wave mechanics has provided much of this understanding: and in so far as these books—particularly those by the Cambridge School—are able to show this pattern, they are to be welcomed most warmly.

C. A. COULSON

TERPENE CHEMISTRY

The Chemistry of the Terpenes

By Dr. A. R. Pinder. Pp. vii+223. (London: Chapman and Hall, Ltd., 1960.) 50*s*. net.

THIS book is intended to provide honours undergraduates with a source of information on terpenes which is intermediate between the general text-books and the comprehensive monographs. There is no obvious reason why terpenes should be singled out for special treatment in this way, and it would be impracticable to require undergraduates to delve into a large number of works of this type each dealing at considerable length with one particular aspect of chemistry. It is, of course, impossible to cover everything in lectures to undergraduates, and there is no denying that it is desirable each year to deal with a few subjects in some detail. The topics selected for such treatment should, if possible, serve to illustrate important general principles or general methods of degradation and synthesis, and there can be no doubt that the terpenes are among those which are ideally suited to this purpose. However, it is questionable whether the students should be provided with an extra text-book to accompany all lectures giving special attention to a particular topic. That such a book might provide a hard-pressed lecturer with considerable assistance in planning a series of lectures is another matter. The present book is intended for students, and it must therefore be considered primarily in this light.

All the main classes of terpenes are covered, including the carotenoids, which, strangely, are omitted in the otherwise admirable reference works by Simonsen and his co-authors and in the excellent two volumes provided recently by de Mayo. Following a short chapter devoted to the determination of structure by both chemical and physical methods, the various classes of terpenes are discussed in a conventional way giving rather greater attention to the mono-, sesqui-, and di-terpenes than to the more complex compounds. More examples of each class are often given than are necessary to illustrate many general points, and details on occurrence, isolation, and physical properties are included which can be of little use to the undergraduate. The text itself is always clear, but at times could with advantage be more critical, particularly when reproducing claims from the earlier literature and for which the evidence would not now be considered conclusive. I should also have liked to see more attention given to the mechanisms of the various reactions described. No explanation is offered for such simple processes as the cyclization of geraniol and the hydrolysis of citral; the direction of additions to carbon-carbon double bonds is explained in terms of Markownikow's rule; and the opportunity of introducing such concepts as non-classical ions and concerted processes is missed. At the end of each chapter references are given, though none was noticed that was later than 1957. Some sections are inevitably a little out of date; thus mevalonic acid receives very little mention in the chapter on biogenesis. However, those who require a brief survey of the terpene field will find it in this book.

B. C. L. WEEDON

ALGOLOGICAL STUDY ON THE EASTERN COASTS OF THE AMERICAS

Marine Algae of the Eastern Tropical and Subtropical Coasts of the Americas

By Prof. William Randolph Taylor. (University of Michigan Studies—Scientific Series, Vol. 21.) Pp. ix+870. (Ann Arbor: University of Michigan Press, 1960. Distributed in the United Kingdom by the Cresset Press, Ltd.) 19.50 dollars; 140*s*.

WR. TAYLOR'S major work is the first complete account of the algae of the eastern coasts of the Americas, from Bermuda and from North Carolina (respecting the more southern species) to southern Brazil.

A historical survey, with bibliography later in the book, is of particular importance because such early records as exist are mainly scattered through general works or hidden in rare volumes. Brief reference is made to geographical distribution, though seasonal changes are much reduced in such warm waters where major currents tend to spread tropical conditions beyond their normal limits.

Preliminary discussion of algal habitats outlines the effect of fluctuating conditions in the aquatic environment. The author stresses the suitability of the region for algal study because of the possibility of a continuous working season with minimal tidal amplitude, although species are restricted by relatively stable water-temperature and insolation. Ecological habitats, intertidal and at greater depth, appear to be comparable in some cases with those in sub-tropical waters off parts of the Australian coasts, especially where terraces clothed with coralline and other algae extend into the sea and the roots of *Avicennia* and *Rhizophora* provide a habitat around the sun-lit margins of the groves. In the sub-littoral, Chlorophyceae, particularly members of the Siphonales, together with members of the Rhodophyceae, have been found at a depth of 90 metres. The author finds no evidence that the pelagic forms of *Sargassum*, which form the bulk of the floating algae in the Sargasso Sea, need to be constantly replenished from a benthonic source.

This section of the book concludes with a helpful chapter on the preservation and collection of specimens, a subject on which the author's painstaking work is well known.

The main text of some 600 pages is a descriptive catalogue of 750 species and 140 varieties, with keys for families, genera and species, bibliographical references, location and ecological notes. Uncertain records are listed at the end of the section on each genus. The book is illustrated by 74 beautifully executed line drawings and 20 black-and-white photographs.

The whole volume is the result of thirty years of patient and skilled endeavour by W. R. Taylor, his wife and a group of young workers. It has added greatly to algological knowledge, and at the same time it will be a foundation and indeed an inspiration, for further taxonomic and ecological work in an area for which no algal Flora had formerly been published. It is a pity that a map has not been included, particularly as locations are cited at the ends of descriptions of species. LILY NEWTON

STEROIDS AND CANCER

Biological Activities of Steroids in Relation to Cancer

Proceedings of a Conference sponsored by the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health, U.S. Department of Health, Education and Welfare. Edited by Gregory Pincus and Erwin P. Vollmer. Pp. xvi+530. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 15 dollars.

THIS book is the record of a conference of American endocrinologists, held in October 1959, to review the progress of a cancer therapy programme set up in 1955 by the U.S. National Cancer Institute. This record, complete with verbatim reports of the uninhibited discussions, reflects the high standard of present-day endocrinology in the United States, and the close alliance, if not identity, between clinical investigators and animal experimentalists. However, although the programme has clearly been intelligently organized and has already given grounds for cautious optimism, "Difficulty has been experienced in making use of information derived from animal studies.... The possibility exists that we may well become quite proficient at treating mouse and rat cancers, but not those found in man" (H. Brendler). Even with animal tumours there are of course numerous difficulties; for example, the admixture of cells dependent on hormones and cells independent of hormones in rat mammary tumours induced by a technique which C. Huggins describes. His paper is notable for the international flavour of its list of references.

The papers on steroid chemistry (J. Fried), on the prostate as a target organ for steroids (W. W. Scott), and on steroid metabolism in human endocrine tumours (R. I. Dorfman) are informative in themselves and indicative of the range of subjects dealt with. V. A. Drill lucidly discusses the physiology and pharmacology of steroids in relation to the growth of experimental tumours. He also deals with the pituitary gland in a short section, which opens with the over-terse phrase: "Estrogens and androgens can inhibit the pituitary gland . . ."; in fact, only some of the functions of the pituitary are known to be thus inhibited. R. Vandewiele and S. Lieberman discuss the mysterious 'adrenal androgen' dehydroisoandrosterone—a major secretory product, the output being 15–25 mgm. a day in man. Among other papers on basic work, G. C. Mueller's is notable for shrewd experiments on possible points of action of œstrogens, ethanolamine phospholipids being a new candidate for consideration. Hydrogen transport may be another candidate in the view of P. Talalay and collaborators, but this view has been challenged.

While the book will be indispensable for clinical investigators, it also offers much of value to workers in basic disciplines, including chemistry. It contains not only an index but also a glossary. E. REID

JUNGIAN PSYCHOLOGY

The Structure and Dynamics of the Psyche

By C. G. Jung. Translated by R. F. C. Hull. (The Collected Works of C. G. Jung, Vol. 8.) Pp. x+596. (London: Routledge and Kegan Paul, Ltd., 1960.) 42*s*. net.

THIS volume of Jung's collected works is not a book devoted to one developed theme but a collection of essays: some written many years ago and worked over more recently before publication. They are a witness to his incredible industry, which seems to have remained undiminished up to the very last years of his long life.

In a way it is a pity that he re-wrote such a great deal since one would like to have observed the evolution of his ideas. Some of the essays do show this, and the one "On Psychic Energy", for example, is really a defence of the stand he took after his book, *Psychology and the Unconscious*, caused such a violent opposition that he resigned his presidency of the International Psychoanalytical Society in 1913. In it he discusses symbol formation, myths and his views on the nature of the libido.

This book shows clearly both Jung's virtues and faults. There is no doubting his tremendous application, his great erudition, and originality. However, this is offset by his vagueness and his tendency to interpret unknowns by unknowns. In spite of this, those interested in Jung's psychology should certainly read these essays. They will find considerable space devoted to his theories of complexes, archetypes and the structure of the psyche. The breadth of his reading is frightening, particularly when one considers that not only has he read very widely the literature of psychology from most countries but also he has made a deep study of mythology as well.

The last essay will not be acceptable to many psychologists—it is on "Synchronicity: an Acausal Connecting Principle" and deals with extra-sensory perception.

Those interested in Jung's thought should certainly read this series. It is beautifully produced in a cloth binding with gold lettering, and clear print. The bibliography takes up seventeen pages and the index thirty-three. The translation by R. F. C. Hull is faultless. C. ALLEN

Rapid Statistical Calculations

A Collection of Distribution-free and Easy Methods of Estimation and Testing. By M. H. Quenouille. Pp. xv + 81. (London: Charles Griffin and Co., Ltd., 1959). 10s.

ORTHODOX statistical techniques usually involve a fair amount of computation. Particularly when data are cheap, there is a need for rapid methods that can be applied with no more than pencil and paper. Some of these methods have the added advantage of being 'robust'—they remain valid (at least approximately) over a wider range of assumptions than do the more usual techniques.

The advantage of speed is lost if the user of a rapid method has to spend time looking up the details in a journal. Mr. Quenouille has accordingly collected together a selection of the most useful techniques and has had them published in a genuine pocket-book, measuring only 16 cm. × 11 cm. Each method is presented with comments and an example on a pair of facing pages. The topics covered include the estimation of means, standard deviations and regression coefficients and tests for inequality of means, differences between means of groups, differences between proportions and association. In the index, the methods are marked "faster than usual", "quick" or "very quick", and tests that are distribution-free are indicated. The list of references shows that several of the tests are new.

Rapid Statistical Calculations is well produced at a reasonable price; those for whom the ordinary statistical techniques are too cumbersome should find that it meets their requirements.

M. J. R. Healy

Theory of Detonation

By Ia. B. Zeldovich and A. S. Kompaneets. Pp. i + 284. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 10 dollars.

THIS book, based mainly on papers written at the Chemical Physics Institute of the Academy of Sciences of the U.S.S.R., gives a systematic account of the theory of detonation. The first chapter considers the relevant fundamental concepts of gas dynamics, and includes a discussion of shock waves, the flow equations, and 'characteristics', for one-dimensional and centrally symmetric flow.

Most of the book is concerned with gas explosions, and throughout the authors are at pains to explain the physical and chemical concepts underlying their reasoning and not merely to manipulate mathematical symbols. For example, in the hydrodynamic theory of detonation, the complex argument required to show that the Chapman–Jouguet plane coincides with the end of the reaction zone in a plane, stable, lossless wave is carefully detailed. Deflagration is discussed, and there is a useful contribution on non-detonative explosions. The effect of thermal and fluid-mechanical losses in smooth pipes, and spin detonation are treated, and so also are detonation in roughened pipes and the transition from combustion to detonation.

Less space is devoted to detonation in condensed explosives. The authors point out that, generally, the density of the gaseous products is so high that the full hydrodynamic theory is inapplicable; they obtain useful results by combining the appropriate hydrodynamic equations with observed empirical relations. The final chapter discusses the motion of the detonation products.

It would have been helpful if reference had been made to a wider range of original papers, but, nevertheless, this is a valuable text-book which should be widely appreciated. The English translation reads well.

W. L. Murray

Thermodynamics with Quantum Statistical Illustrations

By Prof. P. T. Landsberg. (Monographs in Statistical Physics and Thermodynamics, Vol. 2.) Pp. x + 499. (New York: Interscience Publishers, Inc.; London; Interscience Publishers, Ltd., 1961.) 109*s*.

IN an appendix to this book Prof. Landsberg tells us that a common misconception about thermodynamics is that, since the subject is mathematically simple, it is also intrinsically simple. That this is indeed a misconception is demonstrated by the hidden, and sometimes unnecessary, assumptions made in the usual treatments of the subject. In order to avoid these, the author has used some mathematical tools which, sadly, will be unknown to many physicists. However, the reader is carefully introduced to them, and the usual claim, that no previous knowledge of these subjects is necessary, is probably in this case justified.

The first three chapters consist of a discussion, couched in the language of elementary topology, of the three laws of thermodynamics, and the fourth chapter of some rather formal applications. The fifth and final chapter, probably the best in the book, deals with statistical mechanics from the point of view of probability distributions rather than ensembles. Finally, there are seven useful appendixes and a rather brief bibliography.

The book is written throughout in a most readable style. Prof. Landsberg is particularly to be praised for his excellent and unusual selection of examples, and for his references to many little-known parts of the literature. It would be a mistake to use this book as a standard text at any level, but it can be recommended to anyone who has a serious interest in thermodynamics, or indeed, who wants such an interest stimulated.

W. E. Parry

Techniques in Tropical Pathology

By Prof. B. G. Maegraith, Prof. W. E. Kershaw and D. Dagnall. Pp. xi + 165. (Edinburgh and London: Oliver and Boyd, Ltd., 1961.) 25*s*. net.

THIS simple book, written by three workers deeply experienced in the subject, will prove of value to medical men and others who live in the more remote parts of the tropics. Perhaps a better title would have been "Tropical Parasitology" instead of *Tropical Pathology*, because very little pathology in the classical sense is included, and scarcely any histological staining methods. Likewise, the bacteriological side is a little weak, and there is no mention of an incubator in the list of apparatus given in the appendix. With these reservations, the book can be thoroughly recommended; it is divided into two main portions: (1) the technique of examination of different material (blood, urine, fæces, sputum, cerebrospinal fluid, pus, and biopsy specimens); and (2) the diagnosis of specific infections, in which a very short account of epidemiology is followed by a good description of the individual agents of disease.

Three coloured plates (one of which by its presumably unintentional 'fuzziness" gives a life-like impression of a thick blood film stained by Field's method), three photomicrographs, and four text figures illustrate the text.

P. C. C. Garnham

LONG-RANGE RADIO COMMUNICATION BY SATELLITE MICROWAVE DIPOLES

THE WEST FORD PROJECT

IN the autumn of 1959, the Space Science Board in the United States was informed of the proposal by the Lincoln Laboratory of the Massachusetts Institute of Technology to erect a belt of thin microwave dipoles in a polar orbit about the Earth at an altitude of a few thousand kilometres to obtain experimental verification of such a system for reliable long-range radio communications. This experiment involves the establishment of a belt consisting of some 35 kgm. of dipoles, resonant at about 8,000 Mc./s., and therefore serving to reflect radio waves at this frequency. Each dipole is 1·77 cm. long with a diameter of 0·00286 cm. $3·5 \times 10^8$ dipoles are involved, distributed uniformly along the orbit and afterwards dispersing until, at 60 days after launch, a belt 8 km. wide by 40 km. thick is formed. At this time the density will be about 21 dipoles per $km.^3$. The orbital altitude for the experiment has been chosen to ensure that effects of solar radiation pressure will act to produce an ever-increasing eccentricity in the orbit, thus bringing perigee into the atmosphere within a few years with consequent destruction of the belt.

Extensive theoretical and laboratory studies of the properties of orbiting dipole belts have been carried out at the Lincoln Laboratory. In addition, at the request of the Director of the Laboratory, the Space Science Board undertook to examine the effects of the proposed experiment to ascertain whether the project would have any noticeable effects on activity in any field of research.

The Board, on December 24, 1959, appointed an *ad hoc* committee of scientists under the chairmanship of Dr. O. G. Villard, jun. (Stanford University), to examine the consequences of the proposed experiment. Astronomers on this committee included G. M. Clemence (U.S. Naval Observatory), C. H. Mayer (Naval Research Laboratory), and F. L. Whipple (Smithsonian Astrophysical Observatory). The committee held several meetings during the first half of 1960, and invoked the assistance of some twenty additional scientists, including optical and radio astronomers and other specialists.

Acting on the findings of this committee, the Space Science Board in June 1960 reached a number of conclusions and adopted several recommendations. (i) This exploratory test would not have an adverse effect on any branch of science. (ii) There is justifiable concern for the interference which an operational system might entail for optical and radio astronomical observations: any planning for such a system must protect the interests of astronomical research and of science in general. (iii) Full information on the scientific and operational aspects of the initial experiment should be published as soon as possible. (iv) In view of the possible interference to radio astronomy, which might result not only from extensive dipole belts but also from active and even passive communication satellites, frequency bands for radio astronomy should be provided on the basis of world-wide agreements.

The Board also decided that continued study of the subject was worth while, and in this the Lincoln Laboratory concurred. Accordingly, the Board established a special committee on July 29, 1960. The present composition of this committee is as follows: John Findlay (National Radio Astronomy Observatory) (*chairman*), F. T. Haddock (University of Michigan), William Liller (Harvard University), A. E. Lilley (Harvard University), W. A. Hiltner (Yerkes Observatory), and Allan Sandage (Mount Wilson and Palomar Observatories). Leo Goldberg (Harvard University), chairman of the Astromony Committee of the Space Science Board, meets with the group. The committee was asked by the Board to examine carefully all calculations of the effects of the West Ford experiment on astronomy, and to recommend additional necessary research. The committee has maintained continuous liaison with the project throughout the past year and has formally convened with the directors of the West Ford project of Lincoln Laboratory on three occasions. At each of these sessions the committee has received a thorough review of the project and full information on all aspects of the experiment.

The Space Science Board has felt that a discussion of the proposed experiment should not be limited to committee consideration, but should be given critical analysis by the scientific community as a whole. Accordingly, as a result of the foregoing recommendation (iii) of the Space Science Board and following almost immediately the initial discussions of its Astronomy Committee with Lincoln Laboratory scientists (August 29, 1960), the Laboratory agreed to publish its work on orbiting dipole belt properties. Dr. W. E. Morrow, director of the West Ford project, presented a paper on the topic before the general assembly of the International Scientific Radio Union (URSI) in London in September 1960.

The Board has also recommended that the theoretical and technical aspects of the West Ford project should be published in the astronomical literature so that astronomers throughout the world could examine for themselves the calculations on which the project is based. For this purpose, four articles were published in the *Astronomical Journal*, Vol. 66, No. 3, pp. 105–118, April 1961. Some 1,400 copies of these papers have been distributed by the Board to the scientific community, more than 1,100 of them to members of the International Astronomical Union, including 800 astronomers abroad.

During the course of its considerations, the Committee also established the desirability of securing the widest possible participation of observational astronomers to study the characteristics of the West Ford project to determine its performance under actual conditions. In March 1961 the Committee distributed a circular letter to a large number of optical astronomers throughout the world (i) providing a technical description of the experiment, (ii) containing recommendations for an observational programme which might be undertaken, and (iii) inviting the co-operation of individual astronomers in obtaining observations and measurements.

The Space Science Board's recommendations on the West Ford project have been made available to the U.S. Government as they were developed. In response to these recommendations, made by the Board on behalf of the scientific community, the Government has issued appropriate policies. These, as transmitted by the Special Assistant to the President for Science and Technology to the chairman of the Space Science Board, state: "The United States Government, in conducting the West Ford Project, will be guided as follows:

"1. No further launches of orbiting dipoles will be planned until after the results of the West Ford experiment have been analysed and evaluated. The findings and conclusions of foreign and domestic scientists (including the liaison committee of astronomers established by the Space Science Board of the National Academy of Sciences) should be carefully considered in such analysis and evaluation.

"2. Any decision to place additional quantities of dipoles in orbit, subsequent to the West Ford experiment, will be contingent on the results of the analysis and evaluation and the development of necessary safeguards against harmful interference with space activities or with any branch of science.

"3. Optical and radio astronomers throughout the world should be invited to co-operate in the West Ford experiment to ascertain the effects of the experimental belt in both the optical and radio parts of the spectrum. To assist in such co-operation, they should be given appropriate information on a timely basis. Scientific data derived from the experiment should be made available to the public as promptly as feasible after the launching."

In the light of its investigations and of U.S. Government policy, the Space Science Board concludes:

"(1) The Project West Ford experiment will constitute no interference to optical or radio astronomy. As a matter of fact, the belt will be barely detectable, even by astronomers with advance information and on the taking of special efforts for detection. It is true that a belt or belts could be erected which could cause interference to astronomical observations; however, the United States Government policy provides that no further launches of orbiting dipoles will be planned (i) until the West Ford results have been analysed and evaluated and, further, (ii) will be contingent on the development of necessary safeguards.

"(2) The Board will continue its studies of this area of experimentation on behalf of the scientific community. In these studies it will depend on objective and quantitative assessments that constitute the foundation for scientific discussions, recommendations and decisions. These assessments can only be achieved through a carefully controlled, harmless test, and Project West Ford provides a clear opportunity for scientists of all nations to co-operate in making observations to form the basis for an objective understanding of the behaviour of an orbiting dipole belt, both in terms of its astronomical properties and of its possibilities for communication.

"(3) The Board will continue to keep the scientific community everywhere informed and it invites the co-operation and assistance of scientists everywhere who have interest and specialized knowledge in this area. The Board acknowledges with gratitude the assistance of many scientists—both at home and abroad—who have already contributed to its studies."

BIOCHEMISTRY AT THE UNIVERSITY OF MELBOURNE

By Prof. V. M. TRIKOJUS

In April of this year the Russell Grimwade School of Biochemistry at the University of Melbourne was officially opened by Sir John Eccles, president of the Australian Academy of Science. During his opening address Sir John made a strong plea for increased support for the biological sciences and stressed the unifying role of biochemistry in this regard. Fifty years hence we would be judged as having been far too concerned with the sciences of inorganic matter, such as nuclear physics, and the probing of space, and with giving too little attention to the potentialities of biological research for the welfare of mankind. Much the same view had been expressed by the late Sir Russell Grimwade when, in 1944, he made a gift of £50,000 to the University towards a new home for biochemistry. Himself a graduate in chemistry, Russell Grimwade played a leading part in the development of chemical industry in Victoria and elsewhere in Australia. A man of wide vision and interests, skilled moreover in several of the crafts, he exercised a profound influence on the cultural progress of his native city and beyond. He also found time to serve the University for many years as a member of Council and as deputy chancellor.

A start with the new School was delayed for a long period by building restrictions and then inflation, but through the generosity of Lady Grimwade and grants from the University's Building Appeal Fund and from the State and Commonwealth Governments sufficient finance became available over the past six years to bring construction to the final stage.

Erected in two sections, the first, mainly for teaching, being opened by Lady Grimwade in 1958, the completed building, of about 66,000 sq. ft., is by far the largest in Australia devoted to biochemical science. Of modern construction the building consists of a main laboratory wing, running east–west, of five floors, each 200 ft. long and of approximately 10,000 sq. ft., plus a penthouse area. A north extension of three floors at one end houses student facilities, an electrical sub-station, the main entrance and foyer, a lecture theatre and departmental library. The total cost, including furnishings, amounted to approximately £710,000.

The ground-floor of the main structure contains the stores, a large-scale laboratory with associated cold- and hot-room assemblies, an area for physical biochemistry and a mechanical plant section. At this level a bulk solvent store connects with, but is external to, the main building framework.

There are three teaching laboratories situated on the first and part of the second floors, capable of

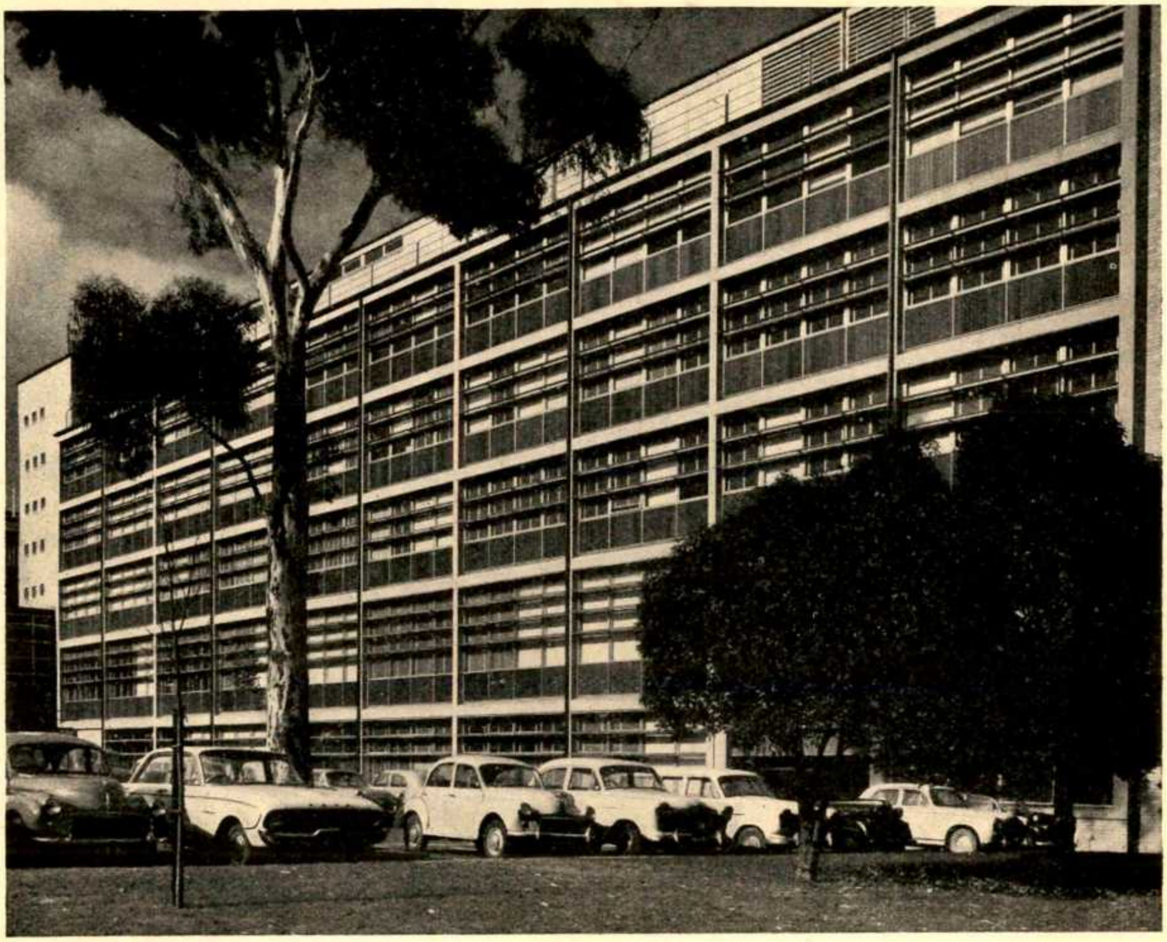

Fig. 1. The Russell Grimwade School of Biochemistry, University of Melbourne (viewed from north-west and showing the main laboratory wing only)

handling up to 180 students at one time. Undergraduate instruction to some 550 students is spread over four faculties: medicine (two years), science (two years), agricultural science (two years) and dental science (one year).

The remainder of the building comprises mainly offices and laboratories for staff and research students and rooms for specialized research facilities, such as air-conditioned areas for physical equipment and chromatography and a section for isotopes. There are cold rooms on each floor. On part of the fourth floor are the Nicholas Nutrition Laboratories for teaching and research, which include the section for the breeding and housing of small laboratory animals and an adjoining incinerator room. The penthouse area, which runs the full length of the building, comprises a second mechanical plant room, a toxic laboratory and a general laboratory section which will house for a limited period the Sugar Research Unit of the Commonwealth Scientific and Industrial Research Organization.

The structure is steel framed with light-weight floors of prefabricated metal units. Steel beams are protected with suspended fire-resistant ceilings. The rectilinear pattern of the steel columns and beams on the elevations of the laboratory wing has been finished in cast stone. Walling is in light-toned brickwork. Window frames are aluminium and along the north side are fitted with horizontal hoods to protect the glass from the summer sun. Spandrels below the windows are faced with aluminium, ribbed and anodized grey.

The general planning of the laboratories permits a wide degree of flexibility to follow changing techniques and methods, and the positions of laboratory benches and the location of partitions are adjustable to revised requirements. The modular system adopted for the purpose provides a series of working bays each equipped with its set of service installations.

The pressure services—compressed air, gas, hot and cold water, filtered and demineralized water, and the heating system—are run in horizontal ducts below the window sills and connect to distribution ducts along the centres of the laboratory benches. The fitments, which have been designed in standard units to reduce manufacturing costs, are protected with a plastic acid-resistant finish.

The drainage system is run in corrosion-resisting polyvinyl chloride piping through polythene traps. Wastes are concealed in ceiling ducts and connected to a series of vertical ducts spaced along the centre of the building; thus all pipes and wastes are readily accessible for maintenance. Various parts of the building are mechanically ventilated, including the larger teaching laboratories, by connexion to a system of positive pressure. Plastic tube vents from the fume cupboards rise in the vertical ducts and terminate with individual exhaust fans grouped at 40-ft.

intervals above the penthouse-level. Automatic fire alarms and extinguishers give protection against the spread of fire and a warning system indicates any failure in the mechanical plant. A passenger lift located in the eastern tower and an electrical hoist from the stores in the centre of the building provide additional services.

The landscaped development of the grounds adjacent to the building includes two levels of lawn and gardens and a parking area for forty cars.

Biochemistry gained its independence at the University of Melbourne in 1938 when the late Dr. W. J. Young—co-discoverer of the Harden–Young ester—was appointed as the first professor and he was succeeded in 1943 by Dr. V. M. Trikojus. From small beginnings the school has now a full-time teaching, research and technical staff of about seventy. A broad pattern of research is in progress, and all members of the staff look forward to a period of vigorous development in their new environment.

PLANT EXPLORATION AND INTRODUCTION

"THE key to our understanding of the evolution of living organisms is, as Darwin discovered, the study of what happens to them in the hands of man. During the past ten thousand years man has transformed the plants with which he has most concerned himself. The origin of cultivated plants, therefore, in some respects proved to be, as Darwin supposed, a model of the origin of species" (C. D. Darlington, *Chromosome Botany*, 1956).

In the years which have elapsed since N. I. Vavilov and his colleagues in the Institute of Plant Industry, Leningrad, carried out their pioneer and fundamental work on the centres of origin of economic plants, considerable progress has been made in the general understanding and application of the principles and techniques involved. Many collecting expeditions have visited what have now come to be called the centres of greatest diversity, simple, multiple or shifting, and studies have been made on the origins and peregrinations of many cultivated plants.

During the past five or six years, the Food and Agriculture Organization of the United Nations has been giving increased attention to the subject, because the assembly and study of wild species and primitive forms appeared to be an activity that called for international action and support. In recent years also, there has been an increasing realization that many important crop plants, particularly in the more developed countries, have a dangerously narrow genetical basis, and at the same time the world gene resources in and around the centres of diversity are being destroyed through intensive and unwise use of land and the advance of 'improved' cultivars into regions of primitive agriculture.

This work recently culminated in the convening at the headquarters of the Organization in Rome of a technical meeting on plant exploration and introduction, held during July 10–20. Seventy delegates and observers from some thirty countries and other international organizations took part. The chairman was Mr. William Hartley (Australia), and the vice-chairmen were Dr. E. Åberg (Sweden), Prof. F. G. Brieger (Brazil) and Mr. A. Marzocca (Argentina).

The programme was designed to permit the presentation of papers and full discussions, first on present-day actions and future requirements with regard to specific major and minor crops (cereals, legumes, industrial crops, tropical perennial crops, fruits, vegetables and potatoes, and the herbage and fodder plants). This was followed by a series of seven papers on the genecological bases of exploration and collection, with contributions by William Hartley on the phytogeographical basis of pasture plant introduction, Prof. H. R. Oppenheimer (Israel) on the origin of cultivated wheat, and Dr. H. Ross (Germany) on the potato gene centre and its importance with respect to the origin and breeding of the cultivated potato. The potato also featured in the plea by Prof. J. G. Hawkes (University of Birmingham) for greater international collaboration in collecting expeditions and the subsequent distribution of the material, and in the report of the British Commonwealth Potato Collection presented by Dr. P. S. Hudson (Commonwealth Agricultural Bureaux).

Prof. J. W. Purseglove (Trinidad) directed attention to the work of I. H. Burkill, and to the fact that not all cultivated plants have necessarily arisen in the eight independent centres of origin recognized by Vavilov. Furthermore, some crops may have died out of the areas where they formerly flourished, and have found secondary centres of diversity in favourable areas where conditions for evolution are different. The generalization that the centre of origin of a taxon is the area in which the most advanced species are found should, according to Prof. Purseglove, also be treated with caution. New cultivars are evolved at the periphery of migration or when encountering unfavourable conditions. Plants rarely occupy anything like the whole of their potential geographical range. Although the Vavilov dispersal centres may show the greatest qualitative variability, they are not necessarily the centres of maximum expression of a character in a new direction.

Although the value and significance of comparative climatic investigations have not yet been generally accepted, there is no doubt that they may ultimately be expected to make a great contribution to the better understanding of the geographical basis of the subject. G. Perrin de Brichambaut (Food and Agriculture Organization), who is at present engaged with C. C. Wallén (Sweden) on a comparative study of agro-climates in the winter-rainfall regions, involving the collaboration of the Food and Agriculture Organization, Unesco and World Meteorological Organization, presented a review on these relations. It must in the first place be emphasized that, in underdeveloped countries and remote areas, microclimatology cannot be taken as a basis for plant introduction and that only regional climatology sometimes permits useful comparisons to be made. Distinctions may be drawn on the following basis:

(*a*) The plant explorer who collects wild species and primitive cultivated forms generally goes to primary and secondary centres which are often located in

International Edition

ANGEWANDTE CHEMIE

– in English –

Volume I, Number I, January 1962

The *International Edition* of ANGEWANDTE CHEMIE is under the editorial supervision of Dr. W. Foerst, who is also chief editor of the German-language ANGEWANDTE CHEMIE, founded in 1888. This journal has achieved great distinction in chemical literature and has often been chosen as the medium of publication by distinguished scientists, including many Nobel Laureates.

Each number of ANGEWANDTE CHEMIE/*International Edition* contains

- review articles
  from all fields of chemistry written by authorities—
  concise, easy to read, well documented
- selected papers
  from the affiliated journal "Chemie-Ingenieur-Technik"
- communications
  from all fields of chemical research, carefully selected to assure highest standards
- conference reports
  abstracts of lectures given at the most important European chemical meetings, covering unpublished results
- selected abstracts
  reporting the highlights from international chemical literature—
  fast, reliable
- book reviews

chosen from the semimonthly issues of the German edition.

Volume 1, about 600 pages (¾ of the German edition), will consist of 12 issues, to be released monthly.

Subscription price: 107*s*. 6*d*. (*plus postage*)

Please place your order with your subscription agent or with one of the publishers.

A limited supply of sample issues, representing a complete translation of Volume 72, No. 22, November 21, 1960, has been prepared. A detailed brochure is available from one of the publishers:

Model 0-1910 Cap: 5kg. Sensitivity 0·5g. Price: £49.15.0d.

These world-famous balances, made by the OHAUS Scale Corporation of America, are justly renowned for their outstanding value. They incorporate special, built-in high-quality features, listed below, making them more durable, more accurate and easier to operate.
1. Self-aligning, semi-rigid agate bearings.
2. Dust-proof, self-locking bearing covers.
3. Patented scale-plates with threaded hubs.
4. Elliptical check rods and spindles. 5. Relief-etched stainless steel beams. 6. Hollow-ground steel knife-edges.

Dust-proof, self-locking bearing covers, designed to protect the vital agate bearings from dirt and dust, help to preserve accuracy and sensitivity.

No. 2 of a series of advertisements highlighting special features of Ohaus balances.

highly dissected topography, creating a mosaic of contrasting environments and thus geographical and genetic isolation in Vavilov's mountain-and-valley regions nearest the equator, but in which microclimatic work is neither feasible nor of value. It is, however, always desirable to have information on the regional climate which determines a number of biological characters.

(*b*) When land-races composed of many related forms are to be introduced, general information on the climate of the region in which they are grown should suffice, since these varieties are generally adapted to a fairly wide range of conditions.

(*c*) Climatic comparisons appear to be promising for introduction of improved cultivars and of ecotypes, and should make it possible to avoid certain errors. A good knowledge of the climate of the site and region where a cultivar is to be found and a study of the response of that variety to certain climatic extremes should indicate where it is likely to be climatically adapted. Introduction nurseries are, however, still essential in the different climatic zones of the importing country.

(*d*) The introduction of highly bred cultivars cannot be based exclusively on the comparability of regional climates. Only microclimatic investigations combined with data on soil and agronomics can, according to Mr. Perrin de Brichambaut, indicate the areas of adaptation of these cultivars.

The general climatic classifications now in use do not make it possible to delimit the regions to which a plant might be climatically adapted. For the interchange of plant material, it is therefore necessary to study all climatic factors in relation to the growing season and climatic thresholds of crop plants, extreme values, and so on. The more progress is made in climatology, the more useful will climatic comparisons become for the purposes of plant introduction.

One of the outstanding conclusions of the meeting was that the precious gene resources of the world, represented more particularly in the wild species and primitive forms in and around and between the centres of diversity, are in great and increasing peril. At a time when the breeders of many crops are suffering from what Prof. P. N. Zhukovsky of Leningrad has called 'gene starvation', the centres of maximum diversity are in many cases being destroyed at an increasing rate, by continuing misuse of land or by modern 'development'. This is more serious in the Middle Eastern centres of diversity, where the natural vegetation has suffered from intensive pressure of human and livestock populations for millenia, than in the South American centres, for example. Yet in both of these and in other important centres of diversity there is an urgent need for the establishment of protected areas of natural vegetation in genetically strategic sites, and Governments in and around centres of diversity are to be requested to take the necessary action in that respect. These protected areas would have to be managed in a special way to prevent desirable species from becoming eliminated through ecological progression. Their establishment was strongly supported by a number of participants, including Dr. P. S. Hudson, speaking on behalf of the Nature Conservancy.

There is also an urgent need to conserve the primitive cultivated forms and local varieties or agro-ecotypes in and around regions of greatest diversity. Old cultivated crops have developed a great number of varieties that are well adapted to local conditions but are often restricted in their area of cultivation; they are well fitted to primitive agriculture, but often do not respond to improved conditions of cultivation. Although they are of great value as a basis for breeding, they tend to disappear with the rapid dissemination of the improved varieties, which often have a very narrow genetical basis, for example, wheat in Australia and Sweden, maize in the United States, *Digitaria decumbens* or Pangola grass in the West Indies. What should and can be done to save these valuable gene resources, to assemble and maintain collections, to examine them and make the material available to breeders everywhere?

The main outcome of the meeting, apart from sixteen recommendations directed to the Food and Agriculture Organization or its member countries, was the preparation of a blueprint for further action, with regard to (*a*) wild species, (*b*) primitive cultivated forms and land races, and (*c*) cultivars improved by selection, hybridization or other breeding methods. For their collection, distribution, maintenance, further study and interchange, it was agreed that the following structure would be a desirable long-term objective:

Plant Exploration Stations. The need to establish outstations of this type in, or reasonably near to, the centres of greatest diversity has been stressed for some years by Dr. R. O. Whyte (F.A.O.) and Prof. W. Rudorf (Germany). It is visualized that these would be national or international stations, and that priority would be given to those proposed at the meeting, namely, a Mediterranean and Middle Eastern station at Izmir, Turkey, a South American station in northern Argentina with possible sub-stations in the high Andes, and a station in Peshawar, West Pakistan, for the Hindu Kush and Western Himalayan region. The scientific staff of these stations would need to have a thorough knowledge of everything from the flora and vegetation to the travelling facilities in their regions, and would make collecting expeditions on behalf of inquirers or as members of special expeditions. The work would be linked to and would largely depend on a network of areas of conserved and appropriately managed natural vegetation, and on the availability within the region of adequate and continuing resources of primitive cultivated forms for collection, study and initial multiplication. The fact that this would be done in or near the centres of greatest diversity would ensure that the collections express the complete range of variability before being distributed to appropriate plant introduction stations with environments that might restrict that expression.

Plant Introduction Stations. These would be established in receiving countries, either on a regional basis where expedient or on a national basis, and would be responsible for groups of plants or individual crop plants. They would undertake the receipt, study and maintenance (and application of quarantine standards) of material from the plant exploration stations and independent expeditions, the assembly and maintenance of local collections of wild species and primitive cultivated forms, and the interchange of cultivars. They might also be responsible for maintenance of discarded but still potentially useful breeders' lines.

Maintenance of Living Collections. This would be the responsibility not only of the plant introduction stations but also of research institutes, botanic gardens, research foundations and similar centres.

Research and Education. This would involve the establishment of a research department in a university, and also the provision of practical training at plant introduction stations or similar centres.

Co-ordinating Bureau. The Food and Agriculture Organization was asked to consider the establishment of such a Bureau, which might be staffed by at least three specialist officers responsible for co-ordination and development with regard to all important food, horticultural, pasture and fodder, and industrial crops, in temperate and tropical latitudes. It was recommended that the publication of the *Plant Introduction Newsletter* should continue as a method of reporting on current developments.

The mimeographed report of this meeting will be available in English, French and Spanish in about three months' time, and it is hoped to publish the complete Proceedings, comprising some forty-five technical papers, in a special issue of the Italian journal, *Genetica Agraria*. R. O. WHYTE

X-RAY DIFFRACTION STUDIES OF BACTERIAL VIRUSES

By DR. A. C. T. NORTH and PROF. ALEXANDER RICH

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts

BACTERIAL viruses are widely used for genetic studies, and a great deal is known about their composition and gross structure. They have polyhedral heads which consist of a protein coat enclosing a volume which contains deoxyribonucleic acid (DNA). Attached to the head is a tail structure which varies considerably in size among different viruses. Electron microscopic studies have yielded much information about the external morphology of these viruses, but not very much is known of their internal structure, especially the mode of organization of the DNA. This has prompted us to carry out X-ray diffraction work in an attempt to learn something about the internal configuration of the virus.

We have chosen for our initial investigation two morphologically extreme types, the *T*2 virus which has a very substantial tail structure, and the *T*7 virus which has a very small tail. From the *T*2 virus we have been able to obtain oriented X-ray diffraction fibre patterns, and we have been successful in crystallizing the *T*7 virus and have initiated an X-ray diffraction study of the crystalline preparations.

In the *T*2 bacteriophage, the polyhedral head has a length of approximately 1000 Å. and a hexagonal cross-section with a width of 700 Å. Its tail, of length 1100 Å., carries a number of fibres attached to the end. This bacteriophage is known to consist of about 50 per cent protein and 50 per cent DNA. Recent work has shown that all the DNA in *T*2 phage is contained in a single continuous molecule[1,2], which would have a length of approximately 60μ if it were stretched out, or 600 times the length of the virus head; thus it is apparent that the DNA is considerably folded. DNA from *T*2 contains hydroxymethylcytosine instead of the cytosine that is normally found in DNA, and glucose molecules are attached to almost 70 per cent of the hydroxymethylcytosine bases. Polyamines have been found in the virus head[3], probably attached to the DNA. In contrast to *T*2, the *T*7 virus has a smaller polyhedral head measuring about 550 Å in width and somewhat less in length. The tail is extremely short, about 140 Å. Its DNA contains cytosine and no glucose.

Recently a report has appeared by Bendet, Goldstein and Lauffer[4], who have presented birefringence evidence which suggests that some of, or perhaps all, the DNA in the *T*2 virus is organized with its molecular axis parallel to the viral tail, since the virus preparations have a negative birefringence on streaking or in flow birefringence experiments. Although the head of the virus is highly symmetrical, the possibility of orienting the preparations in these experiments arises presumably from the great asymmetry introduced by the elongated tail structure.

Oriented Virus Preparations

We have attempted to obtain oriented *T*2 phage specimens for X-ray diffraction studies by two methods. First, material from a centrifuge pellet was slowly sucked into thin-walled capillary tubes in the hope that the velocity gradient would be sufficient to orient the particles and thereby form an ordered gel in a fashion analogous to that found in the case of the rod-shaped tobacco mosaic virus[5].

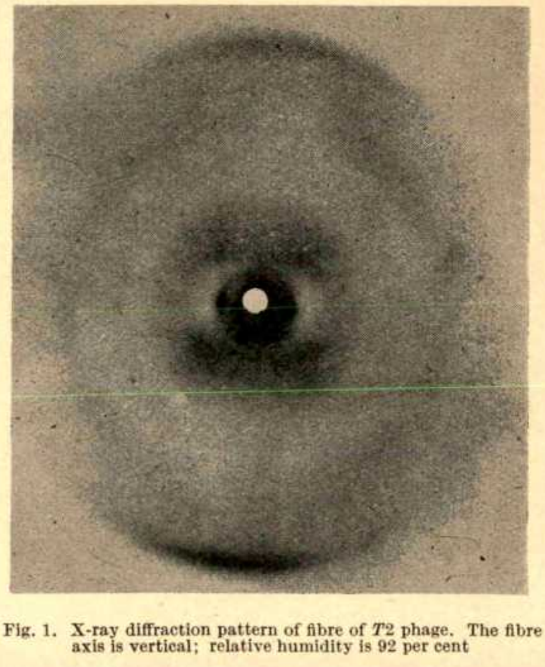

Fig. 1. X-ray diffraction pattern of fibre of *T*2 phage. The fibre axis is vertical; relative humidity is 92 per cent

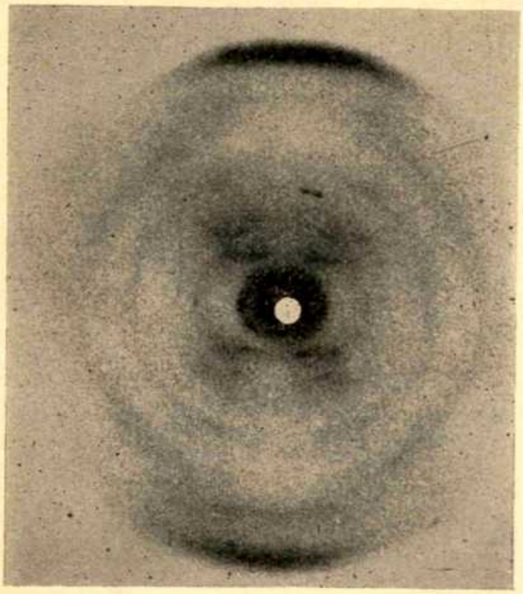

Fig. 2. X-ray diffraction pattern of DNA extracted from $T2$ phage. The fibre axis is vertical; relative humidity is 75 per cent

However, although birefringent, these preparations have not had sufficiently high orientation to produce an oriented X-ray diffraction pattern. We therefore tried to obtain oriented specimens by drawing fibres from a gel of the $T2$ phage.

There is an important difficulty in these experiments, since it is very easy to break open the phage head and liberate the DNA. Great care was taken to avoid this. Fibres were prepared by dipping a fine needle or glass rod into the virus gel, and slowly withdrawing it. It was found comparatively difficult to draw fibres from fresh centrifuge pellets and very much easier to prepare them from pellets which had been manipulated extensively. This was taken to indicate that DNA is released on working the material and, conversely, that the fresh pellets which did not yield fibres readily probably did not contain much free DNA. Therefore, we used only fibres prepared from fresh pellets in our experiments. Deoxyribonuclease was routinely added to all preparations so that DNA released from any ruptured phage would be digested during the centrifugation; however, the deoxyribonuclease could not be expected to digest DNA released in the course of drawing the fibres from the gel. To be more certain that we were actually photographing phage rather than liberated DNA, the effects on the fibres of variations in relative humidity was investigated, as described here.

The virus fibres were negatively birefringent, although the birefringence was not as strongly negative as that of $T2$ DNA alone. Fibres of diameter 50μ were mounted in a microcamera and photographed on a Hilger microfocus X-ray tube using copper-$K\alpha$ radiation. A typical X-ray diffraction pattern is shown in Fig. 1. It can be seen that the pattern is very similar to that of imperfectly oriented DNA. There is a strong 3·4-Å. meridional reflexion and a series of layer lines the spacings of which are sub-multiples of 33·8 Å. The cross-like distribution of diffracted intensity through the centre of the pattern is characteristic of a helical molecule[6]. The first layer line is quite weak, which is in marked contrast to the results obtained from DNA-protamine complexes, in which the protein chain fills the narrow groove of the DNA molecule[7]. The second and third layer lines are strong, while the fourth is absent. On the equator is a strong reflexion near the centre, which arises from the hexagonal packing of the DNA molecules.

For comparative purposes, DNA was prepared from $T2$ phage by osmotic shock. No dialysis was used in the preparation in order to minimize the risk of detaching the polyamines from the DNA. Fig. 2 shows a diffraction pattern given by a fibre prepared from this material. This pattern is similar to that reported earlier by Wilkins and his collaborators for DNA from $T2$ (ref. 8). It is difficult to compare the pattern from DNA with that from the phage preparation, since the orientation in the latter is not so good. On the whole, the two diagrams are similar, which suggests that the protein component represents only a small part of the X-ray scattering power of the virus. Careful scrutiny of the two photographs suggests that there may be some difference in the distribution of intensity along the second and third layer lines; in the pattern of the isolated DNA, the maximum intensity along the layer lines is nearer the meridian than in the phage pattern. This could be due to slight differences in packing of the DNA molecules inside the phage head as compared with the reconstituted assembly of free DNA. However, it is difficult to assess this in view of the difference in degree of orientation in the two fibres.

It is of interest that the phage fibres, as well as the DNA from $T2$ (ref. 8), yield only a B type diffraction pattern[9] at all relative humidities. This is in marked contrast to most preparations of DNA, and the difference may be associated with the attached glucose residues.

We have examined the change in the position of the equatorial reflexion as a function of relative humidity in both the DNA from $T2$ and in the phage fibre. This was done as a means of demonstrating that we were not photographing DNA liberated from broken phage heads. The relative humidity was stabilized by filling the camera with helium gas, which had been bubbled through washing columns filled with a saturated salt solution. The specimen was usually allowed to equilibrate for several hours before the X-rays were turned on. The results are presented in Fig. 3 for both DNA from $T2$ and the phage fibres. The two curves are similar until the relative humidity is raised to more than 90 per cent. Above this the

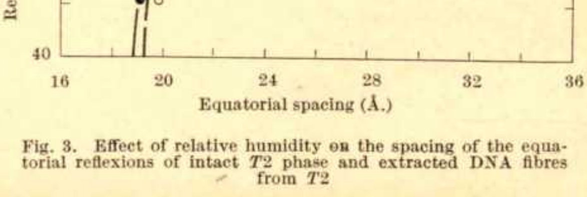

Fig. 3. Effect of relative humidity on the spacing of the equatorial reflexions of intact $T2$ phase and extracted DNA fibres from $T2$

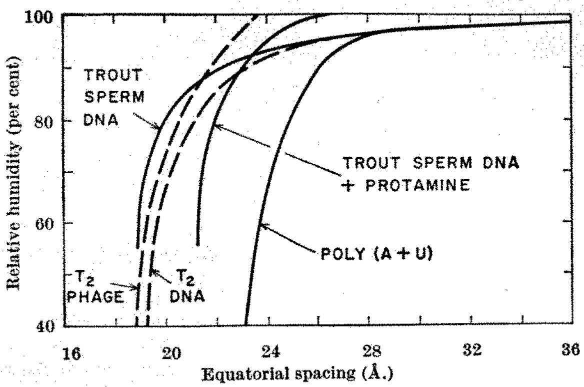

Fig. 4. Effect of relative humidity on the spacing of the equatorial reflexions in various nucleic acids. Poly (A + U) is polyadenylic acid plus polyuridylic acid

DNA molecules move further apart as more water molecules surround them and, approaching 100 per cent relative humidity, the free DNA molecules are very far apart in solution. In contrast to this, in the phage head at relative humidities greater than 90 per cent, the DNA molecules stay close together, constrained presumably by the protein coat of the head, although the polyamines also may play a part in holding the DNA together. At 100 per cent relative humidity the molecules are confined so that they produce a reflexion at 23·8 Å.

Similar work on the effect of changes in relative humidity have been reported for trout sperm DNA and DNA-protamine complexes[7], and for a two-stranded helical synthetic polyribonucleotide, polyadenylic acid plus polyuridylic acid[10]. All these curves are shown in Fig. 4, where it is clearly seen that the phage and the DNA-protamine curves differ markedly from the others. Neither the phage nor the protamine complex goes into solution in water (100 per cent relative humidity); however, the DNA molecules are further apart in the protamine complex than in the phage, presumably because of the interposed protein. The isolated DNA molecules from *T*2 may be slightly further apart than the trout sperm DNA molecules because of the glucose attached to the hydroxymethylcytosine bases. The synthetic polyribonucleotide curve in Fig. 4 is displaced to a greater spacing relative to the DNA curves probably because the additional hydroxyl group in the backbone makes the helical chains assume a slightly larger radius of curvature.

These experiments suggest, but do not prove, that the phage fibre actually contains intact virus rather than ruptured heads and released DNA. It is very difficult, however, to be certain that we have not disrupted the virus head in preparing the specimens. It is clear that virus particles can be oriented in a gel; this has been demonstrated in electron microscope studies of replicas from oriented gel preparations[4]. But since the virus diffraction pattern is similar to that obtained from isolated DNA, we have to be cautious in the interpretation and say that our evidence for orientation of the DNA in the virus head is suggestive but not conclusive. In particular, since X-ray diffraction is enhanced from regions of regularity, we cannot say what proportion of the DNA is oriented parallel to the tail. It is obvious that all the DNA cannot be oriented this way since it must be folded to be contained within the head.

Unoriented Virus Gels

The intense X-ray reflexion on the equator of the oriented virus pattern has its origin in the lateral hexagonal packing of DNA molecules. If it were not for this regular packing, we should see a streak along the equator, which would represent the continuous Fourier transform of the molecule. This reflexion can also be seen in X-ray photographs of unoriented gel specimens, where it appears as a Debye–Scherrer powder ring at 24 Å. The presence of this ring indicates that the DNA molecules are packed parallel to each other inside the virus. We have observed this powder ring not only in *T*2 gel preparations but also in specimens of *T*7 and λ bacteriophages, which are not sufficiently asymmetrical to be oriented in fibres in the same way as *T*2. These observations have been made with the phage in suspension in the presence of DNase, so that there can be no liberated DNA present. We have also taken X-ray photographs of gel preparations of DNA molecules extracted from *T*2 phage; the sharp 24-Å. ring is not observed, which shows that the DNA molecules are dispersed in this case.

We can estimate the average lateral extent of the regions of regular packing of DNA molecules by measuring the breadth of the 24-Å. diffraction line in the unoriented gel preparations. In order to make careful measurements of X-ray line broadening, it is desirable to have an experimental arrangement in which the instrumental broadening is minimized. We have accomplished this through the use of a focusing monochromator, in which the X-ray beam converges to a line focus after reflexion from a curved quartz crystal. This produces a particularly clean X-ray diffraction pattern through the elimination of wave-lengths other than the copper-$K\alpha_1$. The intensity distribution in the diffraction pattern was measured by tracing the blackening on the photographic film with a Joyce Loebl

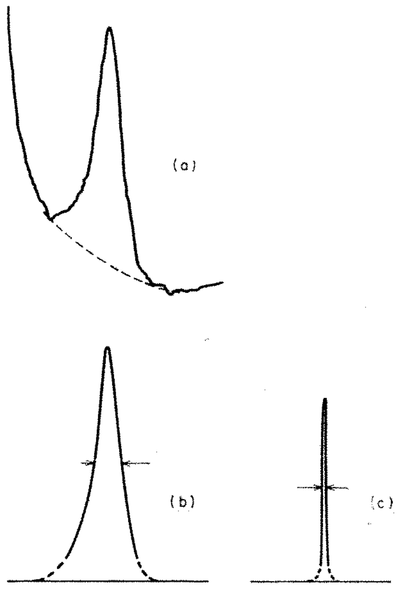

Fig. 5. (*a*) Densitometer tracing of the profile of the 24-Å. ring of *T*2 bacteriophage. Intensity is plotted vertically, the horizontal axis is a radius of the X-ray diffraction pattern. (*b*) Profile after subtraction of the background (dashed line in (*a*)). The arrows indicate the angular width at half maximum (β_0). (*c*) Profile of the direct beam to the same scale. The arrows indicate β_1

recording microdensitometer. A typical curve is shown in Fig. 5, where the peak (*5a*) due to the ring is superimposed on a varying background. The line profile (*5b*) was then constructed by subtracting the estimated background value (shown dashed) from the corresponding peak value. The instrumental broadening is shown in Fig. *5c*, which contains a tracing of the direct beam. Theory shows that the breadth of the angular diffraction line, β_d, is related to the appropriate linear dimension D of the diffracting crystallite by the expression $\beta_d = k\lambda/D \cos\theta$, where θ is the Bragg angle and k is a numerical constant of the order of 0·9 (ref. 11). β_d is defined as the angular width at half peak-height. The observed line-breadth, β_0, in practice arises not only from the diffraction line-breadth but also from instrumental broadening, β_i, the magnitude of which depends on the geometry of the X-ray apparatus. For the monochromator, the use of a converging beam makes β_i very small, and it can be measured by a tracing of the direct beam. Although there are several methods for obtaining β_d from β_0 and β_i, probably the most valid in this case is $\beta_0^2 = \beta_i^2 + \beta_d^2$, which is based on the approximation that the diffraction broadening and instrumental broadening curves are both Gaussian[12]. We think this is a reasonable assumption in the present case (Fig. 5).

Measurements were carried out both for *T*2 and for *T*7 phage. The size of the crystalline domain for *T*2 was 143 ± 15 Å. as measured on several different preparations. In *T*7 the size of domain of the DNA was 119 ± 10 Å.

These sizes of domain are considerably smaller than the diameters of the corresponding phage heads. There are two possible explanations for this finding: one is that the virus head consists of a number of sub-units, each containing 25–30 sections of the DNA chain in a highly ordered array; the second is that the dimensions do not indicate the sizes of separate domains, but that the line-broadening arises from imperfections in the regularity of a single array which fills the entire head. For example, such irregularity might arise from a non-random distribution of polyamines or other substances within the phage head. However, the interpretation of line-broadening in terms of domains is well known in both crystals and fibres, and we believe it is the most probable interpretation here. The difference in size of domain between *T*2 and *T*7 is sufficiently great for us to inquire whether it depends on the size of the viral head. In order to search for such a dependence, further investigations are under way involving a wide variety of bacterial viruses.

At this early stage of the investigation, there are many unanswered questions concerning the organization of the DNA. If the domains are separate units, are they held together by the polyamines which are associated with the phage DNA ? Could the association of these ordered domains give rise to the hexagonal cross-section which is so characteristic of viral heads ? Further: Is this sub-structure of organization important to the folding process which the DNA molecule must undergo to form the virus head when it is made inside bacteria ? We cannot answer these questions at the present time.

Crystallization of Bacteriophage

In the course of taking X-ray photographs with the monochromator camera, we observed a crystalline diffraction pattern from the *T*7 virus. The sample had been prepared by gently sucking the virus gel into a thin-walled quartz capillary, which was left unsealed for a considerable period, during which time the sample evaporated to about half its original volume. There was a change in the birefringence observed in the capillary during this process. The capillary was then sealed, and photographed in the monochromator. The diffraction photograph showed a series of crystalline reflexions which were superimposed on the continuous powder pattern produced by the unoriented gel. An array of well-resolved reflexions could be seen around the beam stop with a prominent repeat distance of 570 ± 20 Å. in one direction, and 470 ± 30 Å. at right angles to it. The resolution was best along the 570-Å. axis because this lay perpendicular to the focal line of the converging X-ray beam. In this direction about 15 orders were visible. In the region of the 24-Å. ring, a series of striations could be seen with the 570-Å. spacing, showing that the Fourier transform had been sampled in that region by a larger lattice.

Up to the present time we have not observed such crystallization with the *T*2 virus. It is of interest that in contrast to *T*2, the *T*7 virus has an extremely short tail and is therefore much closer in shape to the 'spherical' viruses which crystallize with relative ease. Furthermore, one of the observed spacings is quite close to the diameter of the *T*7 virus as observed in the electron microscope, so it is possible that the crystalline organization is a simple one. We are now preparing other crystalline specimens in an attempt to get three-dimensional information about the packing of the *T*7 virus and its enclosed DNA.

Conclusions

These experiments suggest that some of the DNA inside the bacteriophage *T*2 virus head is oriented parallel to the tail. Furthermore, the evidence suggests that the DNA may be organized into crystalline domains about 140 Å. across in *T*2 and 120 Å. in *T*7. The *T*7 virus can be crystallized, and this should prove to be very useful in furthering the study of the internal organization of the bacteriophage.

We wish to thank Drs. P. F. Davison, D. Freifelder and R. Hamers for assistance in obtaining virus preparations. This investigation was aided by grants from the National Institutes of Health, Bethesda, Maryland, and the U.S. National Science Foundation.

OBITUARIES

L'Abbé H. Breuil

The Abbé Henri Breuil died on August 14 at the age of eighty-four. I first met Breuil in 1912 in Cambridge. At that time, except for the interest of a few amateurs and geologists, the subject of prehistory scarcely existed in Britain. It is true that in 1859 Prestwich and Evans had been sent over to France by the Royal Society to study the work of Boucher de Perthes in the gravels near Abbeville, and as a result had accepted the fact of the great antiquity of man on the Earth. But whereas in France interest in prehistory was abounding, there was only a handful of people in Britain who were keen about it. Breuil invited me to go abroad for a year or two and, after assisting at the famous cave excavation at Castillo in northern Spain under his colleague and great friend, Hugo Obermaier, to work with him in Spain. Thus, after a 'campaign' with Obermaier—another Roman Catholic priest, by the way, though few people seem to have known it—I joined Breuil and with him studied and traced the eastern Spanish and the Copper Age rock-shelter paintings of the Peninsula.

The Abbé was at this time thirty-six years of age and then, as always, of an electric character. Travelling for months together, often 'sleeping rough', makes either for enduring friendship or the opposite: my admiration for Breuil both as a prehistorian and as a man never flagged. He had only one really useful eye, but with it he saw far more clearly than did other more normally equipped persons, and his intuitions were brilliant. The working combination of Obermaier and Breuil was perfect. Both had by now become professors of the Institute of Human Palæontology founded by the then Prince of Monaco in Paris. Breuil would see the answer to a problem in a flash; Obermaier, a Bavarian born, built up his solution with careful Teutonic thoroughness and documentation; but almost always they both came to the same conclusions. If you told Breuil a fact he would always remember it; Obermaier would note it down on a special card, of which he kept a supply in his pocket, and would later place it in his card index. Breuil was an artist, but a scientifically accurate one. It has been sometimes suggested that he used too much imagination when copying the cave art, but it is not always realized that there is a close similarity between examples of paintings belonging to the same style, and long experience had enabled him to interpret correctly what were sometimes apparently only faint indications. I can vouch for the meticulous accuracy of the tracings he made during the times I was his assistant.

At the beginning of the First World War we were together in the French Red Cross at a hospital near Bordeaux run by the late Dr. Lalanne. At that time there was not much 'war' work to do, and we spent most of our energies in typing and arranging the immense collections of stone implements which had been excavated by Dr. Lalanne at Laussel, and one could not fail to admire his scientific quickness of eye and his tirelessness in tackling this problem.

After the War, Breuil came often to England and frequently stayed with us at Cambridge, and the University awarded him an honorary doctorate of science. It must have been in about 1921 that I asked him to come over and look at some new tertiary finds of *soi disant* flint tools which the late Reid Moir had unearthed from the Red Crag near Ipswich. He came over, and spent the afternoon somewhat silently examining the finds. In the evening, as I drove him back to our hotel, he turned suddenly towards me and said: "My dear friend to-day has greatly aged humanity". It was a magic moment and a characteristic remark.

From what has been already said, it will be clear that his prehistoric interests were by no means confined to problems of palæolithic art, nor only to the upper palæolithic periods in general. Of course, *Les subdivisions du paléolithique supérieur et leur signification*, published in 1912, remains a classic, as do the series of great cave-art monographs published under the auspices of the Prince of Monaco, but so too does his work on the gravels of the Somme Valley of lower and middle palæolithic ages.

Between the two Wars the Abbé was elected to a professorship at the Collège de France—an honour in which he took a very great pride.

During the Second World War, Breuil did important work on river terraces in Portugal before he went to South Africa. He had stayed in France as long as he could, but both his age and his eyesight precluded him from much active war-work—he did, however, discover a secret underground enemy aeroplane factory and wrote to me on a postcard some lines in Latin about strange subterranean winged birds, purporting to come from a newly discovered MS. of Ovid and labelled "Quelque vers pour vos latinistes". It was duly forwarded to the proper authority in London and, later, I had an acknowledgment asking for more such verses.

The bare facts of Breuil's life have been well set out in the obituary in *The Times* of August 22. But his impact on the study of prehistory throughout the world can scarcely be exaggerated from the time long ago when he started with a study of the Bronze Age in the Paris basin to his later work, much of it in Africa. He inspired, instigated or personally undertook research in an immense number of parts of the Old World and correlated and assimilated the results—you had to go to the chilly cellars of the "Institute" to study the finds from the *Sinanthropus* site of Choukoutien. China, Abyssinia and South and South-West Africa were some of the regions included in his own travels. Thus, his knowledge of world prehistory became immense, and when he spoke at conferences there was little more to be said. He was, it is true, inclined to be a little pontifical—and, after all, after Obermaier's death in the Second World War, there were fewer people equipped to dispute with him—and when he had pronounced about something he had indeed pronounced, and nothing would make him change his mind. As he got older and perhaps less sure of touch in his intuitions—his opinions about Rouffignac and the 'white lady' of South-West Africa were decidedly open to question—he did not become less pontifical and it became more personally difficult to disagree with him. He knew that in the past he had so often been right. He was indeed one of the world's few really great prehistorians, and it is the world, as well as France, that has suffered a loss by his death.

MILES BURKITT

Prof. Enzo Boeri

Prof. Enzo Boeri died on October 28, 1960, at the age of forty-six. He was associated with the Institute of Physiology of the University of Milan in various capacities from 1938 until 1955 and was appointed professor and chairman of the Department of Human Physiology of the Medical School, University of Ferrara, in 1955. In 1958 he also held the post of director of a group in the Biology Division of the Italian Nuclear Research Centre.

During the War his initial studies were on underwater physiology and he was active as a 'frogman'. His more important role was as a leader in the Resistance against the Nazis during 1944–45. He served bravely in great personal danger and under most difficult conditions : he was on one occasion saved from the firing squad by a two-hour margin. His radio contacts with the Allies were most valuable and were recognized by military decorations, including a Bronze Star from the United States.

Even though he had open to him a clear pathway to leadership in the post-war era, his love of science took him back to Naples and to the study of the vanadium compounds of *Phallusia mamillata*. During 1951–53 he undertook biochemical studies with Prof. H. Theorell at Stockholm. There he carried out experiments on the magnetic susceptibility of the vanadium compounds and studied enzymic properties of cytochrome *c* and catalase, particularly the reaction of the latter with thiol compounds. The next topic of research was cytochrome b_2, the flavohæmoprotein prepared from yeast. He made an intensive study of the method of preparing this enzyme from the kinetic point of view. He made important contributions to the mechanism of its action, particularly the stoichiometry of the lactate-flavin reaction and the function of the cytochrome portion in electron transfer from lactate to ferricyanide or cytochrome *c*. A portion of the latter work was carried out as an associate at the Johnson Research Foundation, University of Pennsylvania. Most recently he studied the properties of hæmerythrin.

Boeri's scientific work was characterized by high regard for precision, an open mind in the interpretation of his results and an understanding of the physiological importance of the biochemical data. He had soon established an international reputation as a physical biochemist. As a man, he was endowed with the rich gifts of his people. He was brave and unselfish, having a keen sense of fairness and a great interest in the problems of others. He was articulate —an irresistible conversationalist, and was forthright and often outspoken in his defence of what he believed right—in some cases in opposition to contemporary science in Italy. Therefore, he often embraced unpopular objectives and was a particularly strong crusader in the task of injecting new interests and life into an Italian science that he found to be resting too much on a glorious historical tradition.

He saw the urgent need for the re-introduction of experiments into the physiology course, in reviving the possibilities for foreigners and apostate priests to be eligible for professorial appointments in Italy and in providing adequate funds for the support of departmental chairmen and their research.

Prof. Boeri's example as a man and as a scientist serves as a landmark in his humble yet fearless dedication to high and worthy principles. His early passing leaves many goals unattained, but his ideas and his example clearly survive him.

Britton Chance

NEWS and VIEWS

Statistics in the University of London : Prof. James Durbin

Mr. James Durbin has been appointed to the University chair of statistics at the London School of Economics and Political Science, in succession to Prof. M. G. Kendall (see *Nature*, 190, 1060; 1961). Prof. Durbin read mathematics at St. John's College, Cambridge, and after a period of military service during the War with the Army Operational Research Group, returned to Cambridge, where he took the postgraduate diploma in mathematical statistics, with a special field of application in economics. After a short period with the British Boot, Shoe and Allied Trades Research Association and as a junior research officer in the Department of Applied Economics at Cambridge, he joined the staff of the London School of Economics in January 1950, being appointed a reader in 1953. Prof. Durbin has worked in both theoretical and applied statistics. His major contributions in the former cover time series analysis, regression analysis and social survey methodology. In the practical field he has made equally notable contributions to econometrics, social survey research and model building. He has also been closely associated with editorial work in the University of London, as a member of various committees of the Royal Statistical Society, as an associate editor of *Biometrika*, and as a Fellow of the International Statistical Institute. He has lectured in a number of foreign centres, including Calcutta, Beirut, North Carolina, Stanford University, Uppsala and Copenhagen.

Royal Society of Victoria Research Medal : Dr. George Baker

The first award of the Research Medal of the Royal Society of Victoria has been made to Dr. George Baker of the Commonwealth Scientific and Industrial Research Organization. The citation accompanying the award states that Dr. Baker "has published approximately a hundred original research papers on geological and mineralogical topics, including: (1) the geology of the Port Campbell coast; (2) phytoliths, the minute opaline bodies in plants; (3) the nature and origin of the small glassy meteorites called australites. Dr. Baker originated the theory of aerodynamic control of the shaping and sculpturing of the primary form of australites. Experiments by the American National Aeronautics and Space Administration have proved this theory correct. Australites throw light on the nature of re-entry phenomena of ballistic missiles, and indicate an excellent material for heat shields for manned spacecraft".

Verco Medal of the Royal Society of South Australia : Dr. R. L. Specht

The Verco Medal of the Royal Society of South Australia has been presented to Dr. R. L. Specht, who is distinguished for his contributions in the field of plant ecology, particularly in Arnhem Land and in South Australia. The citation continues: "In the first-named area his work has provided essentially the first critical study of an important area of Australia. In South Australia he has contributed especially to the study of the detailed edaphic and microclimatic factors which determine the nature of the plant associations and the distribution of the dominant species. He has taken full advantage of the recent knowledge gained in geological surveys, in soil surveys and in rainfall studies, particularly in the Mount Lofty Ranges, to establish detailed edaphic and climatic correlations with native vegetation and so has built soundly on the early pioneering work of Osborn and of Wood".

New National Nature Reserves:

Shapwick Heath

THE Nature Conservancy recently declared Shapwick Heath as a National Nature Reserve. This Reserve contains some of the last remnants of the extensive raised bogs, about 15 ft. above sea-level, which once stretched from Glastonbury to within a few miles of the coast. These raised bogs were similar to those now covering a large part of the Central Irish Plain and were gently domed in shape and dominated by communities of *Sphagnum* moss, heather and cotton grass. The Reserve is set up under Nature Reserve Agreements with the Eclipse Peat Co. and the Eclipse Land Co. and covers 484 acres. Extensive peat-cutting has turned the area into a complex patchwork of marsh and scrub woodland. The peat is used mainly for horticultural purposes, and under the Nature Reserve Agreement the Eclipse Peat Co. will continue to extract it. There is a wide range of flora and fauna because of the diverse habitats produced by peat-cutting and because of variations of acidity. For example, heather and bog asphodel are characteristic of one part of the area and a species of sedge, *Cladium mariscus*, of another. The rare royal fern is also present. Peat diggings have uncovered many archæological remains of neolithic, bronze age, iron age and Romano-British date, and Shapwick Heath has been the centre of these discoveries. The area was crossed by a number of timber trackways built towards the end of the bronze age to form a passage between the Polden Hills and the 'islands' in the valley when the climate grew wetter. Blade marks, the size and shape of which are typical of those made by late bronze age axes, can be seen on the larger timbers in several trackways. Within a mile or two of the Reserve neolithic trackways have likewise been identified. Access to the Reserve is by permit only. Applications to visit and for permission to collect specimens of animals and plants should be made to the Regional Officer for the South-West, the Nature Conservancy, Furzebrook Research Station, Wareham, Dorset.

Wye and Crundale Downs

Wye and Crundale Downs have also been declared as a National Nature Reserve. This Reserve forms part of the escarpment of the North Downs between Ashford and Canterbury. It is the first area of chalk downland to be declared as a National Nature Reserve in Kent and adds to the incomplete series stretching from Wiltshire and Hampshire to Bedfordshire and Sussex. To-day the chalk downlands are particularly vulnerable to destruction because of increased mechanization of farming and it is urgent that the Nature Conservancy should acquire further chalk areas to preserve them for study. The present acquisition consists of 123 acres of chalk downland, scrub and mature woodland. The downland is basically a product of sheep-grazing which was practised as early as the Roman occupation, and became such an important feature in the English economy during the fourteenth and fifteenth centuries. The scrub and woodland are the result, at least in part, of the natural colonization of the downland by woody species (such as hawthorn and beech) and clearly demonstrate the necessity for grazing in order to maintain the downland character. The Reserve has a rich flora including the lady orchis, man orchis and fly orchis. One of the many notable insects is the feathered ear moth. The Devil's Kneading Trough, a natural steep-sided valley, cuts into the Downs on the Reserve, forming one of its most conspicuous features. On the crest of the Downs are several tumuli which indicate the antiquity of human influence in this type of country. Access to the Reserve along the public footpath is unchanged; elsewhere it is by permit only. Applications to visit and for permission to collect specimens of animals and plants should be made to the Regional Officer for the South-East, the Nature Conservancy, 19 Belgrave Square, London, S.W.1.

Rehabilitating Lepers

OF an estimated world total of 10 million people suffering from leprosy, probably not more than 20 per cent are receiving treatment of any kind for the severe disabilities that the disease often causes. The World Health Organization scientific meeting on rehabilitation in leprosy, through an on-the-spot examination of leprosy patients with typical varieties of deformity at a research sanatorium in India, set out to determine the extent of the problem of disability, to advise on the best application of available knowledge in prevention, treatment, and rehabilitation of disabled leprosy patients, and to recommend further research (Scientific Meeting on *Rehabilitation in Leprosy*. Report. World Health Organization: Technical Report Series, 1961. No. 221; Pp. 37. Price 3*s*. 6*d*. Published also in French and Spanish).

Teaching Psychiatry and Mental Health

THE need for reform of the medical curriculum in training doctors has been the subject of much controversy, and the place that psychiatry should occupy in the curriculum has often been at the centre of the controversy. The reason for this is twofold. Psychiatry as a medical speciality has now developed to the stage at which it can claim a place of its own in the company of other branches of medicine; it is considered by many to be a leaven permeating medicine as a whole and re-orientating medical practice and medical teaching from its present tendency to separate into compartments towards a better awareness of the human being. A publication (*Teaching of Psychiatry and Mental Health*. Various authors. World Health Organization. Public Health Papers No. 9, 1961. Pp. 186. Price 10*s*. Also published in French. Available through H.M.S.O.) brings together a group of papers by teachers of psychiatry from various parts of the world, describing how the teaching of psychiatry and mental health care can be organized, what problems of content and method are likely to arise, and in what way the teaching should be integrated into the medical curriculum. The authors demonstrate the relationship of psychiatry and mental health to clinical medicine and the sciences of man. They examine the role of neurological investigations in the teaching of psychiatry, the teaching of medical psychology, and the social character of mental disorder. There is also a description of how psychiatry is taught at present in different countries and of the principles being adopted in guiding its future development. The publication presents the basic argument in favour of more psychiatry in the medical curriculum and shows how this can be achieved.

Ageing and the Semi-Skilled

A REPORT by the Medical Research Council's Unit for research on occupational aspects of ageing presents the results of an inquiry into prevailing attitudes and policies towards the older semi-skilled worker in some of the larger manufacturing firms on Merseyside (*Ageing and the Semi-Skilled: a Survey in Manufacturing Industry on Merseyside*, by Alistair Heron and Sheila M. Chown, assisted by M. S. Featherstone and Catherine Cunningham. Medical Research Council Memorandum No. 40. Price 5*s*. H.M.S.O., London). Managers and foremen were agreed that, of the changes which accompany increasing age, some are for the better ; for example, the older worker is more 'steady' and more responsible, while others, such as his slower movement and his slower rate of learning, often tend to impair his working efficiency. The survey also showed that, in the eyes of his superiors, the worker's skill, born of years of experience, often compensates for the 'slowing-up' that occurs with age; in the view of the authors an ever-increasing strain is placed on the older man if he continues to do exacting work.

The findings of the inquiry suggest that, while it is generally accepted in industry that middle-aged and older men should be transferred from physically heavy work, there is little recognition of the fact that work making a constant demand for speed or for close concentration is probably also unsuitable. Moreover, it appears that the possibilities of change of jobs are frequently limited; often the only alternative that can be offered involves both loss of status and loss of pay. An increasing rate of technical innovation in industry may mean that a single group of limited skills will no longer last a man throughout his working life. Both this possibility and the present problems faced by the older worker point to the need for re-training, and the authors suggest that industry should examine methods of training and re-training in relation to the special needs of the semi-skilled worker in the second half of his working life.

Sources of Ionizing Radiation at Public Exhibitions

THE recognition of the need for rigorous control of the use of sources of ionizing radiations has been made evident by the appearance in recent years of codes of practice and regulations concerned with the protection of workers in, for example, hospitals, university laboratories and factories. The latest such publication is a *Code of Practice for the Display of Sources of Ionizing Radiations at Exhibitions* (H.M.S.O., 1961. Pp. 6. Price 6*d*.), and this briefly but clearly sets out regulations aimed at safeguarding both staff and visitors at exhibitions where these sources are used. Thus, maximum permissible dose-rates are specified both in respect of the accessible parts of the shielding and also at positions where visitors may stand. The maximum activities of various radioactive isotopes which may be used unsealed are listed and an example is given of a warning notice to be carried by exhibition stands where radioactive sources are on display.

The Fitzwilliam Museum, Cambridge

THE annual report of the Fitzwilliam Museum for 1960 records the completion of the corridor linking the Museum with Grove Lodge. One of the most important acquisitions was a painted limestone relief purchased from the Elderton Fund. This was from the wall of an eighteenth-dynasty Theban tomb and shows the head and shoulders of a man. An important group of coins forming the Lakenheath Hoard was purchased from the S.G. Perceval Fund. The Hoard included three gold coins, 63 Roman silver coins and 397 silver coins of the Iceni. The fifty-second annual report of the Friends of the Fitzwilliam Museum, also for 1960, indicates important gifts to the Museum including the terra-cotta relief by Clodion, and a double trencher salt of Sèvres white soft porcelain. The total membership at the end of the year was 361.

Control of Soil-transmitted Helminths

AMONG all the species of worms parasitic in man the soil-transmitted intestinal nematodes—the roundworm, the whipworm, and the hookworm—hold the distinction of exerting the greatest influence on individual health and group productivity throughout the world, their prevalence in different communities serving indeed as an index of social and economic standing. Although they cause anæmia, reduce physical and mental capacity, weaken resistance to other diseases, and at times affect health directly and severely, attempts at their control have met with disappointing results. As a consequence they present a health problem that is apt to be given perfunctory attention or even neglected. Prof. Beaver discusses the factors involved in the control of these soil-transmitted helminths, the control methods that have been used and should be used, and the research which problems of control raise (*Control of Soil-transmitted Helminths*. Paul C. Beaver. World Health Organization Public Health Papers, No. 10, 1961. Pp. 44. Price 3*s*. 6*d*. Also published in French. Available through H.M.S.O.). A section is devoted to other miscellaneous helminths the role of which in parasitic infections is still somewhat obscure. An annex deals with diagnostic methods.

British Iron and Steel Research Association : Systems Evaluation Section

IN recognition of the steady growth in the scope of its activities over recent years, the Computer Applications Section of the Operational Research Department of the British Iron and Steel Research Association has now been renamed the Systems Evaluation Section. Mr. D. H. Kelley will be in charge of the new section, which carries out operational research investigations into the automation of large-scale systems. The immediate programme will be to study the automatic production, planning and scheduling of various kinds of steelworks, and to investigate the information requirements of steelworks management. The services to members which were previously supplied by the Computer Applications Section and which included operation of the Association's *Pegasus* computer, advice on the uses of digital computers in steelworks offices and the training of *Pegasus* programmers will be continued unchanged.

Animal Health Trust Research Awards

The Animal Health Trust has announced the following awards under its education assistance scheme which is designed to increase the flow of skilled personnel into the veterinary, medical and scientific fields : *Research Training Scholarships :* W. J. Herbert, for a course in microbiology and a Ph.D. course in virology at the Department of Bacteriology, University of Edinburgh, under Prof. R. Cruickshank; R. C. Chubb, to investigate the use of the gel-diffusion precipitin technique for the diagnosis of infectious bronchitis and pathogenic pleuropneumonia-like organisms. Mr. Chubb will work at the Houghton Poultry Research Station under Dr. R. F. Gordon. *Wellcome Research Fellowships :* B. A. Matson, to make a study of the life-cycle of *Piroplasmosis* under Dr. E. J. L. Soulsby in the Department of Animal Pathology, University of Cambridge; I. E. Lush, to enable him to extend his work on biochemical polymorphism in birds, and its possible connexion with hybrid vigour, at the Agricultural Research Council's Poultry Research Station, Edinburgh, under Dr. A. W. Greenwood.

Unesco Science Study Fellowships

Unesco is offering six study fellowships to Member States to enable specialists to undertake research abroad in either mechanical translation or reduction of geophysical data. The fellowships will be tenable for a period of six months. Travel to and from the country in which the research is to be carried out, and living expenses, will be paid by Unesco. Further information can be obtained from the Unesco National Commission for the United Kingdom, Ministry of Education, Curzon Street, London, W.1.

Transfer of Calcium and Strontium across Biological Membranes

A conference on transfer of calcium and strontium across biological membranes will be held during May 13–16, 1962, at Cornell University, Ithaca, N.Y., under the joint sponsorship of the United States Atomic Energy Commission, National Institutes of Health, National Science Foundation and the New York State Veterinary College. Members of the steering committee are: Dr. R. H. Barnes and Dr. C. L. Comar, Cornell University; Dr. D. Harold Copp, University of British Columbia, Vancouver; Dr. H. E. Harrison, Johns Hopkins University, Baltimore, Maryland; and Dr. R. H. Wasserman, Cornell University. The purpose of the meeting is to discuss present knowledge of basic aspects of movement of calcium and strontium ions across various animal membranes and to present information on physiological, biochemical and nutritional factors which influence this movement. Twenty-two papers are to be presented. Inquiries should be addressed to Dr. R. H. Wasserman, Department of Physical Biology, New York State Veterinary College, Cornell University, Ithaca, N.Y.

Announcements

Dr. F. T. Last, of Rothamsted Experimental Station, has been appointed as head of the Department of Mycology and Bacteriology at the Glasshouse Crops Research Institute in succession to Mr. P. H. Williams, who is retiring after 38 years service, first at the Experimental and Research Station at Cheshunt and latterly at the Institute.

The Nutrition Society's symposium on "Agricultural Problems in Developing Countries" will be held at the National Institute for Research in Dairying, Shinfield, Reading, at 10.45 a.m. on October 13, 1961. Further particulars can be obtained from Miss D. F. Hollingsworth, c/o Ministry of Agriculture, Fisheries and Food, Great Westminster House, Horseferry Road, London, S.W.1.

A lecture entitled "A National Spectra Index: Plans and Problems" is being organized at the University of Reading on September 26 and will be given by P. S. Davison, of the Scientific Documentation Centre, Halbeath House, nr. Dunfermline, Fife, immediately following the meeting of the Infra-red Discussion Group. The lecture is open to all, admission free.

A conference on "Electrically Exploded Wires", sponsored by the Thermal Radiation Laboratory of the Geophysics Research Directorate of the Air Force Cambridge Research Laboratories, is to be held at the Kenmore Hotel, Boston, Massachusetts, during November 13–14. Further information can be obtained from W. G. Chace, Thermal Radiation Laboratory, CRZCM, Geophysics Research Directorate, Air Force Cambridge Research Laboratories, Bedford, Massachusetts.

An interscience conference on "Antimicrobial Agents and Chemotherapy" is to be held at the Hotel Commodore, New York City, during October 31–November 2. The first day will be devoted to "Infectious Diseases" and the second and third to "Various Aspects of Antimicrobial Agents, including their Clinical Evaluation". The conference is sponsored by the American Society for Microbiology, 19875 Mack Avenue, Detroit 36, Michigan, from which further information can be obtained.

Nearly 1,000 members and delegates will be attending the twenty-eighth conference of the National Society for Clean Air, to be held at Brighton during October 4–6. A special exhibition preview for the Press and others will be held at the Brighton Corn Exchange on Tuesday, October 3, from 3.30 p.m. to 5.30 p.m. Coach transport will be arranged if demand is adequate, and will leave Victoria at 1.15 p.m. Full particulars may be obtained from the National Society for Clean Air, at Field House, Breams Buildings, London, E.C.4.

The Winter Meeting of the Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals will be held in the Hoare Memorial Hall, Church House, London, S.W.1, during December 7–8, 1961. The main discussion of the Winter Meeting will be a symposium on "Sintered High Temperature Compounds" on December 8, between 10 a.m. and 5 p.m. The papers comprising the symposium will be published in *Powder Metallurgy*, No. 8. Further details of the Joint Group and its meetings can be obtained from the Secretary of the Powder Metallurgy Joint Group, 17 Belgrave Square, London, S.W.1.

Erratum. In the leading article entitled "Purpose in Publication" in *Nature* of August 5, it was stated that there is no journal which deals exclusively with biological or biochemical research published more frequently than once a month. We regret this is an error, because *Biochimica et Biophysica Acta* (Elsevier Publishing Co.) has appeared fortnightly since January 1, 1960.

MANAGEMENT STUDIES IN BRITAIN

THE frequency with which reference has been made in recent debates in Parliament to the quality of management and the desirability of training for management gives special interest to two recent broadcast talks on management and the universities. It was particularly noticeable in the debate in the House of Commons on July 26 on the economic situation, although the Chancellor of the Exchequer himself, in opening the debate, merely referred to a re-arrangement of priorities in favour of scientific and technical education and expressed his dissatisfaction with the progress being made in training skilled labour. Mr. P. Walker, however, urged that more attention should be given to commercial education; it is not enough, he said, to increase the supply of scientists and technologists if this is not balanced by sufficient skilled administrators to ensure efficient industrial management; this plea was strongly supported by Mr. J. Diamond and Mr. R. Gunter, both in this context and in its bearing on improved industrial relations. Indeed, both Mr. G. Brown and Mr. D. Howell attributed part of our present difficulties directly to bad management. Less was made of this point in the debates on Britain and the Common Market in both Houses of Parliament on August 2 and 3, but whether or not Britain enters the European Common Market, considerable changes in the industrial life of Britain are inevitable, and these will make large demands on management. Lord Poole indeed was confident that in any event most of British industry would be able to deal effectively with competition from Europe or elsewhere; but, while Lord Plowden also believed that large parts of British industry are highly efficient and competitive, he also thought that it is doubtful whether, in certain industries at least, the United Kingdom offers, on its own, a market large enough to support units of the most economic size.

It is certainly true that, if Britain is to take advantage of the opportunities which entry into the Common Market would offer, industrial management must be competent to meet the most searching demands for efficiency. Nor is management likely to be adequate to meet the situation alone, although, as Mr. D. F. Hutchison pointed out in a broadcast talk on authority and the individual in industry (*Listener*, Feb. 2, 1961), the management function is essentially an autocratic one which should be clearly differentiated from the function of a trade union. It is indeed this conflict between management and the unions that retards the vital function of taking decisions, and although Mr. Hutchison sees such conflict as inherent in the industrial situation, he insists that it should be constructive conflict. He does not suggest that the managerial function should be weakened—that indeed would be detrimental to the trade union members themselves in the long run—but it follows that in his view it is a vital test of the competency of management that it should, while in no way yielding its power to take decisions, fully safeguard the rights and personality of individuals and secure, so far as possible, the understanding and co-operation of all concerned.

Mr. Hutchison was concerned both that management should be effective and dynamic, and that the trade unions also should exercise their proper function and regain the ground they have lost with the community. His talk thus provides an interesting introduction to the two talks some months later on management and the universities, in that he emphasized practical points that lie rather outside the scope of either Dr. V. L. Allen or Mr. J. H. Smith's talk (*Listener*, July 13). Mr. Allen, like Mr. Hutchison, recognizes the inherent conflict of interests in industry, and because social scientists have tended to ignore this question of power and conflict, he is inclined to reject the whole idea of management training or studies as at present practised in the universities. Management, he argues, is not a self-contained activity; it is a single layer of control in a hierarchical structure involving power relations in industry and power and status relations in the community at large, and nothing makes sense unless due account is taken of these relations. It might be interpolated that some status relations in industry also need to be recognized. Furthermore, Mr. Allen rejects, perhaps too precipitately, the idea that any body of knowledge about the subject is being built up; little serious research has been done and less has involved structural or comparative analysis.

If Mr. Allen is right here, it is indeed difficult to maintain that management meets the requirements for an academic discipline sufficiently to justify its being taught in universities. He dismisses, too, the idea that the study of management is vocational, and he is highly critical of all three main methods of teaching management which are in use. In so far as managers can be trained, he suggests that they should be trained through other firms and outside agencies, such as technical colleges, and he would alter both the substance and direction of existing management courses in the universities. Recognizing that industrial behaviour as a whole must be studied if any part of it is to be properly understood, he would give priority to large-scale comparative studies, which should yield results of value both to management and to trade unions, and from which, ultimately, a sociology of industry would emerge, standing in its own right as an academic discipline, and which could be taught openly and honestly and usefully in our universities.

Mr. J. H. Smith (*Listener*, July 20) takes the opposite view. Management studies in British universities, he maintains, deserve much more prominence than they have had so far, both on academic grounds and in terms of what universities could usefully do to raise standards of management in British industry. The most urgently needed development is a strong postgraduate business school, mixing graduates from different disciplines and focusing attention on a common core of subjects which illumine the principles and practice of management. Such a school should be part of a university already strong in the social sciences, but it could be closely linked with other postgraduate administrative studies, notably in public and social administration, which are already well established in some universities.

Mr. Smith points out that it is now widely recognized that the social sciences can be regarded as having the same bearing on the practice of management as the natural sciences have on the practice of medicine, and agrees that research in industrial behaviour is an indispensable condition of the growth of management studies. He thinks Dr. Allen is too pessimistic as to the amount and extent of fundamental research in this field. He does not believe that the universities are pushing ahead too quickly and too uncritically. On the contrary, he considers that the new developments give an impression of caution and of conscious experiment: published plans seem prudently tentative, taking different starting points, and ready to try new combinations of disciplines and unfamiliar disciplines.

By and large, the picture of the present position which Mr. D. Freeth, Parliamentary Secretary for Science, gave in the debate in the House of Commons on August 4 on the need for a social sciences research council seems to support Mr. Smith's view rather than that of Dr. Allen. Moreover, Mr. Smith suggests that much of the impetus towards education for management derives from industry's wish to broaden the intellectual outlook of its managers, to take an outside view of the industrial system, particularly in its social and international context. He challenges Dr. Allen's assertion that the universities are simply seeking to meet the desire of the managers to know how to manipulate a labour force under full employment.

The demand for higher education bearing on management is a direct consequence of the growth of large organizations in industry and commerce, and in public administration. The complexities of these organizations pose problems of a high intellectual order: how to control and co-ordinate individuals responsible for diverse activities, how to direct and re-shape these activities in response to technical, economic and social change, how to deal with an increasingly literate and independent labour force. The administration and organization of scientific research and the problems of Government and science are a particular example where there is need for constructive and creative thought and experiment. Mr. Smith points out that if the universities do not take up this challenge, industry must almost certainly attempt to do so alone, and there will then be little chance either that management studies will be liberated from the framework of discussion fixed by industry itself or that the whole subject will be studied with the freedom and objectivity it deserves.

Accordingly, he takes the view that the universities should move much faster; that they are already in a position to develop management studies much more vigorously if they wish; and that there is a core of subjects now generally agreed to be relevant, and a growing body of research findings to provide, *inter alia*, material for a critical understanding of the industrial system in general, and the management function in particular. He sees nothing in the programmes of existing courses in Britain or in the attitude of those teaching them, which suggests a departure from the high standards claimed for the universities, nor does he believe that real weight is now attached to social harmony rather than conflict, or that social scientists are eager to help managers to manipulate behaviour.

Dr. Allen's objection that management education is directed towards producing an *élite* is treated as more substantial. Many of those receiving it will come to occupy positions of considerable authority and exercise power in large measure over their fellow human beings. The view they take of their responsibilities is a matter of the utmost concern to society, and the role of the universities in shaping that view is highly important. Mr. Smith is undoubtedly right in suggesting that this is no reason for suggesting that the universities should move still more cautiously in this field: rather it is a reason for them coming to terms with management education, and quickly. The real question is not whether there will be a management *élite* but what sort of *élite* it will be. If, as seems certain, this *élite* is increasingly educated in the universities and in the colleges of technology, it follows that those institutions must pay more attention, through research and teaching in the social sciences, and through education for management at the postgraduate-level, to the world in which this increasing proportion of their graduates will spend their working lives. A recent statement issued by the Manchester College of Science and Technology, in connexion with Mr. R. B. Dew's appointment as first visiting professor in industrial administration from October 1, is worth noting here. The statement indicates that the College hopes to expand the work of the Department under Prof. R. W. Revans and affirms a strong belief in the value of management studies. The College believes that a university can make three distinct contributions. First, by its own research, the study of the problems of management and analysis of the consultant's case-book to extract basic teachable ideas; secondly, by communicating these ideas to students so as to encourage them to seek the underlying structure within which the problems of management may be more fully identified and progress more readily controlled; and thirdly, to study the actual processes of management. That statement is both in accord with the general sense of the debate in Parliament on August 4 and with Mr. Smith's argument rather than that of Dr. Allen.

INDUSTRIAL RESEARCH IN BRITAIN

RESEARCH FOR INDUSTRY 1960, follows the same pattern as the past three reports on the industrial research associations in the Government scheme*. The report of the Industrial Grants Committee is followed by a review of the achievements of the 10 research associations, the terms of grant of which came up for review during the year, and two chapters in which Dr. A. H. Sully reviews the contributions of the research associations to health and safety, and Dr. T. Moran the position of food research in the United Kingdom, including the role of the research associations. The remainder of the report (roughly two-thirds) comprises a list of the associations, their officers and publications during the year with a brief indication of the scope of their work.

---

* Department of Scientific and Industrial Research. Research for Industry 1960: A Report on Work done by Industrial Research Associations in the Government Scheme. Pp. iv+148+12 plates. (London: H.M.S.O., 1961.) 8s. net.

The total income of the associations has now risen to £7·9 million and the Department's grant to £1·8 million, while the number of organizations is 52. The Research Council has accepted the Industrial Grants Committee's recommendation regarding admission of non-Commonwealth firms to membership: such firms may now be admitted, subject to certain safeguards, but no grant will be payable on income received from such firms. The Committee has also been concerned with the rising cost of research and the minimum level of income needed if the level of research is to be maintained in real terms, particularly in associations serving small industries. The Cutlery Research Council, which first received a grant-in-aid in 1951, is instanced as serving one such industry which has faced this problem and placed the Council on a sounder financial basis by arranging for a statutory levy. The two new associations coming into the scheme during the year are the British Industrial Biological Research Association, incorporated in October 1960, chiefly to examine the effects on health of chemicals likely to be ingested with food, and the British Brush Manufacturers' Research Association, formed in 1946. Stress is laid on the co-ordination of research effort between the associations, and following the formation of the Cotton, Silk and Man-made Fibres Research Association, the Research Association of British Rubber Manufacturers was re-organized to serve the plastics industry also, as from January 1, 1961, under the title "Rubber and Plastics Research Association of Great Britain". Stress is also laid on the application of the results of research, and it appears that the scheme under which the Research Council made available special grants to accelerate applications appears to have had some effect.

Reviewing the work of the Cutlery Research Council, the report notes that the adoption of a higher carbon stainless steel which keeps an edge far longer than traditional non-stainless steel saves at least 75 per cent of the time a butcher normally spends in whetting his knives. A special investigation undertaken to determine the acceptance in the industry of new ideas propagated by the Council revealed the danger of distortion through inaccurate verbal transmission of information, and indicated generally the conditions under which innovations might become acceptable to manufacturers. The British Glass Industry Research Association's work on instruments for controlling quality has led to the production of an improved strain viewer, to more efficient means of calibrating the subsidiary standards known as strain disks, and to the development of an automatic apparatus which will plot a thermal-expansion curve, and other work has indicated that great increases in the strength of glass articles can be produced under laboratory conditions. A new and permanent fire-proofing process for jute cloth, which gives a high degree of protection against fire and afterglow and is unaffected by prolonged immersion in water, has been developed by the British Jute Trade Research Association, which has also found that by careful choice of cloth and by applying a special chemical finish, jute-resin laminates of a wide range of types can be fabricated from jute fabric impregnated with polyester or epoxy resins.

Work by the Linen Industry Research Association has led to the virtually complete change-over in the industry from bleaching linen yarns in the hank to bleaching in the more economical package form, and very encouraging results have been obtained by blending flax with a proportion of an inherently non-inflammable fibre to give a blend which is itself non-inflammable. A simple method of severe cold-rolling of highly stressed areas of heavily loaded components of motor-cars, such as the fillets of stab-axles and crank-shafts has been shown by the Motor Industry Research Association to increase the fatigue strength by more than 100 per cent, while the Printing, Packaging and Allied Trades Research Association has developed an instrument which measures the resistance to abrasion of two printing surfaces rubbed against each other. Work on cutting and creasing cartons has enabled an important cause of spoilage to be eliminated almost completely, and also increased the speed at which boxes will run on automatic filling machinery, while information acquired in a study of journey hazards in road, rail or mixed goods transport and of the choice of suitable cushioning material is being utilized in the design of packages. The British Scientific Instrument Research Association, besides an ultra-sonic flow-meter, which should be on the market in 1961, has developed a position-sensitive photocell, with 3 or 5 electrodes, which easily detects a movement of 0·01 millionth of an inch, while, besides pioneering work in industrial roofing, the Research and Development Committee of the Timber Development Association designed a prefabricated portable plywood building for the Himalayan Scientific and Mountaineering Expedition, led by Sir Edmund Hilary in 1960, and has used the ultra-sonic pulse technique to trace the extent of decay and insect attack in structural timbers in old buildings. The improved dryers resulting from the Wool Industries Research Association's work on the rate of diffusion of water into fibres are used now by the entire industry, and productivity continues to be improved by the Raper autoleveller and the Raper drawing system. In the study of the structure of keratin the emphasis is now placed on the chemistry of the more reactive amino-acids such as cystine and tryptophan, and fundamental research on the diffusion of dyestuff anions into wool fibre has been linked with the discoloration and variable dyeing properties of wool after storage.

In the debate on science in the House of Commons on July 10, Mr. Aubrey Jones and some other speakers were highly critical of the work of the research associations in general, criticizing the scale of their effort, which was regarded as too small to be effective, and the concentration on fundamental research. This view was not generally accepted in the debate, the preoccupation with fundamental research being flatly denied by Mr. Denzil Freeth, while Mr. J. H. Osborn and others wished to see their activities extended, the use of operational research being specially mentioned. *Research for Industry 1960* is not sufficiently detailed to go far in resolving any doubts expressed in the debate, but it does display something of the range of problems in which co-operative attack promises effective results, and the extent to which the Council for Scientific and Industrial Research is concerned both to see that research effort between different industries, as well as in particular industries, is effectively co-ordinated, and to encourage as much as possible the early utilization of research results in industry. On the educational functions of the associations and the question of research-mindedness in industry, by and large, the report is again silent.

THE ONTARIO RESEARCH FOUNDATION

THE annual report of the Ontario Research Foundation for 1960 contains interesting accounts of sponsored research in its various departments*. In biochemistry, for example, work has been carried out on such projects as the tanning of leather with spruce bark from northern Ontario, the improvement of household sanitation units, the utilization of rice-hull ash, and the properties of pozzolans and other cementitious materials. Besides many existing investigations, four new industrial projects were initiated in the Chemistry Department in 1960. Work for the Reichhold Chemical Co. was started and contracts negotiated with the Brick and Tile Institute of Ontario, Toronto; L'Air Liquide, Montreal; and the National Starch and Chemical Co., Plainfield, New Jersey.

Of particular interest in this Department was work carried out under the Moore Business Forms, Ltd., Fellowship. The investigators designed and constructed instruments to measure manifolding characteristics and developed analytical methods for carbon paper coatings based on new physical methods of analysis. The instruments developed permit a study of the density and clarity of carbon copies, the formation of 'haloes' in high-speed printing, the pressure-time relationship for various impacts of type on multilayers of paper and carbon paper, and provide a visual demonstration of the clarity of carbon copies. The analytical methods permit analysis of very small specimens of carbon ink such as may be recovered from carbon copies and thus yield basic information on transfer and other properties.

In the Engineering and Metallurgy Department, service work increased by about 25 per cent and accounted for about 70 per cent of the external revenue, and more than 50 per cent of the total work load of the Department. The total number of investigations in the Ore Dressing Division increased from 45 in 1959, to 56 in 1960, 55 different clients being served. The Engineering Division provides engineering services for a number of industries, and operates the Gas Appliance Testing Laboratory for the Canadian Gas Association.

Another department, Industrial Research Services, helps industries in the Province by providing a free technical information service coupled with a field engineering service. The latter delineates technical problems and recommends means for their solution. Any industry in Ontario may use this confidential service without obligation. This work is carried out under contract for the Ontario Department of Commerce and Development and for the Technical Information Service of the National Research Council.

This Department also keeps a record of the Foundation's activities. In 1960, more than 4,300 separate contacts with manufacturing and service industries, individuals, associations and departments of Government were recorded. Nearly 1,400 investigations were carried out in the scientific laboratories of the Foundation, ranging from short-term evaluations of a special nature through minor research and development projects, field engineering studies, consultation, project management and technical surveys to major research and development fellowships. Answers to nearly 1,900 technical problems were provided by Industrial Research Services and more than 400 problems requiring laboratory work were co-ordinated by the Department either at the Foundation or in some other appropriate and competent agency.

For many years the Department of Parasitology has been building up a body of knowledge concerning the parasites occurring in fish, birds and mammals of Ontario. Thirteen scientific papers were published in 1960, an outstanding contribution from a small group which is also responsible for a teaching and research programme in parasitology at the University of Toronto.

Service work undertaken by the Department of Physics included work on back-scattering of electrons from surfaces, a test-jig for an extensometer, tests of insulation tape, and consultation regarding electronic instruments, optical measuring systems, light meters and radioactive tracers.

* Ontario Research Foundation Annual Report, 1960. Pp. 46. (Toronto: Ontario Research Foundation, 1961.)

THE COUNCIL OF SCIENTIFIC AND INDUSTRIAL RESEARCH, NEW DELHI

THE annual technical report, 1959–60, of the Council of Scientific and Industrial Research, New Delhi, covers the work of twenty national laboratories, including the National Botanic Gardens, Lucknow, and the Birla Industrial and Technological Museum, Calcutta, as well as sponsored research in progress or completed at the Rain and Cloud-Physics Research Unit of the National Physical Laboratory, New Delhi, and at the three Essential Oils Research Centres at Kanpur, Bangalore and Ootacamund*. There are also notes on the work in progress under some fifteen research committees and under fellowships, as well as on completed projects. Lists of 379 research schemes in progress in 106 centres in 1959–60, of grants-in-aid, of 306 fellowships, of 738 research papers published during the year, and of patent applications filed are appended. Besides the Central Mechanical Engineering Research Institute and the Central Indian Medicinal Plants Organization, which are still being planned, the Council has approved the establishment of a National Aeronautical Laboratory at Bangalore, a Regional Research Laboratory at Jorhat (Assam), a Central Scientific Instruments Organization and a Centre for Research, Training and Documentation in Petroleum and Natural Gas.

* Council of Scientific and Industrial Research, New Delhi. Annual Technical Report, 1959–60. Pp. iv+440. (New Delhi: Council of Scientific and Industrial Research, 1961.)

The research schemes covered a wide range of problems in biology and public health, engineering, essential and vegetable oils, fuel, leather and food technology, metallurgy, pharmaceuticals and drugs, and physics, while a research school in earthquake engineering was established at Roorkee University.

It is impossible here to do more than refer very briefly to a few features of the work of some of the National Laboratories and Institutes to illustrate the range of the Council's activities. The National Physical Laboratory, New Delhi, was responsible for theoretical investigations on the conduction of heat in solids, and an evaluation of the convolution integral with particular reference to its application in heat conduction when the excitation function is an arbitrarily plotted function of time. Broadcast transmission of time signals over a standard carrier of 10 Mc./s. continued for 5 hr. daily on an experimental basis, and also investigations on the determination of the minimum amount of costly materials which suffices for the correct measurement of their melting points which are fixed points of temperature, and the internal energies of tantalum, platinum and titanium have been calculated. The National Chemical Laboratory, Poona, has developed a new complexing eluant, sodium triphosphate, particularly useful in preparing pure samaria from a 30 per cent samarium concentrate, and has also developed a general theory of super-exchange interaction mechanism and satisfactory processes for production of theophylline, sodium warfarin, *N*-methyltaurine and methylamine and for recovering quinine and quinidine from cinchona febrifuge, as well as a new route to naturally occurring anthraquinone carbinols using diborane.

The Central Drug Research Institute, Lucknow, has found, in indigenous medicinal plants screened for pharmacological activity, a good cardiovascular drug in ruvoside, from *Thevetia neriifolia* (Kaner) and a drug with musculotrophic properties in *Daemia extensor* (Utranjutaka), and obtained evidence of amœbicidal activity in deoxyhexahydroquinine, while immunochemical work on *Vibrio cholerae* has shown that neutral and acid polysaccharide fractions possess high serological activity. The Central Electroclinical Research Institute, Karaikudi, has developed a new technique for preparing 2 : 4-diaminophenol by electrolytic reduction of *m*-dinitrobenzene, and has used a rotating-cathode technique in the preparation of benzidine and substituted benzidines, while a new cathodic technique has been developed for the study of cathode protection based on the use of the Hull cell and a polarographic technique used for the determination of cystine. The Regional Research Laboratory, Hyderabad, has prepared short-, medium- and long-oil varnishes from maleic and modified phenolic resins, using dehydrated castor oil, bodied dehydrated castor oil and linseed stand oil, and established optimum conditions for the preparation of terpeneol from carene, 8-hydroxyquinoline from *o*-aminophenol, phenylacetic acid from benzyl chloride and phenylacetamide from benzyl cyanide.

The Indian Institute for Biochemistry and Experimental Medicine, Calcutta, has gained a clearer understanding of the biological activity of human chorionic gonadotrophin which accelerates the transformation of germ cells in the male toad, and has also obtained a comprehensive idea of the pattern of metabolism supporting growth and activity in *Leishmania donovani*.

RADIO RESEARCH 1960

THE Radio Research Board of the Department of Scientific and Industrial Research was established in 1920, and has in the intervening forty years continuously advised the Department on its programme of research in the radio field. For many years the work was centred on the National Physical Laboratory at Teddington, although facilities for field experiments were long ago made available in the grounds of the Admiralty Compass Observatory, at Ditton Park, near Slough. Dr. R. L. Smith-Rose has been associated with this research programme from its inception, and in 1947 he was appointed as the first director of radio research of the Department of Scientific and Industrial Research. Following this appointment, the Radio Research Station at Slough, with its new laboratories erected in 1956, became the centre for the radio research work of the Department and independent of the National Physical Laboratory.

The report of the Radio Research Board for 1960, published recently*, records that Dr. R. L. Smith-Rose retired from his post of director of radio research on September 30, when he was succeeded by Mr. J. A. Ratcliffe from the Cavendish Laboratory, University of Cambridge.

During the year, the work of the Station was re-oriented so as to apply about 50 per cent of its effort to some space research problems, which are now being actively investigated. To assist in this work, a major development during the year under review was the installation of a 'Minitrack' equipment for tracking artificial satellites of the Earth, and for communication with, and reception of, telemetry signals from such satellites. The equipment has been provided on loan by the National Aeronautics and Space Administration (N.A.S.A.) of the United States, and is operated by staff of the Station. Data obtained from it are available for use by both organizations.

Predictions, on an increased scale, have continued to be issued during the year, giving the positions of all satellites of interest to observers in the United Kingdom. Signals have been received from a number of satellites at Winkfield, near Slough, and at the Radio Research sub-station at Singapore; and measurements have been made of signal strength, Doppler frequency-shift, and Faraday fading effects. The results are of particular interest in work on the ionosphere both in temperate and equatorial regions.

For many years the Radio Research Station has been very actively engaged in exploring the ionosphere by radio waves sent up from the surface of the Earth. During the past year, collaboration with the corresponding Canadian and United States laboratories has continued in the development of a technique to use satellites for sounding the ionosphere from above—'top-side sounding' as it is called. The station at Port Stanley in the Falkland Islands, one of the Department's ionospheric observatories for many years past, will also be engaged in receiving signals from these and other satellites.

---

* Department of Scientific and Industrial Research. Radio Research 1960: The Report of the Radio Research Board and the Report of the Director of Radio Research. Pp. iv+23+4 plates (London: H.M.S.O., 1961.) 2*s*. 6*d*. net.

The ionospheric forecasting service provided by the Radio Research Station has always been used by civilian and defence organizations in the planning of their long-distance high-frequency communication circuits. With the knowledge of ionospheric behaviour that has been accumulated at the Station, consideration is now being given to the production of a reference book containing details of all ionospheric conditions likely to be encountered throughout the world. A single figure or index derived from observations at a few ionospheric sounding stations would be used as a guide to find out the conditions prevailing at any time and place.

During the period under review, the analysis of the atmospheric radio noise data obtained during the International Geophysical Year has been continued. The main experimental work during the year has been the recording of single atmospherics from storms at known short distances; and the evaluation of the peak power and total radiated energy from lightning discharges. At frequencies greater than 30 Mc./s., interference from atmospheric noise is not of major importance for ground receiving stations. But the need to find a 'quiet' site for the Station's projected radio telescope has indicated that man-made noise, due to electrical machinery and the like, may cause serious disturbance. Accordingly, measurements are being made in the higher radio frequency bands to determine more precisely the levels of such man-made noise.

There are still many problems awaiting solution in connexion with the transmission of radio waves over both long and short distances through the troposphere. A detailed knowledge of the propagation conditions for very-high and ultra-high frequencies is of particular importance in connexion with the future development and planning of broadcasting, including television, services throughout the world. Staff of the Radio Research Station collaborate with the Post Office and the British Broadcasting Corporation in experimental investigations in Britain. But, on a wider scale, they also participate in the work of the International Radio Consultative Committee (C.C.I.R.), concerning the planning, over a wide geographical area, of transmitters using the same or adjacent frequency channels, in such a way as to avoid mutual interference.

Closely associated with this work is the direct experimental study of the refractive index structure of the troposphere by two techniques: one of these uses an airborne micro-wave refractometer for direct measurements at various heights; the other comprises radar sounding of the tropospheric layers at vertical incidence. Preliminary investigations have been made by both methods, and improved equipment has been under development during the year.

While the work on the electrical properties of components and materials, such as transistors and ferrites, has been terminated during the year, the past experience gained in this type of investigation is proving valuable in the development of techniques and equipment used in other parts of the research programme. Apart from this, however, all aspects of the programme demand facilities for the accurate measurement of various parameters; it is a continuing policy of the Station to conduct research on the appropriate measurement techniques.

As in the case of former published reports, that for 1960 contains three appendixes. The first gives the references to 36 scientific papers published by the staff during the year. The second is a list of staff of the Radio Research Organization on January 1, 1961; while the third gives the terms of reference and constitution of committees of the Radio Research Board. These committees provide the expert advice on which the Board frames its recommendations for the present and future programmes of research.

BIOLOGICAL CONTROL OF CONCEPTION*

By Dr. A. S. PARKES, C.B.E., F.R.S.

National Institute for Medical Research, Mill Hill, London, N.W.7

THE Oliver Bird Lectures and the Oliver Bird Prize were instituted with the idea of reviewing and stimulating work bearing on the control of conception in man. Such review and stimulation were badly needed. In many countries of the world, population is increasing at an unprecedented and accelerating rate. The increase is not due to any sudden increase in human fertility; it is due to the work of medical science in decreasing mortality and increasing the expectation of life at birth in many parts of the world where the birth-rate is still high. Total world population is now around 3,000 million, just about double the number thought to have existed at the beginning of this century. Population growth cannot go on indefinitely at this rate. Something will happen to stop it, and the human race must decide whether that something is to be pleasant or unpleasant.

Different countries are contributing in very different degrees to this population explosion. In the United Kingdom the small natural increase in population now occurring is not in itself causing any new problems. But the practical, æsthetic and eugenic requirements of the individual in relation to the control of conception are far from satisfied. In countries faced with a crippling increase in population it is vitally necessary that a simple and effective method of controlling fertility shall be evolved. It is not surprising, therefore, that intensive, though belated, work is now in progress with the view of applying existing knowledge of the physiology and biochemistry of the processes leading to conception to provide better methods of preventing it, and to extend our fundamental knowledge of the processes so as to broaden the basis of possible applications. In general, therefore, the trend of thought is towards what may be called biological means of fertility control, involving systemic treatment, and away from local action of a mechanical or chemical nature. Systemic treatment is, of course, most easily made by mouth, in other words by 'the pill'.

---

* Substance of the fifth Oliver Bird Lecture delivered on June 20.

Biological control involves one or other of three things: (*a*) the prevention of formation or release of germ cells in male or female; (*b*) the prevention of fertilization; (*c*) the prevention of implantation of the fertilized egg. The first of these involves either preventing the release of ova from the ovary or the formation of spermatozoa in the testis. Spectacular progress has been made in the past few years towards the use of orally active progestagens (the 'Pincus pill') to depress the ovary-stimulating activity of the anterior pituitary body and thus to prevent release of the ovum. The Pincus pill has been the subject of extended trials, and is likely to come into routine use to at least a limited extent. The outstanding problem of the Pincus pill is not as to whether it works —it certainly works—but as to the extent of uncomfortable side-effects and of possible hazards arising from the long-term inhibition of a vital gland and the prolonged induction of an artificial rhythm in the uterus.

Work on the inhibition of spermatogenesis by oral medication is not so far advanced. Obvious disadvantages attend the depression of ovary or testis activity by the use of substances, particularly steroid hormones, reducing pituitary gonadotrophic activity; but encouraging results on the direct inhibition of spermatogenesis without interference with the androgenic interstitial tissue have been obtained by the use of various non-steroidal compounds. In any event, there is little doubt that a pill for males will be forthcoming in the future. When this happens the obvious course will be for husband and wife to take, say, yearly shifts in consuming pills, so as to minimize the risk of adverse effects arising in either sex through indefinitely prolonged treatment.

So far, little progress has been made with the problem of preventing fertilization by biological means in circumstances where both male and female are producing viable germ cells, that is to say, in preventing effective contact between egg and sperm. It is possible, though not certain, that the most hopeful line of work here is towards immunizing the female against spermatozoa and thence against pregnancy, a possibility which arises from the fact that spermatozoa are antigenic when administered parenterally to animals of a different species from the donor, and that the antibodies raised are organ- rather than species-specific. A serious difficulty, however, lies in obtaining an effective concentration of antibody at the necessary site of action within the female reproductive tract, and only recently, by the use of adjuvants, has it been possible to obtain any serious indications of a positive result. However, other immunological approaches to fertility control exist.

Work on the prevention of implantation raises the important question as to what constitutes conception. Biologically there can be little doubt that implantation of the fertilized egg in the uterus, not fertilization of the egg, constitutes conception, and that contraception can therefore properly be exercised up to the time of implantation. This is important because much interesting work is now being carried out on inactivating the fertilized egg or preventing the changes in the endometrium necessary for implantation. A method of fertility control based on such work would have the great advantage of requiring retrospective action rather than action anticipating the uncertain contingency of exposure to the risk of pregnancy. Scope for inactivating the fertilized egg is perhaps limited, but there are many possibilities of disturbing the hormonal, metabolic, pharmacological, or neurohumoral relationships necessary for the development of progestational changes in the uterus. A particularly interesting line of thought in this field arises from the observation that newly mated female mice fail to become pregnant if exposed to the smell of alien males from a different strain. The effect is exerted first through nervous and then through hormonal pathways, and the observation is evidently of great interest and potentiality; the attractive idea of a contraceptive perfume is no longer quite incredible.

In conclusion, it must be remembered that the best methods will be of little value in countries faced with an explosive growth of population unless people can be persuaded to use them, and this may not be easy in countries conditioned to the idea of a high birth-rate and a high death-rate, and in which public health measures have reduced the death-rate so rapidly that the social background has had little chance to adjust itself. But at least we should ensure that demographic and personal aspects of human reproduction are as widely understood as possible, and that simple and reliable methods of fertility control are available for those who wish to use them. In this we have far to go. Established methods of fertility control, being archaic in principle, are a disgrace to science in this age of spectacular achievement. In general, I am in favour of science pushing on in every possible direction, but I sometimes think that the further exploration of inner man would be more immediately useful than the exploration of outer space.

SAFE HANDLING OF RADIOACTIVE SUBSTANCES

In 1949 a printed version of the booklet *Introductory Manual on the Control of Health Hazards from Radioactive Materials*, prepared by the Atomic Energy Research Establishment, was issued by the Medical Research Council. This manual has been in great demand by those working with or just beginning to work with radioactivity, but, as it has not been available for some years, a new edition*, commissioned by the Medical Research Council's Committee on Protection against Ionizing Radiations, is timely and welcome. It is intended to give guidance on the principles of safe working to those handling radioactive substances in laboratories and elsewhere, and contains a valuable summary of the recommendations on maximum permissible doses and the state of legislation in the United Kingdom at the end of 1960.

---

* Privy Council. Medical Research Council Memorandum No. 39: *Introductory Manual on the Control of Health Hazards from Radioactive Materials*. (Committee on Protection against Ionizing Radiations.) Pp. vi+21. (London: H.M.S.O., 1961.) 1*s*. 9*d*. net.

In Section 3, which follows a brief introductory section and a descriptive section on the general nature of the hazards, are given the present recommendations on maximum permissible levels of radiation for those occupationally exposed to radiation and for those working nearby; these are based on the Medical Research Council's evaluation of the recommendations of the International Commission on Radiological Protection. In addition to listing the levels for external radiation, examples are given of actual values of maximum permissible body burdens and maximum permissible concentrations in air and water.

There is a brief outline of the measurement of radiation dose and dose-rate in Section 4; monitoring for neutrons is outside the scope of the manual. Due consideration is given to the use and value of film dosimeters, but there is no mention of whether any film-badge service is generally available. In this section reference is made to the selection of radiological safety officers to ensure that protection measures in a particular department are carried out; and to the appointment of an appropriately qualified physicist as 'radiological protection adviser' to advise the head of each department. These officers are akin respectively to the departmental radiation supervisor and university radiation protection officer recommended in the recently published *Code of Practice for the Protection of Persons exposed to Ionising Radiations in University Laboratories* (The Association of Universities of the British Commonwealth, London, 1961). It is also pointed out in the manual that the radiological protection adviser should work in close association with a qualified medical adviser. These officers can also be compared with the "competent persons" in the Factories Acts Regulations whose duties are to "exercise special supervision with regard to the requirements of these Regulations and to assist in enforcing the observance of them". (*Factories, The Ionising Radiations (Sealed Sources) Regulations*, 1961 (London, H.M.S.O., 1961); Ministry of Labour, Factories Acts, 1937–1959, *Unsealed Sources Regulations, Preliminary Draft of Regulations* (London, H.M.S.O., 1961).)

Sections 5 and 6, on "Acceptable and Hazardous Amounts of Radioactive Material", contain a table classifying isotopes according to their relative radiotoxicity. This table is in line with the table in the first schedule of the Unsealed Sources Regulations. Laboratories are graded as *A*, *B* or *C* according to the quantity of radioactivity involved and its radiotoxicity; in addition, account is taken of the nature and complexity of the processes involved. This method of classification is the one that is most often given in codes of practice for safe handling of radioactive materials; however, it is not the only one, and practical experience has shown that other systems of classification of radiation and contamination give effective control of exposure to radiation.

The remaining sections of the manual cover protective clothing and devices; exhortations on 'do's' and 'don'ts' when handling radioisotopes; eating, smoking and washing; storage; a valuable section on disposal of radioactive wastes which takes account of what the situation will be when the Radioactive Substances Act, 1960, comes into force; and a final short section giving advice on where to apply for particulars concerning transport of radioisotopes.

The bibliography covers publications issued up to the end of 1960. In the field of radiological safety so much coding and regulation is in progress that there have been at least three major documents issued since the manual was published. With this accretion of regulations and advice the manual is invaluable for all those concerned with the use of radioactive substances and the control of health hazards as a handy summary of authoritative advice at a given point in time.

NEUTRON CAPTURE THERAPY

NEUTRON capture therapy is an experimental radiotherapeutic procedure involving new concepts in the treatment of cancer. This treatment is a means of achieving selective irradiation of a tumour tissue by inducing throughout that tissue radioactivity of high biological efficiency. The radioactivity is induced *in situ* by means of the capture of thermal neutrons by a suitable target element. To develop the most efficient system, a target element is chosen which, on thermal neutron capture, decays immediately through emission of energetic heavy particles such as α-particles. Since the range of heavy particles of 2–4-MeV. energy in tissue is very short, of the order of less than 15μ, the resulting radiation effects are limited to the region of origin. Because radioactive decay is practically instantaneous and results in a stable element, physiological dispersion from the origin is prevented. Only those elements which have a high thermal-neutron capture cross-section, such as boron-10, lithium-6, and uranium-235, are useful. This suggestion was first put forward in 1936 by Locher. The utilization of thermal neutron capture by boron-10 for the treatment of human-brain tumours, chiefly glioblastoma multiforme, has been under investigation at the Medical Research Center of Brookhaven National Laboratory, New York, since 1949.

An account of the biological effectiveness of thermal neutrons and of heavy particles from the $^{10}B(n,\alpha)^{7}Li$ reaction for the rabbit's ear and its utilization for neutron capture therapy has been given by Yaskazu Lucas Yamamoto (*Yokohama Medical Bulletin*, 12, No. 1, February 1961).

Throughout this series of cases, the pathological effects of thermal neutrons and of the heavy particles from the $^{10}B(n,\alpha)^{7}Li$ reaction on human skin occurring at the point of neutron entry have been known as one of the most vexing side-effects of neutron-capture therapy. Among other side-effects such as boron toxicity, radiation parotitis, and radiation conjunctivitis, it has particularly attracted the attention of investigators, and an effort has been made to prevent or reduce the complication. In reviewing the brain tumour cases treated by neutron-capture therapy at the Medical Research Center, Yamamoto and his co-workers have encountered varying degrees of skin reactions in a large percentage of the cases ranging from erythema to severe radiation dermatitis.

In a previous series of experiments on human brain tumours, attempts were made to decrease skin radiation by decreasing the boron concentration in the skin while maintaining a maximum concentration in the neoplastic tissue in the brain. The methods used were those of scalp pressure bandages, temporary bilateral ligation of external carotid arteries, and boron-10 infusion into the internal carotid artery on the same side as the tumour. These methods were not adequate in preventing severe reaction since a large neutron dose was required to treat a deep-lying tumour because the thermal neutrons attenuate rapidly in tissue.

A research project has therefore been undertaken to determine the minimal dose of thermal neutrons and of the heavy particles from ^{10}B(n,α)^{7}Li reaction to produce radiodermatitis on the ear of the rabbits, and to investigate the details and characteristics of skin reaction and their prevention, especially by the employment of neutron-shielding materials for medical use.

The findings show that the safe skin dose (no more than grade-2 skin reaction) of thermal neutrons and of the heavy particles from the ^{10}B(n,α)^{7}Li reaction on rabbits' ears are established to be less than 10×10^{12} n/cm.^{2} with thermal neutrons exposure alone and $1{\cdot}5 \times 10^{12}$ n/cm.^{2} with 35 mgm. ^{10}B per kgm. body-weight. A review of clinical data shows the maximum safe skin dose to be roughly $0{\cdot}5 \times 10^{12}$ n/cm.^{2} with 25–50 mgm. ^{10}B per kgm. body-weight. These clinical data have been correlated with work on the differences of radiosensitivity between human beings and rabbits' ears by Ellinger.

The medical uses of neutron-shielding materials from both physical and biological points of view have been considered, and the utilization of the above data to avoid skin complications in neutron-capture therapy for human brain tumours is indicated by Yamamoto. The use of the temporary skin flap and lithium metal shielding has been successful in avoiding skin complications. The value of relative biological effectiveness is calculated to be 3·9 from thermal neutron exposure alone and to be 1·87 from neutron-capture therapy from the ^{10}B(n,α)^{7}Li reaction, with 35 mgm. per kgm. body-weight.

LAND-USE SURVEY: NICARAGUA

It is now well recognized that the world's agriculture must become more intensive if it is to keep pace with the increasing population of this planet. Earlier warnings by Lord Boyd-Orr can now only be accepted as fundamentally real, and have been placed in perspective by Dr. Norman Wright, deputy director of the Food and Agriculture Organization of the United Nations. He estimates that if agriculture makes use of all the technical assistance available, there is no reason why it cannot keep pace with the increasing demands for food, at least to the turn of this century. One of the first technical contributions to agricultural intensification of a country is a survey of the optimum uses of land, and the first parts of such a survey in Nicaragua have been published recently.

Nicaraguan agriculture is at present not very intensively developed. The latest returns (for 1952, in the Food and Agriculture Organization's *Yearbook 13*, 1959) show it to have a total area of 14,800,000 hectares of which more than 26 per cent is built on or otherwise unusable. Of the productive area the largest proportion is forest (57·5 per cent). Pastures account for nearly 6 per cent and arable crops nearly 8 per cent, while 29 per cent is potentially productive, though not used at present. This should be a most rewarding setting for a land-use survey, shows particular foresight of the originators, and Dr. Taylor has indeed produced a report which demonstrates how Nicaragua could not only feed more than her own rapidly expanding population for some time to come but also maintain and increase the forestry assets*.

Grassland improvement is perhaps the most basic, for stock depends on it more than on arable crops. Enhanced grazing value of the savannah is possible by mowing or controlled burning, and on more fertile ground, the wasteful bush fallow should be replaced by a period of from four to six years of rotation pasture with controlled grazing by stock. There is, however, urgent need to introduce more productive grasses and legumes.

Perhaps the greatest need for the survey is shown in forestry organization. In the Puerto Cabezas–Rio Coco area, the pine forests are only sufficient for a further seven years supply, yet the industry could be built up to have a perpetual annual income of at least 23,000,000 dollars (U.S.), and measures to effect the transition are discussed. On the other hand, in an area to the north of Santo Domingo, standing timber valued at approximately 100,000,000 dollars (U.S.) is likely to be destroyed in the gradual clearing of land for agriculture and grazing. A project to utilize it is described. It is recommended that a small forest service concentrating on fire control be established, pasture and plant introduction officers be appointed and that there should be a small service for crop protection, for diseases and pests are severe in the condition of high rainfall.

Climate and soils in Nicaragua are very suitable for a considerable expansion of cash crops. Large areas would, for example, be suitable for growing rice, with or without low-lift irrigation, which could cover immense areas at low cost. The survey indeed leads to the conclusion that Nicaragua might well export rice, meat, milk, cheese, sugar, citrus products, peanuts, beans and cacao. This raises one of the main difficulties of expanding world food production, namely, of adjusting increased production to new markets. Unplanned flooding of world markets would destroy the whole economics of production, and Dr. Taylor very rightly considers this aspect in addition to the detailed ecology of his valuable report. The population of Nicaragua, however, has increased from 765,000 in 1937 to 1,378,000 in 1958, so if this very rapid increase persists, the internal market alone will demand considerable expansion of food supply and resources.

The classic instances of Israel and Taiwan show what can be achieved by the planned use of land, and, in complimenting Nicaragua and the Food and Agriculture Organization on this progress, we look forward to the remaining parts of the survey and to the implementation of its recommendations.

John Grainger

FOREST INSECT PESTS AND DISEASES IN CANADA

IN 1935 a Forest Insect Survey was begun in Canada with a small organization located at Ottawa and Fredericton, mainly concerned with European spruce sawfly. It has now expanded to the extent of having 11 laboratories and a permanent staff of 100 employees. In 1957 a Forest Disease Survey was initiated concerning itself with diseases due to organisms and agencies other than insects. Late in 1960, with the formation of a Department of Forestry which absorbed the Forest Biology Division of the Department of Agriculture, a combined survey of all forest diseases became possible.

The size of the annual report for 1960 of the combined survey indicates the extent of the work now being undertaken.* In it each province reports separately, and a rough glance over the index shows that almost 400 individual organisms living on Canadian trees are the subject of record and observation. Compared with tropical rain-forest the number of Canadian tree-species is not large, yet they seem to harbour a considerable number of organisms injurious to them. Not all these are of primary importance, however, and the early spring and hot summer of 1960, except in British Columbia, were not favourable to fungous diseases. A northward spread of Dutch elm disease in Ontario and New Brunswick was recorded. The major insect marauders are the spruce bud-worm, the larch sawfly and the forest tent caterpillar on aspen, reported from all regions. The bud-worm has severely defoliated spruce and silver fir over an area of nearly 8 million acres in British Columbia.

The survey makes considerable use of aeroplanes for locating certain diseases the distribution and spread of which are shown on appropriate maps. Aerial spraying is used in trying to control the spruce bud-worm and other insects. The introduction of various insect predators to combat pests like the balsam woolly aphid is on trial, and in Newfoundland a shrew has been introduced, apparently with some success, as a predator on larvæ of the larch sawfly. Quite a number of diseases have been imported from Europe, but not the dwarf mistletoe which infests lodgepole pine in Alberta, and spruce in the Maritime provinces. A damaging ice-storm occurred in Quebec province and frost and storm damage occurred elsewhere.

The minute size of certain organisms is often in inverse proportion to the length of their names. Little did the unsuspecting Indian of a bygone era realize that he was surrounded by such formidable creatures as *Pseudexentera improbana oregonana* Wlshm. or *Lambdina fiscellaria fiscellaria* (Guen.). The general value of this annual report would be immensely enhanced if the survey dealt first with the individual organisms in order, using the regions as a secondary basis of reporting and not as the primary one.

HEALTH IN YUGOSLAVIA

IN 1957 the School of Public Health, Zagreb, Yugoslavia, conducted an inquiry into the health, living conditions and social and economic problems of the 880 inhabitants of eleven mountainous villages in the Velebit highlands above the Adriatic coast. The report of the inquiry has now been published by the World Health Organization (*WHO Chronicle*, 15, No. 7; July 1961). These villagers have no roads, no electricity, no radio and no newspapers; the region in which they are has no developed agriculture or cattle breeding, no industry, or mining. Life is just what it was fifty years ago—simple and hard, perhaps harder, since goat-raising is now forbidden, and the trade in wood, wool and cattle that used to be carried on along the coast has fallen into decay. The young people no longer emigrate to the United States as they used to, but try to get away to other parts of Yugoslavia where conditions are easier.

This situation has left a deep mark on the villages. Since 1900 the population has gone down. In 1900 there were 94 women to 100 men; in 1953 the figure was 112. The average age of the population has gone up, the percentage of people aged 65 and more increasing from 4·4 per cent in 1900 to 11·1 per cent in 1953, the percentage of children aged 14 decreasing from 43·1 per cent to 32·6 per cent in the same period.

Infectious diseases accounted for 46·5 per cent of deaths at the end of the last century. Now they have almost ceased to be a cause of death, the chief causes for 1953–57 being: from infant diseases 35·9 per cent, from old age 33·3 per cent and from pneumonia 10·3 per cent. Infant mortality has always been a serious problem. Cancer and cardiovascular diseases have been responsible for very few deaths.

The majority of cases of respiratory disease found in the investigation lay on the borderline between pathological and the physiological. Diseases of the digestive tract were strikingly low, perhaps because of a diet containing much milk. The nutritional status of the villagers was good. The intestinal parasites found were similar to those of neighbouring districts. Syphilis was diagnosed in only two villagers. Investigation for antibodies to the polioviruses showed that contact with the viruses and immunity to them must have occurred in early childhood. Antibodies against *Q*-fever were found in 26·4 per cent of the population—not surprisingly, as the villagers live in close contact with sheep.

This health study was carried out by teachers and students of the School of Public Health, and, apart from the knowledge it gave of conditions in a remote area, brought the students into contact with the life of the villages, taught them public health techniques, such as analytical methods and sampling, and afforded them opportunity to develop into research-minded workers. It showed that collaboration between university institutions and public health services can be of benefit to both. It also showed that much valuable information can be gleaned in a short time by work such as this and used by the public health authorities as a basis for their health programmes.

DRINKING-WATER STANDARDS

IT is frequently not realized that in Great Britain there are no legal standards of quality to which water supplies must conform; nevertheless the quality of our public supplies is such that it is automatically assumed that water from the tap is safe. This is not the case in many parts of the world, and in 1958 the World Health Organization published the minimum standards which it considered should be required everywhere in the world[1]. It was always hoped that these standards would be surpassed in more highly developed areas, and a second publication has now appeared which recommends higher standards which should be attainable in all European countries[2].

The recommendations specify the minimum bacteriological and chemical qualities that should be expected of piped supplies of water for domestic use. In the section on bacteriological examination, methods of sampling are described, the organisms which should be regarded as indicators of pollution are discussed, and tests for coliform organisms, fæcal *Streptococci*, and anaerobic spore-forming organisms are outlined, before specific recommendations for bacteriological standards are made. It is considered that, in any water entering the distribution system, coliform organisms should be absent in 95 per cent of the 100-ml. samples taken each year, and that at least 100 such samples should be examined at regular intervals during the year.

In the section on physical and chemical examination the main requirements limit the concentrations of toxic substances (lead, arsenic, selenium, chromium, cadmium, cyanide and radioactivity) and give the methods of analysis which should be used to estimate them. In addition, limits are suggested for certain constituents of water which may give rise to trouble if present in excess (for example, fluoride, nitrate and zinc), and of others, such as free carbon dioxide, and hardness, which should preferably be controlled although they do not affect the hygienic quality of the water. SPECIFIC HEAT AND EXPANSION COEFFICIENT OF LIQUID HELIUM-3 UNDER PRESSURE BELOW 0·1° K.

By DR. D. F. BREWER and J. R. G. KEYSTON
The Clarendon Laboratory, Oxford

RECENT measurements of the specific heat of liquid helium-3 near its saturation pressure have shown that the second-order phase transition predicted by theory[1–4] does not occur above 0·008° K. Anderson, Salinger, Steyert and Wheatley[5] found a linear variation of specific heat with temperature between 0·008° K. and 0·04° K., and Strongin, Zimmerman and Fairbank showed that no anomaly occurred between 0·054° K. and 0·085° K.[6], the latter being the lowest temperature to which previous measurements had been made[7]. Unpublished measurements by us, also near the vapour pressure, between 0·03° K. and 0·1° K., covered the intermediate region. According to the theory of Emery and Sessler, the transition temperature, T_c, is given by the equation:

$$kT_c = 1{\cdot}09\,\frac{\hbar k^2_F}{m}\,\frac{m}{m^*}\,\exp-\left(\frac{\pi}{2}\,\frac{m}{m^*}\,\frac{1}{t}\right) \qquad (1)$$

(provided that the Fermi liquid model holds above the transition temperature), where $\hbar k_F$ is the Fermi momentum and m^*/m (the ratio of the effective mass at the Fermi surface to the true mass of the helium-3 atom) is equal to the ratio, as $T \to 0$, of the observed specific heat and the specific heat of a perfect Fermi gas with the same particle mass and number density as liquid helium-3. The quantity $1/t$ takes the values 5·56 for the Yntema–Schneider potential, and 5·46 for the de Boer–Michel potential between helium-3 atoms, yielding transition temperatures at the vapour pressure which are only slightly below 0·1° K. (later modifications of the theory by Anderson and Morel (*Phys. Rev.*, to be published) and by Bardasis and Schrieffer[8] reduce the transition temperature to about 0·01° K. and 8×10^{-4} ° K., respectively. Details of this work are not yet available, but according to Emery (private communication), the functional dependence of T_c on m^* would not be drastically changed from that given by equation (1)). Specific heat measurements by Brewer, Daunt and Sreedhar[7] allowed a provisional computation[9] of m^*/m at high pressures, and showed it to be increasing quite rapidly, in general agreement with the Fermi liquid model[10]. It follows from equation (1) that T_c will also increase with pressure, but the variation cannot be calculated with certainty since at the lowest temperature reached by Brewer *et al.* (0·12° K.) the specific heat was not linear in the temperature, and their values of m^*/m were not considered completely reliable.

We have now carried out measurements of the specific heat at constant pressure, C_p, at several different pressures between 15 cm. mercury and 27 atmospheres, and between the temperature limits 0·04° K. and 0·35° K. Again, there is no indication of any anomaly in the specific heat, which decreases smoothly with decreasing temperature, tending to a linear dependence at the lowest temperatures. We have also measured the change in temperature on adiabatic expansion and compression of the liquid near the melting pressure, and find that the mean expansion coefficient (over a range of pressure and temperature) is always negative between 0·04° K. and 0·32° K.

The calorimeter was a hollow copper cylinder (wall thickness 0·3 mm., length 1·5 cm., internal diameter 1·0 cm., approximately) of total capacity about 1·2 cm.[3]. It was packed with powdered cerium magnesium nitrate serving as a thermometer, occupying roughly 70 per cent of its capacity, and the end closed off and sealed, using cold-setting 'Araldite' type *X* 83/11. A manganin wire heater was packed evenly with the cerium salt, one end being shorted to earth and the other spot-welded to a niobium lead which was brought out of the calorimeter through a 0·5-mm. diameter german silver tube filled with the same type of 'Araldite'. Helium-3 (containing less than 1 part in 10,000 of helium-4) was condensed into the calorimeter through a 0·5-mm. diameter german silver tube. The calorimeter was connected through an indium thermal switch (actuated by a superconducting solenoid) to the refrigerant salt, about 50 gm. of potassium chrome alum, which also cooled a copper thermal shield surrounding the calorimeter. The whole assembly was enclosed in a vacuum jacket surrounded by a bath of liquid helium-4 just below 1° K., then by another vacuum jacket and a 4° K. bath of liquid helium. The chrome alum was demagnetized over a period of about 5 hr. from 25 k.gauss and about 0·5° K., the latter temperature being achieved by means of a small copper helium-3 cryostat incorporated into the refrigerant salt, which also cooled the high-pressure helium-3 through the thermal switch. The thermal switch was then closed and final temperatures of about 0·04° K. achieved. Two-stage demagnetization was not successful, probably because of eddy current heating in the calorimeter.

Temperatures of the helium-3 were determined from the ballistically measured susceptibility of the cerium salt. Background heating-rates varied from about 0·1 m.deg./min. at the lowest temperatures to effectively zero above 0·1° K., and were observed for times varying between 5 min. and 12 min. before and after the heating periods. The heater current was put on for times of 0·5–1·5 min., to give rises in temperature of about 5 m.deg. below 0·1° K. and 10–50 m.deg. at the higher temperatures.

A plot of C_p as a function of temperature at pressures of 15 cm. mercury, 11·5 atm. and 26·6 atm. is shown in Fig. 1. The calculations of Brewer *et al.*[7] show that the difference between C_p and C_v is negligible and the difference between C_p (or C_v) at 15 cm. mercury and C_{sat} is also very small. (C_{sat} is the specific heat at the saturated vapour pressure.) Since the volume of helium-3 in the calorimeter has not yet been determined with great accuracy, we have derived absolute values by normalizing the specific heat at 18 atm. to the previously determined values[7] between 0·12° K. and 0·3° K. This pressure was chosen because the present results at 18 atm. show the least scatter (less than ± 2 per cent). When the same normalizing factor is applied to our measurements at the other pressures, the results agree within ± 2 per cent with the earlier determinations, as shown by the crosses in Fig. 1, representing the values of Brewer *et al.* Near the vapour pressure, however (15 cm. mercury), the new values lie rather higher than the linear extrapolation of Brewer *et al.*, who pointed out the possibility of a residual curvature below their lowest temperature of measurement. This will bring the value of effective mass at the vapour pressure into closer agreement with the more recent experiments[5,6], and reduce the discrepancy found between the earlier entropies and those of Abraham, Osborne and Weinstock[11].

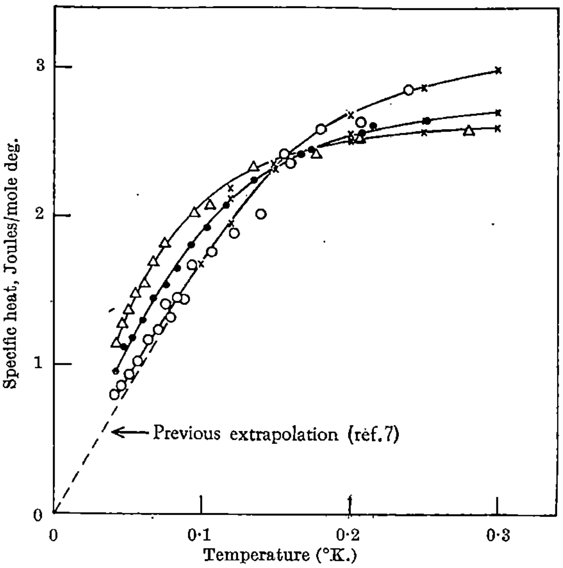

Fig. 1. Specific heat at constant pressure as a function of temperature
○, pressure p = 15 cm. mercury; ●, p = 11·5 atm.; Δ, p = 26·6 atm.; ×, previous measurements (ref. 7). The broken curve gives the linear extrapolation used in ref. 7

The reversal in sign of the pressure dependence of the specific heat[7] at about 0·16° K. is confirmed in these experiments, and positive values of $(\partial C_p/\partial p)_T$ are found down to 0·04° K. Even at this low temperature, it is still not clear that the specific heat has become linear with temperature. However, entropies (S_p) derived by integration of these curves, and using the previous entropy determinations under pressure down to 0·12° K., are more nearly proportional to temperature[9], and we have used them to derive new values of m^* under pressure. At 26·6 atm., the effective mass is found to be 1·78 times greater than at the vapour pressure. It may be calculated from equation (1) that the predicted transition temperature at our highest pressure should be about 3·2 times greater than T_c at the vapour pressure, if we use for $1/t$ the average given by the de Boer–Michel and Yntema–Schneider potentials. Taking an upper limit of 0·008° K. for T_c at the vapour pressure[5], we obtain a maximum value of 0·029° K. for T_c at 26·6 atm., which may be expected to be lower still if the specific heat is not linear at these low temperatures. We wish to emphasize that since the specific heat is still not linear at our lowest temperature, this result is still subject to revision.

As discussed by Brewer and Daunt[9], values of the expansion coefficient at constant pressure, α_p, can be determined from the change of temperature on adiabatic expansion and compression of the liquid, with the help of the equation:

$$\alpha_p = \frac{C_p}{VT}\left(\frac{\partial T}{\partial p}\right)_s \qquad (2)$$

where V is the molar volume. We have determined mean values, $\bar{\alpha}_p$, between 0·045° K. and 0·32° K., over changes in pressure of 4·7 atm. and 1·4 atm., and at average pressures of 25·2 and 26·9 atm. Fig. 2 shows the observed values of $\Delta T/\Delta p$, which are reasonably consistent with the previous observations at higher temperatures and lower pressures[9].

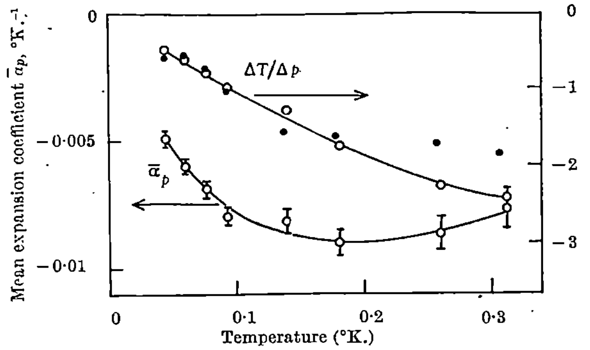

Fig. 2. The change in temperature on adiabatic compression and expansion, $\Delta T/\Delta p$ (in m.deg. atm.$^{-1}$), and the mean expansion coefficient, $\bar{\alpha}_p$ (°K.$^{-1}$), as a function of temperature

○, $\Delta_p = 4·7$ atm., average pressure = 25·2 atm.; ●, $\Delta_p = 1·4$ atm., average pressure = 26·9 atm.

Since the changes in temperature on expansion or compression through 1·4 atm. are very small, the results at the average pressure 26·9 atm. may have an error of up to 50 per cent. Values of $\bar{\alpha}_p$ shown in Fig. 2 have been calculated only for the larger changes in pressure, but in all cases the mean expansion coefficient is found to be negative, as is the case at higher temperatures[9,12,13]. This observation does not fit in readily with the result of Mills, Grilly and Sydoriak[14] (based on measurements of the molar volume near the melting curve), who conclude that $\alpha_p = 0$ at the minimum in the melting curve (0·32–0·33° K. and about 29 atm.[13–15]).

Although results for $\bar{\alpha}_p$ obtained by the present method are inherently not very accurate, it is difficult to find any qualitative error, since expansion always leads to a warming and compression to a cooling effect, which, within experimental accuracy, are of the same size. It therefore appears that there may be some discrepancy in the experimental observations of α_p, unless the behaviour of the liquid changes quite sharply between our average pressure of 26·9 atm. and the melting curve.

We are grateful to Dr. N. Kurti for several helpful discussions and suggestions. We also wish to thank Dr. V. J. Emery for discussions during the writing of this article, Mr. R. March for assistance with experiments and computer programming, and Miss K. Merrick for help with data processing on the computer.

INTRACELLULAR FREEZING AND FROST RESISTANCE IN EGG-CELLS OF THE SEA URCHIN

By E. ASAHINA

Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan

Intracellular Freezing as a Cause of Frost-killing in Relatively Rapidly Frozen Cell Suspensions

It is well known that in a variety of living cells, when they were subjected to freezing, a considerable number of them are very liable to be damaged within the first very short period of time unless the cooling is very slow. Luyet and Menz demonstrated in freezing blood cells that even at near-zero temperatures the degree of hæmolysis increased markedly within the first twenty minutes of freezing[1]. Because of the negligible increase in hæmolysis before the frozen blood is cooled to temperatures below −3° C., they seem to favour the view that injury due to dehydration (or concentration) is a main cause of frost-killing. However, the result of their experiment did not, as they suggested, exclude other interpretations. After the frozen blood was cooled to a temperature near that of the cooling bath, there was found only a very slight increase in hæmolysis. This is by no means explained by salt-injury due to concentration at the time of freezing. Since the cooling-rate of freezing blood was shown to be rapid only within the first twenty minutes, the rate of cooling may perhaps be responsible for frost-killing. Also in freezing sea-urchin egg-cells suspended in sea-water nearly the same result as mentioned above was found (Fig. 1).

Unfertilized eggs of *Strongyrocentrotus nudus* were used as material. Four test-tubes containing 0·5 ml. of egg suspension were cooled simultaneously in a cooling bath of ice–salt mixture at − 16° C. In each test-tube, the egg suspension was seeded with small ice-crystals when it was cooled to about −2° C. As the change of temperature of the egg suspension measured by a small thermistor (1 mm. in length) was very similar in each of the four test-tubes, only one typical freezing-curve is shown in Fig. 1. After 2, 5, 15 and 30 min. from the time of ice-seeding, these test-tubes were removed singly and each of them was re-warmed rapidly in water at 20° C. Egg-cells frozen and thawed in this way were observed under a microscope for counting the intact cells. The percent-

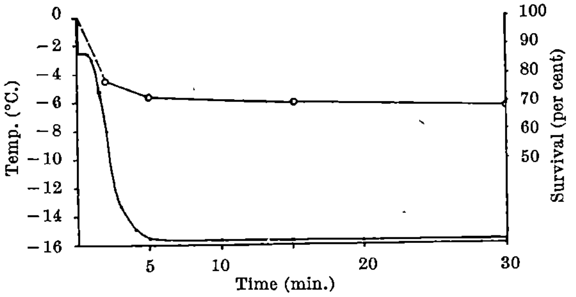

Fig. 1. A freezing-curve of cell suspension (●), and the percentage survival in cells frozen for various lengths of time (○)

age survival in Fig. 1 is based on the number of intact cells counted. At the same time, microscopic observations of the freezing process of sea-urchin eggs were made many times at nearly the same cooling-rate in a special cold room. A small amount of egg suspension was cooled under the microscope in a silicone-oil hanging drop in which the tip of a fine thermocouple was inserted. When the egg suspension was cooled to -4° C. it was seeded by means of an ice-tipped pipette. Soon after they were surrounded by frozen sea-water the egg-cells began to freeze intracellularly. At a cooling-rate of 5° C. per min., the type of intracellular freezing in a sea-urchin egg was a typical 'flashing', a very rapid darkening due to an almost instantaneous formation of a large number of minute ice-crystals throughout the cell[2]. 'Flashing' most frequently took place in egg-cells within about 30 sec. from the time of seeding, but afterwards its occurrence was reduced rapidly. After a few minutes some of the egg-cells, in which some degree of dehydration by extracellular freezing had already been found, still froze intracellularly, but the freezing process in these cells was not 'flashing'. Ice formed from a few centres of crystallization at the cell surface and gradually grew in the cytoplasm within some twenty seconds as 'irregular rosette'-type crystals[3] (Fig. 2). The amount of intracellular ice crystal varied; ice usually never occupied the whole of a frozen cell. After 4 min. or more of freezing, no additional egg-cells were found to freeze intracellularly; instead, they underwent a marked contraction. On thawing most of those cells recovered their normal size and shape.

The egg-cells of the sea-urchin can, as a rule, resist extracellular freezing without any protective additives[2]. Unfertilized eggs of *S. nudus* survived freezing at -10° C. for a full day and even at -20° C. at least for 30 min. provided they were cooled very slowly to that temperature (Asahina, unpublished results). Also in the present experiment, insemination after rewarming was followed by normal cell division in nearly all the intact cells. Intracellular freezing, on the other hand, always resulted in apparent cytolysis or a fatal coagulation of cytoplasm regardless of the amount of ice formed in the cell. It seems reasonable to assume, therefore, that under the present experimental conditions the main cause of frost-killing is intracellular freezing, and that after a cell is in contact with ice the rate of cooling may be responsible for the initiation of intracellular freezing. In freezing plant tissues, too, it has long been known that a rapid rate of cooling is highly effective in causing intracellular freezing[4,5].

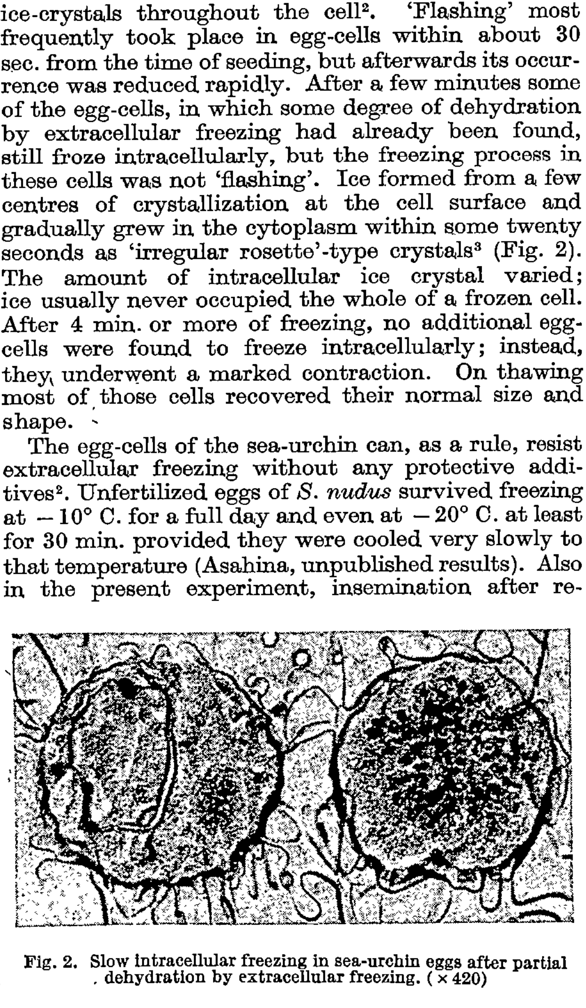

Fig. 2. Slow intracellular freezing in sea-urchin eggs after partial dehydration by extracellular freezing. (×420)

A Mechanism to prevent the Seeding of Intracellular Ice in Freezing Living Cells

The experiment reported in the previous communication clearly demonstrated that the main cause of frost-killing in relatively rapidly cooled cell suspensions is intracellular freezing, and that a high rate of cooling is very effective in causing intracellular freezing in a living cell which has been in contact with ice. A careful microscopic observation revealed that egg-cells of sea-urchin, suspended in silicone oil, never froze spontaneously even when they were cooled to a temperature as low as -15° C. (Asahina, unpublished results), but in these egg-cells, ice seeding on to the surrounding sea-water film could cause intracellular freezing even at a temperature of -8° C. (ref. 2). These results can be explained as due to the initiation of freezing within the egg-cell as a result of inoculation from the outside with ice crystals at least at moderately low temperatures. If this hypothesis is valid, an elevation of temperature at the interface between the cell and the surrounding ice-mass will be effective in preventing the ice seeding into the cell. The present article deals with evidence on this problem.

Egg-cells of a sea-urchin (*Strongyrocentrotus nudus*), both fertilized and unfertilized, were used as material. The apparatus and the method in the present experiment were almost the same as those described in the previous investigation. In the case of fertilized eggs, they were subjected to freezing after having been kept at 15° C. for 30 min. after fertilization. Four test-tubes containing 0·5-ml. aliquots of suspensions of egg in sea-water and a small thermistor for temperature measurement were cooled simultaneously in a cooling bath at -20° C. In each test-tube, egg suspension was seeded with small ice crystals when it was cooled to about -3° C. To achieve slow cooling, a double-walled test tube with adequate distance between the two walls was used. After preliminary freezing tests, two rates of cooling were applied for the experiment. One of these, rapid cooling, had a cooling-rate of about 9° C. per min., while the other, slow cooling, had a rate of about 1° C. per min. These cooling-rates were measured between -7° C. and -13° C., because, when cooled at these cooling rates, intracellular freezing in suspended cells was most frequently observed under the microscope within this temperature-range. In the case of rapid cooling the test-tubes were immersed in the cooling bath for only 5 min., while in the slow cooling they were kept there for 30 min. Egg-cells frozen in this way were thawed rapidly by immersion of the test tubes in water at 20° C.; then they were observed under the microscope for counting intact cells.

The result of this experiment showed that most of the fertilized eggs were very resistant to both rapid and slow freezing, while practically all the unfertilized eggs

Table 1. PERCENTAGE SURVIVAL AFTER FREEZING IN THE EGG-CELLS OF SEA-URCHIN

	Mean values of 6 experiments		
	Cooling rate	Fertilized eggs	Unfertilized eggs
Rapid cooling	9° C./min.	84·1 ± 7·6	2·2 ± 2·1
Slow cooling	1° C./min.	90·3 ± 5·0	74·0 ± 5·9

could not withstand rapid freezing although they, too, could survive slow freezing (Table 1). After thawing, a characteristic pattern[2] of coagulated protoplasm, which resulted from intracellular freezing, was found in most of the killed cells. The intact cells, on the other hand, could generally resume their development. Even the very few survivors in rapidly frozen unfertilized eggs could cleave normally after insemination. The high frost-resistance[8] noted in fertilized eggs was certainly not due to the existence of a fertilization membrane which is formed on fertilization, because a fertilized egg from which the fertilization membrane was removed artificially was found to be as resistant as intact fertilized eggs to rapid freezing.

A reasonable explanation of these observed results may be that in egg-cell suspensions, after the sea-water has begun to freeze at near zero temperatures, the frozen mass is promptly or gradually cooled. As the cooling proceeds, the ice which is now in contact with the cell surfaces withdraws water from the cell interior because of the difference in chemical potential between the ice and supercooled water within the cell. The water withdrawn in this way successively crystallizes at the interface between the cell and surrounding ice until most of the easily freezable water at a given temperature is lost from the cell ; after this time ice-formation within the cell is scarcely achieved even with intracellular ice seeding[2]. In these processes, if the cell surface is promptly cooled far below the freezing point, the water molecules within the living protoplasmic system can be caused to arrange themselves as an ice crystal by seeding from outside ice. But if the temperature at the cell surface is kept only a few degrees below the freezing point, the water within the protoplasm cannot crystallize and only the outside ice-crystal grows, withdrawing water from the cell interior. This can be performed effectively in the case of slow cooling since the release of latent heat of ice-crystallization at the cell surface is supposed to be sufficient to keep the temperature not much below freezing-point.

It has been amply demonstrated by many authors that, in the egg-cells of various kinds of sea-urchins, the rate of entrance or exit of water into or from the cell increases remarkably after fertilization. In an egg of the *Arbacia* the permeability of the plasmic membrane to water was found to be four times as great in the fertilized as in the unfertilized egg[6]. In the cooling of egg-cells which have been in contact with ice, this character may certainly cause a larger decrease in cooling-rate at the surface of fertilized than of unfertilized cells. The reason is that in a fertilized egg the release of latent heat per unit period of time at the cell surface is larger than in an unfertilized one, because of the higher rate of extracellular ice formation in the former unless the cooling is sufficiently slow. Even if such decrease in cooling-rate is only temporary, the cell protoplasm may be sufficiently dehydrated, within the first short period of freezing, to prevent intracellular freezing. It was reasonable therefore that in the freezing of egg suspensions cooled at an adequate rate, say 9° C. per min., intracellular freezing occurred much more rarely in fertilized than in unfertilized eggs.

In freezing plant cells, almost the same mechanism to prevent the intercellular freezing has already been suggested by me[4]. By using freezing yeast cells, Mazur recently came to a somewhat similar conclusion[7].

ELECTRICAL ACTIVITY OF A GIANT NERVE CELL UNDER ABNORMAL CONDITIONS

By DR. YUTAKA OOMURA, SACHIO OZAKI and TAKASHI MAÉNO
Department of Physiology, Faculty of Medicine, Kagoshima University

RECENTLY it was found that a node of Ranvier of the toad's nerve could generate action potentials in sodium-free isotonic choline chloride, calcium chloride, potassium nitrate or even in a sucrose solution, when an adequate intensity of hyperpolarizing current was applied to the nodal membrane[1]. Some results from experiments on the spinal ganglion cells of frogs also have shown that the electrical activity was maintained in a sodium-free solution of nitrogenous compounds[2].

On the giant nerve cells (150–400μ in diameter) of the supracœsophageal ganglion of a marine pulmonate mollusc, *Onchidium verruculatum*, observations basically similar to those of the node of Ranvier were made by us. These cells were able to generate the action potential in the 'all or none' manner in various sodium-free solutions, when the normal concentration of calcium ions was maintained.

Two intracellular micro-electrodes filled with 3 *M* potassium chloride were inserted into the single cells, one for recording potential, and the other for passing current through the cell membrane (to direct stimulation of the cell membrane). For synaptic and antidromic excitations, two groups of the roots of the ganglia, placed on two pairs of electrodes, were stimulated. The experiments were carried out at a temperature of 15–25° C.

As reported in ref. 3, the resting potentials of the giant nerve cells in normal sea-water (sodium chloride 459·6 m*M*, potassium chloride 13·7 m*M*, calcium chloride 10·4 m*M*, magnesium chloride 48·5 m*M*) were 40–60 mV., the inside being negative. The

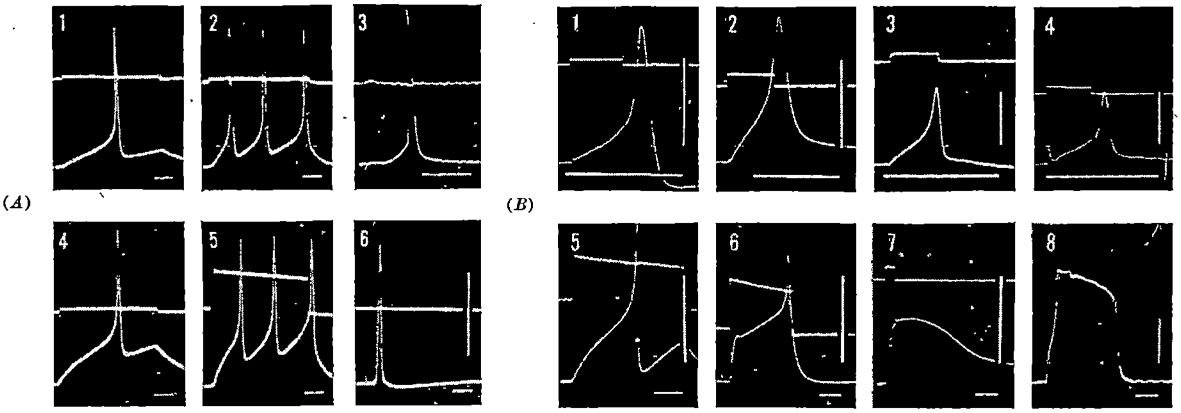

Fig. 1. *A*: Action potentials in normal sea-water (upper) and in sodium-free choline sea-water (lower) at 21° C. 1, 2, 4 and 5, action potentials generated by directly applied transmembrane current of long duration; 3 and 6, by stimulations of the roots. The resting potential increased by about 12 mV. in choline sea-water. *B*: Action potentials in various sodium-free solutions. Sodium ions in the external solution were replaced with sucrose (1), choline (2), inositol (3), ethylene glycol (4), calcium (5), magnesium (6), potassium (7) and barium (8). 20° C. Upper trace, transmembrane current; lower trace, membrane potential. Vertical and horizontal scales, 50 mV. and 100 msec., respectively

average membrane resistance and capacity were 6·8 MΩ and 0·027 μF. The amplitude of the action potentials produced by both synaptic and indirect stimulations were 75–95 mV., and if a supra-threshold polarizing current were prolonged, similar spike potentials appeared repetitively (Fig. 1*A*). With increase of hyperpolarizations in the membrane, in most cells, the spike potential produced by the direct stimulation increased the value in the critical threshold potential and failed to grow to a full-sized spike. Since such abortive pre-potential appeared by antidromic stimulations under hyperpolarization, it was concluded that the pre-potential represents an electrotonic spread of the spike in the axon to the soma membrane due to the small safety factor at the soma-axonal junction.

When the perfusing external solution was changed to choline sea-water in which total sodium chloride was replaced with isomolar choline chloride and the other components unchanged, the resting potential was hyperpolarized by about 12 mV., and full-sized action potentials without appreciable reduction in the height of the spikes were recorded for more than 3 hr. in this perfusing solution by the direct, synaptic and antidromic stimulations. The membrane resistance was not altered. In some cells only the abortive prepotentials appeared by direct stimulations, due to the hyperpolarization caused by choline. Thus the full-sized action potential was produced by the restoration of the resting potential towards the normal level by an application of a depolarizing current. Similar results were obtained with the replacement of sodium chloride in sea-water with sucrose, inositol and ethylene glycol, though the spike-height decreased by about 5 mV. in these solutions (Fig. 1*B*).

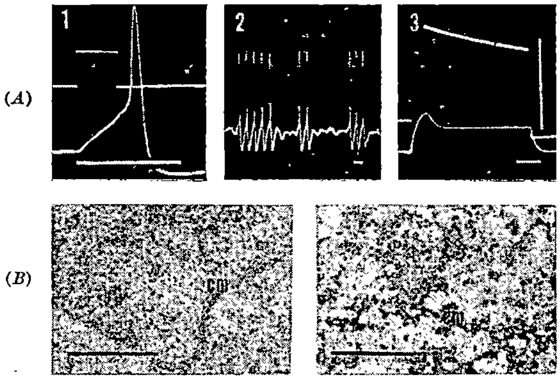

Fig. 2. *A* : Changes in electrical activity in calcium-free solutions. 1, action potential in normal sea-water; 2, increased spontaneous firing in the early stage in calcium-free sea-water; 3, graded response in calcium-free isotonic choline solution at 20° C. The resting potential decreased by 10 mV. in this medium, and no action potential could be generated. Note the decrease in the membrane resistance. Vertical scale, 50 mV. for 1 and 3, and 20 mV. for 2; horizontal scale, 100 msec. *B*: electronmicrographs of nerve cell membrane in normal sea-water (left) and calcium-free sea-water (right) showing deteriorations in the membrane structures. c.m., cell membrane; scale, 2μ

The presence of a diffusional barrier around the cell membrane for producing the action potential in a solution deficient in sodium is inconceivable, because the resting potential was depolarized abruptly when the perfusing external solution was changed to sea-water containing potassium. Even in sea-water free from sodium but containing potassium, action potential could be generated if the resting potential were hyperpolarized beyond the normal level, similar to the case of the node of Ranvier[1].

In ethylene glycol sea-water, however, the electrical activity was maintained for about 30 min. and the membrane had a tendency to deteriorate, especially when the external solution was changed to normal solution after long exposure in ethylene glycol sea-water. The deteriorative effect was attributable to the relatively high permeability of ethylene glycol into the cell membrane and to the reduction of the membrane resistance.

The action potentials also could be produced in isotonic sea-water containing magnesium chloride (magnesium chloride 370·4 m*M*, potassium chloride 13·7 m*M*, calcium chloride 10·4 m*M*) with a higher level of critical threshold depolarization than that in normal sea-water.

It is well known that marked electrophysiological disturbances occur in excitable tissues in calcium-free Ringer solutions[2,4]. Similar observations were made in the sodium-free solutions.

The action potentials in the various solutions also could be abolished by the withdrawal of external calcium and magnesium ions from the perfusing solutions. During 30 min. in this solution, the resting potential depolarized gradually by several millivolts, the value of the membrane resistance was gradually, then abruptly, reduced to one-third. The cell membrane could not produce the action potential by direct, synaptic or antidromic stimulations. Only in the very earlier stages of the calcium-free media could the membrane properties be restored by application of the calcium ions or by application of a few millivolts of anodal polarization to the cell membrane. In both cases an accompanying increase of the membrane resistance resulted. In later stages the anodal polarization did not affect the loss of excitability of the cell membrane. This is contrary to the case of the Ranvier node[1]. The effect of magnesium ions on the membrane properties was similar to that of calcium, but they were less effective.

Light-microscopic and electronmicroscopic observations revealed a considerable deterioration and myelolysis in cell soma and nerve fibre, and a thinning and decomposing of the membrane structure of the cell and of mitochondria after 30 min. immersion in calcium-free sea-water (Fig. 2*B*). This histological evidence accords with the reduction of membrane resistance.

We conclude that the electrical activity of the nerve cell membrane of *Onchidium* depends only on the calcium ions, and that keeping the membrane resistance at a normal value, that is, a normal configuration of the cell membrane by the calcium ions, is most important for excitation.

This investigation was supported by a grant from the Ministry of Education and from the Muscular Dystrophy Associations of America, Inc.

BLOOD-TYPING COMPACT HUMAN BONE TISSUE

By H. E. EZRA-COHN and PROF. S. F. COOK

Department of Physiology, University of California, Berkeley

IN a series of papers after 1935, Candela[1] reported that he was able to secure positive blood group reactions in human skeletal material from archæological sources. He was of the opinion that his method yielded results of adequate reliability. Schiff and Boyd[2] also argued that blood-typing procedures could be adapted for work with bone as well as mummified muscle. More recently, Thieme and Otten[3] have questioned the validity of such tests when applied to archæological material. They cite various sources of error: bacterial enzyme destruction of blood-group antigens, non-specific absorption of contaminants, and even the presence of adventitious antigenic elements which cannot be distinguished from blood-group substances. They say: "In conclusion, results obtained in the typing of aged bone or stains by the inhibition test do not appear reliable under some conditions". It is to be noted that Thieme and Otten did not report in this paper any work done with archæological specimens, but rather with synthetically aged specimens. Their bone samples, mostly lumbar vertebræ, were taken at autopsy, ". . . were buried in stone jars in sandy soil, and aged from 2 to 3 years". It is thus apparent that the physical and chemical conditions to which the bones were exposed resemble very little those governing the history of skeletons preserved in caves or buried directly in the ground for centuries.

There is one consistent feature of the research carried on in the recent past by archæologists with bone blood grouping, and it is carefully pointed out by Smith[4], who surveys the present status of palæoserology. This feature is that in all reported cases the bone tissue used for testing has been cancellous. Wiener[5] pointed this out in his discussion of Candela's work, and said: "The success in the grouping of skeletal remains by the absorption technique probably depends on the presence of dried marrow and blood on the lining of the cancellous bone used for examination". At the same time it seems altogether reasonable that the organic substances present in the relatively large quantities of blood stored in the cavities of the spongy bone would be exposed particularly to the action of chemical changes and micro-organisms. Organic material locked in the interior of solid, compact bone such as the diaphysis of the humerus or femur, would be much less accessible to destructive or modifying influences.

Very recently new light was shed on the entire problem by Weinberg and Makin[6]. These workers made a careful comparison of the presence of *A* and *B* antigens in fresh human bone. They made three distinct preparations: (1), clean, compact, cortical bone; (2) cancellous bone which was taken, without modification, directly from the cadaver; (3) cancellous bone which had been subjected to very thorough washing. They found a great deal of antigen in the untreated cancellous bone, much smaller, but still perceptible amounts, in the cleaned cancellous bone, and no detectable quantity in the cortical bone. The conclusion is therefore admissible that the appearance of antigen is associated with the body fluids (blood, for example) in contact with the bone at the time of death. The findings of Weinberg and Makin render very doubtful the presence of antigens in compact bone tissue itself. Hence, the appearance of positive typing in archæological compact bone tissue strongly implies an external or post-mortem origin of the antigen-like substance.

With these considerations in mind, it seems worth while to describe a series of tests made in this laboratory on samples of compact bone which had been exposed to weathering in the soil for periods of 1,000 years and more.

Our tests were made on 21 samples of compact bone from various sites (see Table 1). Triplicate tests were run on each sample. For comparison we also ran tests on 14 compact bones from fresh autopsy material. Only the *ABO* antigens were tested. The archæological material consisted of 14 samples from White Mound, Arizona, an open site of the Gila Pueblo culture, dating A.D. 700–850, four specimens from four different open sites in Marin County, California, and two from Piedra Gorda, Baja, California.

The natural (not immune) *A* and *B* sera were prepared in suitable dilution. Merthiolate 1 : 5,000

was added to the typing sera as preservative. The samples of bone were moistened with normal saline, homogenized and dried at 37° C. for three days.

To each of a series of tubes was added 100 mgm. of sample and 0·5 ml. of *A* and *B* serum. These were mixed thoroughly, incubated in the cold for 48 hr. with shaking at 12-hr. intervals, and centrifuged at 1,500 r.p.m. The supernatant fluid was tested by the Moss–Lee–Vincent rapid slide method for residual anti-*A* and anti-*B* agglutinins. (We use these terms in the senses indicated: agglutinogen, agglutinable substance in blood corpuscles; agglutinin, agglutinating substance in blood serum; antigen, general term referring to any agglutinable factor; antigen *A*, a substance which, with respect to agglutination, behaves chemically as agglutinogen *A*; antigen *B*, analogous to antigen *A*; blood group substance, antigen found in some tissues and fluids of the body other than blood, which conforms in chemical reaction to agglutinin in the manner of the agglutinogens of that body.)

From Table 1 we see that the compact bones from the 14 autopsies (the blood types of which were known) gave no antigenic reaction. These results would, therefore, tend to confirm those of Weinberg and Makin. On the other hand, of the 21 samples of compact bone from the Indian burials, 9 were type *O*, 4 were *A*, 5 were *B* and 3 were *AB*.

The findings with ancient bone would at first sight seem to contradict the thesis that compact bone cannot be typed, for it is clear that a relatively large proportion of the specimens tested showed an *A*, a *B* or an *AB* reaction. Nevertheless, we believe that the evidence is sufficient to warrant the conclusion that the observed *A*, *B* and *AB* reactions are not referable to blood group substances contained in the bone at the time of death. The following considerations support such a theory.

(1) Weinberg and Makin were unable to detect any blood group substances in numerous samples of fresh bone from tibia, ribs, sacrum and phalanges. Likewise, we were unable to find any antigen-like substances in 14 different compact bone samples from 14 different autopsies. In contrast, we observed positive reactions in 12 out of 21 cases of archæologically preserved bone. The statistical disparity is definite and striking.

(2) Since the prehistoric samples were all derived from native American Indians the high incidence of the *B* group is peculiar, for this blood group has been demonstrated repeatedly to be very nearly absent among North American aborigines.

(3) The climatic conditions to which the 21 bones were exposed were widely different. Fourteen were derived from open burial sites in the south-western United States, and two were from Lower California. Both these areas have been characterized by unusually hot, dry climates since the probable date of interment. The five bones from Marin County, California, had been exposed to the moderate climate of the Pacific coast. The former group showed 8 out of 16 *A*, *B* or *AB* reactions, whereas the latter group showed 4 out of 5 such reactions. There is not enough difference in the relative proportion of antigenic reactions to warrant ascription to climatic factors. This is noteworthy because in a climate characterized by relatively warm summers and cool, rainy winters there was adequate opportunity for bacterial action and chemical alteration to have occurred in the compact tissues so as to result in a product which could conceivably have an antigenic nature. This explanation, however, cannot be used to account for the high occurrence of *A*, *B* and *AB* types in samples which had been exposed to a very dry, warm environment.

(4) It is very probable that in clean, compact bone the blood present in the capillaries is not sufficient in quantity to give a positive blood group test. It would be expected, therefore, that archæological bone material would likewise be unreactive. The fact that it is reactive may be considered to be due to the effect of soil solutes and organisms. The organic matrix of the bone undergoes decomposition into products which are capable of generating antigenic reactions, or such substances are formed by biological (enzyme) action and penetrate the bone. Full consideration of these influences will be found in the papers of Iseki[7] and Salazar Mallen[8]. Hence it is likely that the 14 positive reactions which we observed in the 21 excavated bones were artefacts and bore no necessary relation to the true blood group of the individuals from whom the bone was derived. It would appear that serological techniques can yield no results of validity when applied to compact bone from burial sites.

(5) Similar considerations apply to cancellous bone. It is of course true that cancellous bone may give valid blood group reactions by virtue of retention of traces of blood. Here the test would actually be on the agglutinogens, or their products, which were derived from the blood, not on the bone tissue itself. The use of cancellous bone, however, is also complicated by the same factors which produce spurious positive tests in compact bone, that is, the possible presence of either decomposition products of the organic matrix of the bone (and/or residual body fluids) or of antigenic compounds formed by factors from the soil. Unless these factors can be eliminated positive blood group tests with ancient or archæological cancellous bone must be accepted only with serious reservation.

CHROMATOGRAPHY OF PROTEINS ON DIETHYL-AMINO-ETHYL (DEAE) CELLULOSE PAPER

By C. C. CURTAIN
Baker Medical Research Institute, Alfred Hospital, Prahran, Melbourne

CHROMATOGRAPHY of proteins on columns of DEAE cellulose powder[1] has proved a valuable preparative tool, but it is unsuitable for analytical work on very small samples, or large-scale surveys of serum proteins or other fluids.

This article outlines a system for the quantitative chromatography of proteins on Whatman DEAE cellulose paper, *DE*20. The paper (supplied by Messrs. Reeve, Angel, London) has an exchange capacity of approximately 0·4 m.equiv. per gm. or 0·003 m.equiv. per cm.^{2}.

As with cellulose ion exchangers in columns, the R_F value of most proteins on the paper is either 0 or 1, and except over a very narrow range of *p*H and ionic strength, virtually specific to each protein. Separation of mixtures must therefore be achieved by *p*H and ionic strength-gradient elution. Moreover these gradients must be controlled so that the entire pattern is developed within the length of the paper strip. This can be achieved either by making the gradient generated in a conventional mixing chamber pass through the trough in which the upper end of the paper is dipped or by using a generator the rate of flow of which can be matched accurately to that of the paper.

I used the second method, producing the gradient with a photoelectrically controlled gradient generator. A block diagram of this device is shown in Fig. 1. It consists of a photoelectric scanner which translated the light and dark areas in a graph of the gradient curve into varying currents in two electrolysis vessels, and hence into varying gas pressures in two bottles containing the respective gradient limits. Tubes pass from these bottles to a micro-mixing chamber which feeds the top of the paper strip. Detailed circuits of the generator and particulars of its application to column chromatography will be published later.

Before chromatography, the DEAE cellulose paper is cut into strips 5 cm. wide by 50 cm. long, which are placed in the chromatography tank and washed by a descending, successive flow of the following: 0·05 *N* hydrochloric acid, distilled water, the buffer representing the initial gradient limit. The paper is then dried in a current of cool air. 0·05–0·15 ml. of the protein mixture, which has been dialysed against the starting buffer is pipetted in a line 3–5 cm. from the top of the strip, which is inserted into a slit in a piece of 3-mm. polyvinyl chloride cannula and the edge sealed with silicone grease. This cannula, which is sealed at its outer end, is fitted to the outlet of the mixing chamber. The cannula between the chamber and the strip is kept as short as possible (< 5 cm.). The mixing chamber and strip are then inserted into a chromatography tank, which is kept in a room at 4° C. The bottom of the tank is filled to a depth of 1 cm. with water to saturate the atmosphere with water vapour. The gradient generator is set to run at the flow-rate of the strip. At the conclusion of the run the strip is removed from the tank and dried for 30 min. in a stream of air at an average distance of 20 cm. from a 500-W. infra-red lamp. After drying, the strip is immersed for 5 min. in a bath consisting of 60 parts of aqueous 0·075 *M*, *p*H 9·0 borate buffer and 40 parts of methanol. It is then transferred to a bath containing 500 mgm. of victoria blue *B* in 100 ml. of the same solvent. After staining for 10 min., the strip is decolorized by washing for 4 hr. in hourly changes of a bath consisting of 65 parts of 0·075 *M* *p*H 9·0 borate buffer and 35 parts of methanol. The strip is then dried in air.

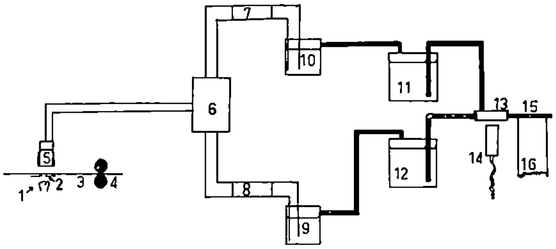

Fig. 1. Block diagram of gradient generator. 1, lamp; 2, slit; 3, 35-mm. film on which is photographed a blocked-in graph of the gradient function; 4, clock motor; 5, photocell; 6, phase inverter; 7, 'dark' d.c. amplifier; 8, 'light' d.c. amplifier; 9, 10, electrolysis vessels; 11, 12, buffer bottles; 13, mixing chamber; 14, 50-cycle electromagnet (to stir 13); 15, polyvinyl chloride cannula; 16, paper strip

Because of the basic nature of the paper, the anionic dyes used in paper electrophoresis give heavy background staining. Of the basic dyes

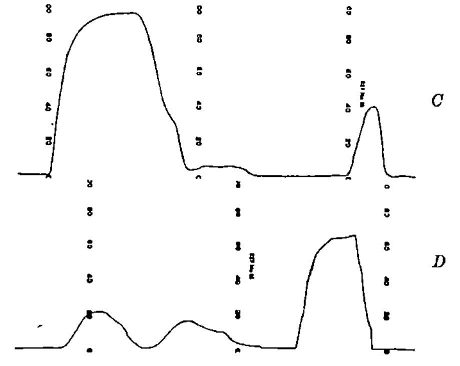

Fig. 2. *A*, separation of human γ-globulin and albumin. The point of application is at the extreme left-hand edge of the strip. The arrows represent the gradient limits, computed from the rate of flow along the strip. (1) *p*H 7·0, *M* = 0·005 phosphate; (2) *p*H 6·3, *M* = 0·010 phosphate. *B*, sub-fractionation of human γ-globulin. (1) *p*H 8·0, *M* = 0·005 phosphate; (2) *p*H 8·0, *M* = 0·350 phosphate. *C*, scanner recording of strip *A*. *D*, scanner recording of strip *B*

tested, malachite green, basic fuchsin and victoria blue *B*, the last was found to give the most intense staining of the protein bands with the least background on the paper. Care must be taken not to dry the paper at too high a temperature, particularly when it is impregnated with acid buffer salts. Under these conditions victoria blue gives a violet background which cannot be washed out.

Some typical separations are shown in Fig. 2, *A*, *B*. It is seen that the apparent position of the initial gradient limit is a considerable distance in front of the paper. Measurements of *p*H and conductivity made on the paper show that this limit is actually just at the end of the strip. As in the case of columns[2], the buffering action of the paper has a marked influence on the gradients. This buffering action places a limit on the degree of resolution attainable with short strips. With a 50-cm. strip this is only sufficient to separate serum into albumin, β- and γ-globulin. The sub-fractions of purified γ-globulin are, however, well resolved and chromatography on DEAE paper could be of great value in a large-scale survey of hyper-γ-globulinæmic sera.

The protein on the strips may be determined quantitatively by colorimetry of the dye eluted with 100 per cent methanol from each fraction. Alternatively, the strip may be scanned intact with a photoelectric electrophoresis strip scanner. In this case the height of the scanning slit should be equal to the width of the strip to allow for the irregularity of the bands.

Recordings of patterns obtained with a transistorized scanner[3] are shown in Fig. 2, *C*, *D*. I have found that the staining with uncleared paper obeys Beer's law over the range of protein concentrations encountered in the chromatograms.

I am investigating at present differences in dye uptake between the different serum protein fractions.

Stains for specific protein components may also be used, provided they are not affected by the ion-exchange properties of the paper. For example, it is possible to detect cæruloplasmin by Uriel's[4] technique and to demonstrate its heterogeneity (Fig. 3).

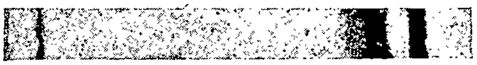

Fig. 3. Chromatogram of cæruloplasmin. 0·5 ml. of human serum in *p*H 6·4, M = 0·05 phosphate was applied to the top of the strip. The chromatogram was developed by a gradient to *p*H 6·4, M = 0·05 phosphate; M = 0·33 sodium chloride. The initial gradient limit was taken to twice the length of the strip

Further sub-fractionation of the cæruloplasmin can be carried out by cutting the bands out of unstained strips and inserting them in starch-gels[5] made in *p*H 5·1, M 0·025 acetate buffer and submitting them to electrophoresis. This technique may be of considerable value in the large-scale surveys necessary for the study of the racial and genetic variations on the individual cæruloplasmin heterogeneity reported in ref. 6.

Part of the expense of this work was defrayed by the National Health and Medical Research Council, Canberra. A.C.T.

PHOTO-POLAROGRAPHY WITH A FLASH-LAMP

By DR. H. BERG and H. SCHWEISS

German Academy of Sciences, Institute of Microbiology and Experimental Therapy, Jena

PHOTO-POLAROGRAPHY, originating from the synthesis of photo-chemistry and polarography, records photokinetic-currents caused by photo-depolarizers, as well as their dark reactions. Photo-depolarizers in a restricted sense can be defined as follows. They originate from a photo-reaction, for example:

$$A \xrightarrow[h_\nu]{k_\nu} B \qquad (1)$$

(with visible or ultra-violet light), reach a steady-state, and disappear in a following dark reaction ('Durchtritts'-reaction, combination, disproportion, etc.):

$$B \xrightarrow{k} C \qquad (2)$$

Hitherto, the photo-depolarizers (B), ketyl radicals[1] as well as hydroquinones[2] caused by photokinetic-currents have been demonstrated by means of continuous irradiation.

Photokinetic-currents are caused by intense irradiation of mercury electrodes during electron exchange. In analogy to classical polarography there are three principal groups:

(*a*) Photokinetic-currents preceding the 'Durchtritts'-reaction may occur because of a modification of the 'Nachlieferungs'-velocity in the dark (from k' to k_ν) of phototropic equilibria produced by irradiation.

$$A + B \underset{k}{\overset{k',k_\nu}{\rightleftarrows}} C + D \qquad (3)$$

(Examples for equation (3): A = leucomethylene blue; B = benzenediazo-sulphonate; C = methylene blue; D = phenylhydrazine sulphonate).

(*b*) Photokinetic currents in opposite direction to the 'Durchtritts'-reaction (4*a*) are brought about by the regeneration (4*b*) of the photo-depolarizer according to the following scheme:

(4*a*)

(4*b*)

(Examples for equation (4) are found in ref. 2: B = anthrahydroquinone-2-sulphonic acid or other stable hydroquinones; C = anthraquinone-2-sulphonic acid or other quinones easily photo-reducible in alcoholic solution).

(*c*) Photo-reaction, following the 'Durchtritts'-reaction, frequently occurs in connexion with (*a*) and (*b*):

$$B \xrightarrow{e^-} C \xrightarrow{h_\nu} D \qquad (5)$$

(Examples for equation (5): B = anthraquinone; C = anthrahydroquinone; D = anthrone → 9,10-dihydroanthranol). For purposes of calculation, we have inserted the equations for the photo-reaction v_v, adapted to the reaction-layer into the differential equations of Koutecky:

$$\frac{dB}{dt} = v_D + v_v \qquad (6)$$

and have obtained in case (*b*), for example, good conformity between the velocity constant for (4*b*) calculated with equation (6) and the direct photo-reduction (k_v = 0·63–1·4 sec.$^{-1}$) of 4 × 10^{-4} M.C. in the solution (40 per cent *iso*propanol, phosphate buffer, *p*H 7), observed by means of current-time curves[3].

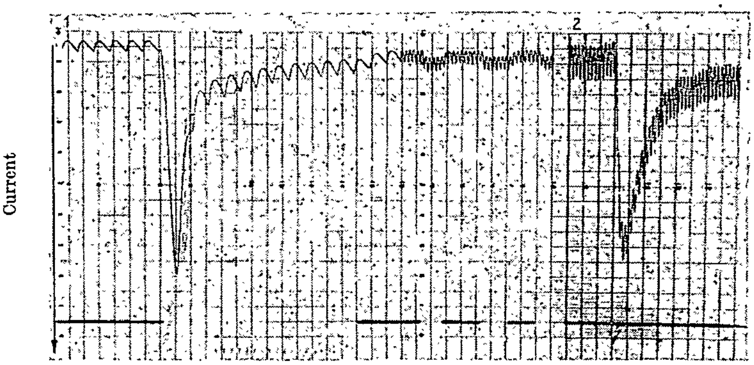

Fig. 1. Continuous irradiation (curve 1) and flash irradiation (curve 2) of 4 × 10^{-4} *M* benzophenone in 40 per cent *iso*propanol with 0·1 *N* sodium hydroxide, recorded with the selector polarograph (Atlas-Werke, Bremen); recording width, 20 cm. Curve 1: formation and decrease of II^- according to equations (7), (8) and (9). Towards the end of the reactions intermittent irradiation was used (dark period ——); sensitivity, $S = 2·5 \times 10^{-8}$ amp. cm.$^{-1}$; dropping time, τ = 2·2 sec.; time-scale, 1 cm. represents 1·95 sec., and in the last part, 1 cm. represents 7·5 sec. Curve 2: flash exposure ↙ and course of the dark reaction of the radical according to equation (8); sensitivity, $S = 3·75 \times 10^{-9}$ amp. cm.$^{-1}$; dropping-time, τ = 0·47 sec.; time-scale, 1 cm. represents 1·95 sec.

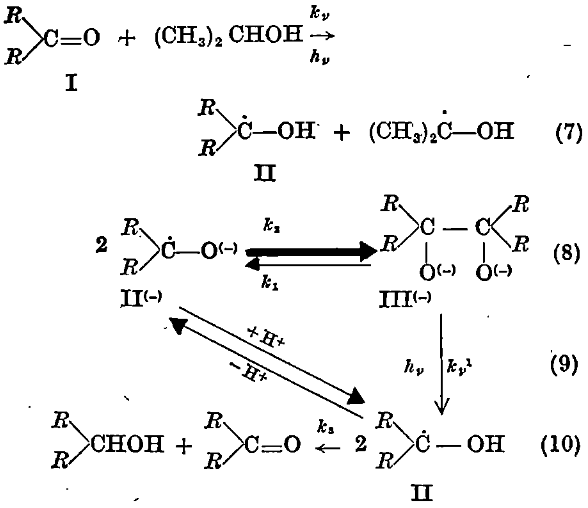
In our endeavour to clarify the photo-reduction mechanisms (equations 1 and 2) particularly of ketones, by means of continuous intense irradiation with a high-pressure mercury arc *U*-500 (this process requires a great deal of sensitivity and a high recording velocity), we noticed other consecutive reactions in addition to the reactions as in (*b*) and (*c*); this is demonstrated in the case of benzophenone. On irradiation of 4 × 10^{-4} *M* benzophenone in a solution of 0·1 *N* sodium hydroxide in 40 per cent *iso*propanol, the following gross reactions are recorded by means of the dropping electrode:



I causes a reduction wave ($\pi_{1/2}$ = − 1·52 V.), II or anion II(−) causes a reversible reduction-oxidation wave, and III(−) an irreversible oxidation wave ($\pi_{1/2}$ = − 0·65 V.). Apart from III(−) being photolysed in accordance with equation (9), the recording of II or II(−) respectively (Fig. 1, curve 1) must be superimposed by a photokinetic current in the opposite direction (as indicated by scheme *b*):

$$II^{(-)} \rightharpoonup I + 1e^- \qquad (11)$$
$$\underset{h_v}{\uparrow\; k_v \;|} \qquad (7).$$

the half-life period of the pseudo-monomolecular reaction (7) being only 0·6 sec. (Fig. 1 in ref 3).

Another photokinetic-current of opposite direction is indicated by the current-time curves ($\bar{\alpha}$ = 0·64) of the oxidation wave of III(−) according to scheme (4):

$$III^{(-)} \rightharpoonup 2I + 2e^- \qquad (12)$$
$$\underset{h_v}{\uparrow\; k_v' \;|} \qquad (7)+(8)$$

Considering an equilibrium (8) the sequence of reactions:

$$2I \xrightarrow{k_v} 2II^{(-)} \underset{k_1}{\overset{k_2}{\rightleftarrows}} III^{(-)} \qquad (13$$

is of special interest. (Protonization equilibria have been omitted in equations (11), (12) and (13).)

Although in equations (7) to (10) the detailed reaction scheme of Schenck[4] has not yet been taken into consideration, an exact calculation of equation (13) meets with greater difficulties because of the photokinetic currents (11) and (12) in the opposite direction.

For these reasons we have passed from continuous irradiation to the flash-light technique. As the excitation time of a flash is only about 10^{-4} sec., it becomes possible to record the combination of the radical photo-depolarizer $II^{(-)}$ separately as a dark reaction, and, moreover, to avoid the photokinetic current (11).

A flash from our unit (argon lamp, capacitor 64 μF., 4 kV.) produces the radical ($[II^{(-)}]_0 \approx 1·6 \times 10^{-5}$ *M*), which, according to curve 2, combines in a reaction of second order. Principally, the calculation of k_2 would be possible from the following equation:

$$k_2 = 2·303 \quad \log \frac{[\overline{II^{(-)}}]([II^{(-)}]_0 - [II^{(-)}][\overline{II^{(-)}}])}{([\overline{II^{(-)}}] - [II^{(-)}])[II^{(-)}]_0^2} \cdot \frac{[\overline{II^{(-)}}]}{t([II^{(-)}]_0^2 - [II^{(-)}]^2)} \qquad (14)$$

wherein $[II(-)]_0$ is the initial concentration of the radical, $[II(-)]$ the actual concentration of the radical and $[\overline{II^{(-)}}]$ the concentration of the radical at equilibrium. There are, however, two reasons causing the determination of the concentration at equilibrium to become faulty: (1) The concentration of $[\overline{II^{(-)}}]$ is at the limit of sensitivity of average polarographs, and will be obscured by oscillations of the photo-residual-current during irradiation. (2) From equation

(8) one might expect the limiting current of $[\mathrm{II}^{(-)}]$ already to be superimposed by a preceding kinetic dark current (k_1) and possibly by the oxidation current of a stabilized radical adduct[4].

For these reasons we have only evaluated the beginning of the reaction (8) with the simple equation of second order, as Porter *et al.*[5] did in the case of semiquinones, and the result is $k_2 = 13 \times 10^4$ l.mole^{-1} sec.$^{-1}$ (curve 2).

Further recording trials with benzophenone and other ketones[6], using the cathode-ray oscillograph, indicate clearly that after introduction of the flash-light technique into photo-polarography it will be necessary to increase further the measuring sensitivity of the polarographic method; only thus will it become possible to demonstrate photo-depolarizers in the triplet state with similar success as Porter was able to do by spectrographic analysis. On the other hand, the flash-method represents a new possibility for clarifying electrode processes.

INDUCED ENZYME SYNTHESIS IN AQUEOUS SUSPENSIONS OF STARVED STATIONARY PHASE *AEROBACTER AEROGENES*

By R. E. STRANGE

Microbiological Research Establishment, Porton, Near Salisbury, Wiltshire

THERE is evidence that the survival of *Aerobacter aerogenes* held in aqueous suspension without added nutriment involves the utilization of cell polymers such as protein, ribonucleic acid (RNA) and glycogen, fragments of which are excreted[1]. Several workers have reported losses of substantial amounts of RNA from suspensions of starved bacteria and yeasts which remained viable[2,3]. There is also evidence that in the absence of an exogenous nitrogen source yeasts and bacteria make adaptive enzymes, for example, maltozymase by yeast in response to α-methyl-glucoside[4] and β-galactosidase by *Escherichia coli* in response to lactose[5] or methyl-β-D-thiogalactopyranoside (TMG)[6]. Apparently, such enzyme synthesis occurs at the expense of the endogenous amino-acid pool[4–6] and depends on protein turnover[6,7]. Ability to make adaptive enzymes in the absence of an exogenous nitrogen source is probably important for bacterial survival, but such ability might be expected to decrease if cell polymers were utilized when starvation is prolonged. Investigation of β-galactosidase synthesis by starved *A. aerogenes* in nitrogen-free medium indicates that this is so.

A. aerogenes, grown in various media as described in ref. 1, was collected after being in the stationary phase for 0·5 hr. and washed twice with buffered saline by centrifugation. Suspensions of washed bacteria (4–4·5 mgm. dry weight/ml.) in buffered saline, *p*H 6·5, were incubated in gas wash-bottles at 37° with aeration and samples were removed at intervals for viable bacterial counts, determination of per cent viability by the microscopic plate method of Postgate *et al.*[8], estimation of protein[9] and RNA[1], and for induction experiments. The latter samples (20 ml.) were centrifuged and the bacteria re-suspended in a sterile solution (50 ml.) containing TMG (synthesized according to the method of Helferich *et al.*[10]) or lactose. Bacterial suspensions (1·5–2·0 mgm. dry weight/ml.) containing inducer were incubated in small gas wash-bottles at 37° with aeration and samples were taken at intervals for measurements of viability and β-galactosidase activity. Before enzyme assay, bacteria were washed, re-suspended in water and shaken with benzene[3]. Measured volumes of benzene-treated samples were incubated with *O*-nitrophenyl-galactoside (ONPG)[11], and activity is expressed as µmoles ONPG hydrolysed/hr./mgm. dry weight bacteria at 37° in sodium phosphate buffer (0·14 *N*–Na$^+$, *p*H 7·2). *A. aerogenes* β-galactoside appeared to be less stable than the enzyme from *E. coli*[3] since activity was lost rapidly when dilute suspensions of benzene-treated bacteria were held at 20–37°. Benzene-treated suspensions containing 1–2 mgm. dry weight/ml. retained activity for at least 24 hr. at 2°.

The changes which occurred during storage of stationary phase *A. aerogenes* gathered from three different growth media are shown in Table 1. Losses of protein and RNA from viable bacteria were paralleled by a reduction in the ability of the organisms to synthesize β-galactosidase in nitrogen-free medium containing lactose. Results for β-galactosidase synthesis using TMG, which is an inducer but not a substrate[12], again showed that stored bacteria formed less enzyme than freshly gathered organisms (Fig. 1).

Harrison[14] has directed attention to the fact that in buffered suspensions of *A. aerogenes* held at 37° with

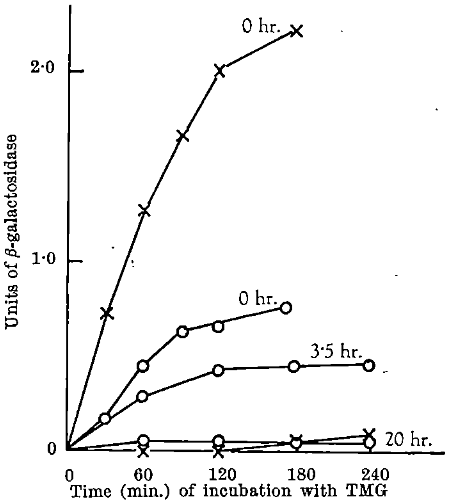

Fig. 1. Synthesis of β-galactosidase by washed stationary phase *A. aerogenes* gathered from a carbon-limiting, defined medium[1] (○) and tryptic meat broth (×), before and during storage in buffered saline, *p*H 6·5, at 37° with aeration. Bacteria were induced in buffered saline, *p*H 7·0, containing TMG (10^{-3} *M*) and metal ions. Figures on the curves refer to storage period before induction

Table 1. CHANGES IN VIABILITY, PROTEIN, RNA AND INDUCED β-GALACTOSIDASE SYNTHESIS IN STATIONARY PHASE *Aerobacter aerogenes* HELD IN BUFFERED SUSPENSION AT 37° WITH AERATION

Bacteria were stored in buffered saline at *p*H 6·5 and induced at *p*H 7·2 in a solution containing lactose (1 per cent, w/v), metal ions, citric acid (10^{-3} *M*) and phosphate buffer (0·2 *N* sodium). Enzyme synthesis was measured after induction for 3 hr.

	67	91·0	25·5	33·4	—

* Bacteria freshly collected from tryptone-glucose medium contained about 15 per cent dry weight of glycogen (ref. 1).

aeration, surviving organisms may maintain viability at the expense of material derived from dead bacteria. Therefore, in investigations of induced enzyme synthesis in nitrogen-free medium, it is important that the percentage of dead bacteria present in suspensions should be low. In the present experiments, the initial viability of freshly collected bacterial suspensions was usually 98 per cent or more, and, immediately before induction, the bacteria were separated from the suspending medium. It appears unlikely that the small number of non-viable organisms present supplied sufficient nitrogen-containing material to account for the enzyme synthesis observed. Neither the percentage viability of suspensions nor the total number of viable bacteria present, altered significantly during the induction period in the experiments described here.

In starved bacteria, depletion of cell components and/or available energy may account for a fall-off in adaptive enzyme synthesis (ref. 5). Since adenosine triphosphate (ATP) is concerned in energy supply and transfer reactions, the concentration of this substance in *A. aerogenes* was measured during storage and induction. Cold perchloric acid extracts of washed bacteria were neutralized with potassium hydroxide, freed from precipitated salt and assayed for ATP with the fire-fly luminescence technique[15] and a scintillation counter. The results (Table 2) showed that bacteria held for 19 hr. at 37° contained rather more ATP than freshly collected organisms and that the level fell only slightly during the induction period. Thus, reduced enzyme synthesis in these starved bacteria was apparently not due to a deficiency of ATP.

Storage of buffered stationary phase *A. aerogenes* suspensions at 37° with aeration for up to 68 hr. did not reduce the ability of the bacteria to form β-galactosidase in the presence of inducer and a suitable nitrogen source such as peptone (Fig. 2). In fact, under these conditions, the initial rate of enzyme formation was often more rapid with stored than with freshly collected organisms. Evidently, starvation did not affect the mechanism for enzyme formation, but depleted potential substrates.

Table 2. CHANGES IN ENDOGENOUS ATP AND INDUCED β-GALACTOSIDASE SYNTHESIS IN STATIONARY PHASE *Aerobacter aerogenes* COLLECTED FROM CARBON-LIMITING DEFINED MEDIUM AND HELD IN BUFFERED SUSPENSION AT 37° WITH AERATION

Bacteria were stored at *p*H 6·5 and induced at *p*H 7·0 in buffered saline containing TMG (2 × 10^{-3} *M*) and metal ions

	Storage period (hr.), 0		Storage period (hr.), 19	
Induction period (min.)	ATP (μgm./ml. suspension)	Galactosidase (units)	ATP (μgm./ml. suspension)	Galactosidase (units)
0	0·67	0	0·86	0
60	0·65	0·26	—	0·07
90	—	0·41	0·85	0·09
120	0·84	0·47	—	0·08
150	1·04	0·60	—	—
180	—	—	0·80	0·08
240	—	—	0·79	0·10

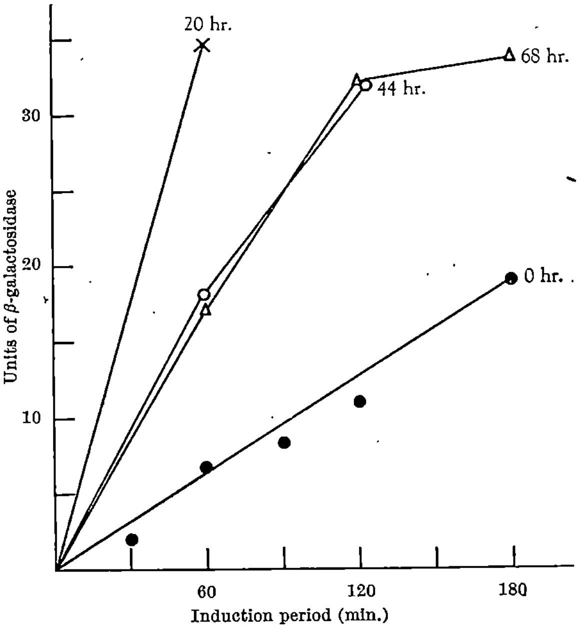

Fig. 2. Synthesis of β-galactosidase by washed stationary phase *A. aerogenes* gathered from tryptic meat broth, before and during storage in buffered saline, *p*H 6·5, at 37° with aeration. Bacteria were induced in peptone water containing TMG (10^{-3} *M*). Figures on the curves refer to storage period before induction

It is concluded from these results that utilization of cell polymers (protein, RNA and, if present, glycogen) by starving stationary phase *A. aerogenes* held at 37° in buffered suspension with aeration so depletes the reserves of these materials that, while viability may not be affected, the ability of the bacteria to make adaptive enzymes in nitrogen-free medium is reduced markedly.

I am grateful to Dr. J. R. Postgate for suggestions, Mr. J. H. R. Slade for synthesizing thiomethylgalactoside and Mr. S. Lovett for the use of a scintillation counter.

COMPARISON OF REDUCED ALKYLATED DERIVATIVES OF SOME MYELOMA GLOBULINS AND BENCE-JONES PROTEINS

By Dr. M. D. POULIK
American National Red Cross, Washington, 6, D.C.
AND
Dr. G. M. EDELMAN
The Rockefeller Institute, New York, 21

MYELOMA globulins are abnormal serum proteins distinguished from normal γ-globulin by their relative homogeneity and their chemical individuality. A number of comparative chemical and immunological studies[1-3] have been aimed at elucidating further their relations to normal γ-globulins. The demonstration[4] that normal and abnormal proteins of the γ-globulin family dissociate into separable sub-units after cleavage of disulphide bonds has made it possible to compare myeloma proteins with each other and with normal γ-globulins at the level of their sub-units[5,6]. This article presents additional data on 10 human myeloma globulins and some correlative experiments on myeloma proteins and Bence-Jones proteins derived from the same patient.

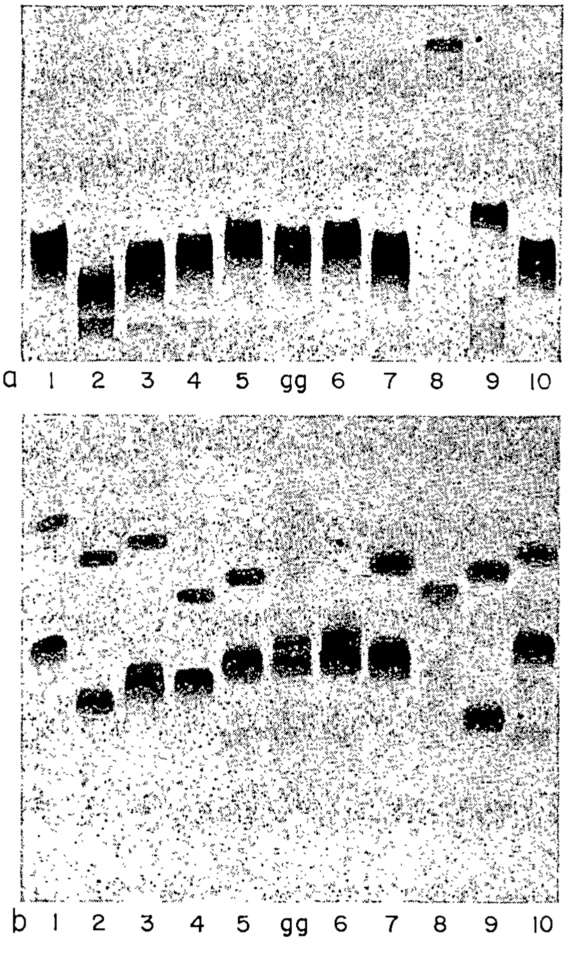

Fig. 1. Comparison of myeloma globulins and normal human γ-globulin. *a*, Before reduction and alkylation; *b*, after reduction and alkylation. 1-10 Different myeloma globulins; *gg*, normal human γ-globulin

Ten myeloma proteins of γ-mobility were isolated from individual sera of patients with multiple myeloma by means of starch-zone electrophoresis[7] and stored in lyophilized form. Bence-Jones proteins were isolated from the urine of two of the patients by precipitation at *p*H 5·0 after addition of an equal volume of saturated ammonium sulphate solution at 4° C., and one sample was further purified by starch-zone electrophoresis. Pooled normal human fraction II γ-globulin was obtained from Lederle Laboratories. Reduction and alkylation were carried out using procedures previously described[6]. In certain experiments, samples were reduced with 0·1 *M* β-mercaptoethanol in 8 *M* urea under pre-purified nitrogen for 16 hr. at room temperature. Starch-gel electrophoresis in 8 *M* urea was done following the procedure of Smithies[8,9] with modifications previously described[6,10,11]. Chromatography on carboxymethyl cellulose in acetate buffer made with 6 *M* urea was also performed as described[6] except that the apparent *p*H was 5·6 at 25° C.

In Fig. 1*a* are shown the electrophoretic patterns in the urea–starch gel of the ten myeloma globulins and of human fraction II γ-globulin. Sample No. 8 showed, in addition to the slowly migrating myeloma protein, a sharp band of higher mobility which possibly represents Bence-Jones protein in the serum[12]. Faint bands of similar type could be seen in some of the other patterns, although in reproduction they do not appear. After simultaneous reduction with mercaptoethanol and alkylation with iodoacetamide, the samples were again compared (Fig. 1*b*). The pattern of reduced alkylated γ-globulin showed a diffuse band moving ahead of two narrower bands. Each of the treated myeloma proteins differed in number and position of the bands. A striking feature was the sharpness of the fast-moving bands obtained after reduction and alkylation. The mobilities of these bands were distributed within the range of mobility defined by the diffuse fast-moving band of normal γ-globulin. Moreover, when nineteen isolated myeloma globulins were mixed in varying proportions and then reduced and alkylated, starch-gel patterns were obtained which were similar to that of reduced alkylated normal γ-globulin. In some cases, the slower-moving bands of reduced alkylated myeloma proteins had mobilities similar to those of the slower bands of normal γ-globulin.

By chromatography on carboxymethyl cellulose in 6 *M* urea the reduction products of one myeloma protein (No. 5) could be partially separated. This is shown in Fig. 2 in which the patterns of the reduced alkylated protein and the material from the first and second peak of the chromatogram are compared. Separation was effected although it should be noted that the overall yield from the chromatogram was only 32 per cent.

Previous experiments[6] indicated that, in most cases, complete reduction of all the disulphide bonds of

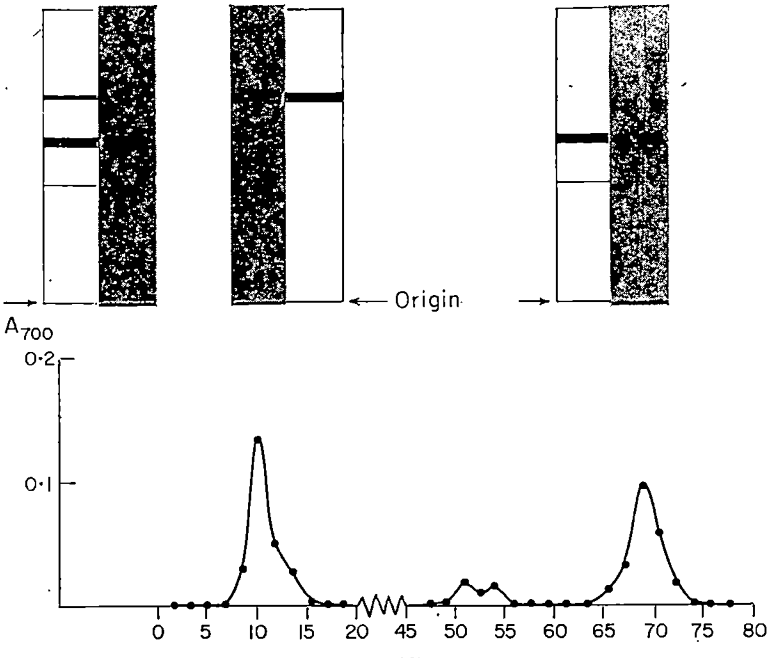

Fig. 2. Chromatographic and electrophoretic separation of myeloma globulins. Above each peak of the chromatogram is placed the pattern obtained by starch-gel electrophoresis of material from that peak. At the left is the starch-gel pattern of reduced alkylated myeloma protein (No. 5, see Fig. 1*b*) before chromatography. Total column load, 20 mgm.; A_{700} = optical density of Folin reaction at 700 mμ

γ-globulin and myeloma proteins was not achieved. The question therefore arose as to whether new bands would appear on the starch-gel as reduction proceeded to a greater extent. Three myeloma proteins were reduced with 0·01 *M* mercaptoethanol in 8 *M* urea under pre-purified nitrogen for 16 hr., before alkylation. The products were then compared on the same starch-gel. In addition to the characteristic patterns resulting from reduction, the less-completely reduced samples showed the presence of a band corresponding to untreated myeloma protein. The more extensively reduced samples showed much less of this material. Regardless of the extent of reduction, the faster-moving sharp bands for each sample were unchanged in mobility and width, and no evidence of additional bands appeared after long times of reduction. Thus, although extensive reduction led to dissociation of more of the starting material, no new sub-units were revealed by this procedure.

A large proportion of patients with multiple myeloma excrete Bence-Jones proteins in the urine. These proteins appear to be precursors of myeloma globulins or abortive by-products of their synthesis[1], although no uniform structural relation between these proteins and myeloma proteins has been established[13,14]. Antigenic similarities between Bence-Jones and myeloma proteins prompted a search for structural similarities using the methods described above. In Figs. 3*a* and 3*b* is shown the comparison, in two different instances, of a myeloma protein and a Bence-Jones protein from the same patient both before and after reduction and alkylation. Although the mobility of the Bence-Jones protein (Mul) before treatment was not greatly different from that of the myeloma protein, the band of the Bence-Jones protein was sharper and narrower. After simultaneous reduction and alkylation of the two proteins, similar patterns were obtained, each composed of two sharp bands of different mobility. The pattern of the reduced myeloma protein had, in addition, two faint bands of lower mobility (Fig. 3*a*). Bence-Jones protein (Bar) showed multiple bands in the urea–formate gel, and no similarity could be seen between this pattern and that of the myeloma protein from the same patient. After reduction and alkylation, however, two bands of the Bence-Jones protein derivative corresponded in mobility with two of the fast-moving bands of the myeloma protein derivative (Fig. 3*b*).

The findings discussed here suggest that dissociation of myeloma globulins into their constituent polypeptide chains occurs in a fashion similar to that of normal γ-globulin. Starch-gel electrophoresis of the derivatives following reduction of myeloma proteins yielded distinctive and sharp band patterns. Up to the present, nineteen myeloma proteins have been compared; the pattern obtained in each case was reproducible and unique. In several instances, bands of common mobility were found among the myeloma globulins.

Recently, it has been shown that the myeloma proteins of the mouse, although much less heterogeneous than normal γ-globulin, may nevertheless consist of several molecular species[15]. Such hetero-

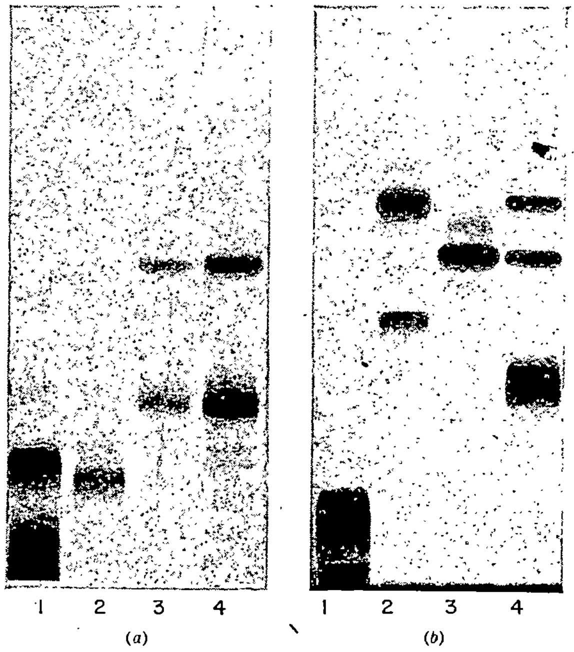

Fig. 3. Comparison of myeloma globulins and Bence-Jones proteins before and after reduction and alkylation. *a*, Patient Mul. 1, Myeloma protein (No. 9 of Fig. 1); 2, Bence-Jones protein; 3, reduced alkylated Bence-Jones protein; 4, reduced alkylated myeloma protein. *b*, Patient Bar. 1, Myeloma protein (No. 3 of Fig. 1); 2, Bence-Jones protein; 3, reduced alkylated Bence-Jones protein; 4, reduced alkylated myeloma protein

geneity may be reflected in the band patterns of certain reduced human myeloma globulins. The presence of multiple bands after reduction is not merely the result of heterogeneity, however, since γ-myeloma proteins appear to be dissociated by reduction in 8 *M* urea[6].

In both instances examined here, reduced alkylated Bence-Jones proteins and myeloma globulins from the same patient possessed certain bands of common mobility in the starch gel. Unreduced Bence-Jones protein (Bar) showed multiple bands in the urea–formate gel. This finding is in line with an earlier report of dissociation of Bence-Jones proteins at acid *p*H (ref. 16), and raises the possibility that urea may help to dissociate these proteins. The results obtained with reduced alkylated Bence-Jones proteins are consistent with the previously suggested hypothesis[6] that Bence-Jones proteins may be composed at least in part of chains of the same type as those present in the myeloma protein from the same patient.

We wish to thank Dr. R. E. Engle, jun., Dr. C. Zarofonetis and Dr. M. Bryant for the generous provision of serum and urine samples.

MULTIPLE INHIBITIONS OF CELL METABOLISM BY A SINGLE SUBSTANCE

By M. HARRIS and Dr. G. A. MORRISON

Department of Chemistry, University College of Wales, Aberystwyth

ANTIBIOTICS frequently inhibit more than one part of metabolism, and the mode of action may be different for different organisms and/or different environments[1]. Thus any method which indicates the nature of a number of underlying causes of bacteriostatic action in one set of connected experiments should be valuable, and particularly so if it selects those which operate at clinically possible concentrations of the antibiotic.

Consideration of the functioning of enzymes in a multi-enzyme system indicates that measurements of the rates of growth of bacterial cultures in the presence of a series of concentrations of any substance which combines with and inactivates enzymes could be used to demonstrate the existence of a number of such modes of action of the substance.

In a bacterial cell, series of enzymically controlled reactions are closely co-ordinated to form a chemical mechanism which converts foodstuffs into new cells and waste materials, and in a pure culture of a single strain the mechanisms of the individual cells are connected by their sharing of those intermediates which diffuse into the medium. In the phase of logarithmic growth the whole culture must operate as a single system in a steady state, and the rate of its expansion is controlled by the particular reaction which is the slowest.

The equation[2] for the rate of an individual effectively irreversible reaction in such a mechanism is a complex function C (less than unity), of the concentration(s) of the substrate(s) of the reaction multiplied by the concentration, e, of the enzyme, En; that is, $dp/dt = Ce$ where p is the concentration of a product, P. In the logarithmic phase, a steady state, C becomes constant and the rate of utilization of P must equal the rate of its production. If P is required for the production of new cells then $dp/dt = \alpha\, dn/dt$ where α is a constant and n is the concentration of cells. Hence $dn/dt = Ce/\alpha$. But $dn/dt = kn$ and $km = \ln 2$, where k is a reaction velocity constant and m is the mean generation time of the culture, and thus:

$$m = \alpha n(\ln 2)/Ce = (\alpha'/C).(n/e) \qquad \text{(i)}$$

and will be constant so long as the enzymic composition of the cells does not alter, that is, n/e remains constant.

In the presence of a substance D', concentration D, which combines with the enzyme non-competitively and renders it inactive (that is, $D' + En \rightleftharpoons D'En$, dissociation constant $= K_D$), the concentration of uncombined enzyme is $K_D e/(K_D + D)$ and this concentration must replace e in the above equation. There are, however, two possibilities for the effect of D' on C. If the materials, the concentrations of which are involved in the function C, are being produced and/or utilized by other parts of the metabolism which are not affected directly, their concentrations may be stabilized and C may not change significantly. In the absence of such stabilization these concentrations must increase and C must increase until it becomes equal to the reaction velocity constant C' for the reaction. Thus in this case a smaller concentration of active enzyme is compensated-for by a greater efficiency in its use until this is maximal.

In the first case, after a small or negligible threshold concentration of the inhibitor, and in the second case after a considerable threshold concentration, the mean generation time should give a linear plot against concentration of inhibitor.

If the substance is a competitive inhibitor, similar equations can be derived to relate m and D: for example, for a single substrate reaction $m = \beta(K_S + S + K_S D/K_D)/S$ where β is a proportionality constant, S the concentration of the substrate and K_S the dissociation constant for the enzyme-substrate complex. With these equations increases in S in response to increases in D theoretically can compensate infinitely, but when other parts of the metabolism stabilize S the equations assume the form:

$$m = \beta(A + BD) \qquad \text{(ii)}$$

and the linear plot should hold after a threshold concentration of inhibitor.

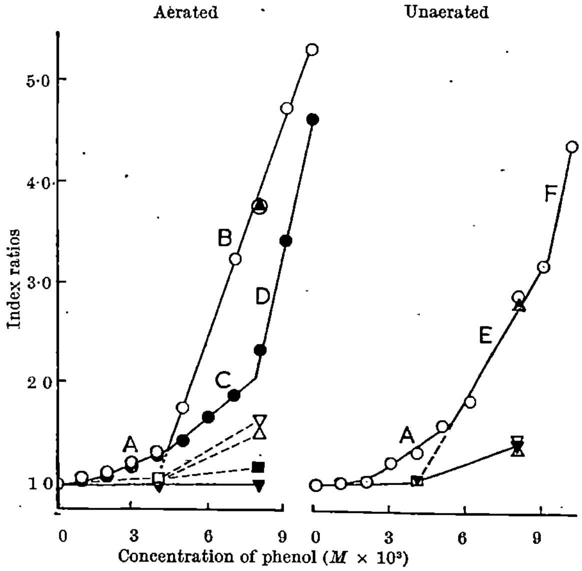

Fig. 1. ○, Control: ●, plus brilliant cresyl blue; ▽, plus phenylalanine; ▲, plus glutamate or tryptophan; △, plus casein hydrolysate; ▼, plus bacteriological peptone; □, plus glutamate, tryptophan, phenylalanine or casein hydrolysate; ■, plus brilliant cresyl blue and phenylalanine

If D_0 is the threshold concentration of inhibitor then $m = m_0$, the mean generation time of the uninhibited culture, and $m_0 = \alpha''(K_D + D_0)/C_0K_D$ from (i), or $= \beta(A_0 + B_0D_0)$ from (ii). Hence the ratio of the mean generation times of the inhibited and uninhibited cultures, which we term the index ratio, I, is given by:

$$I = m/m_0 = C_0(K_D + D)/C(K_D + D_0) = \gamma + \delta D$$

$$\text{or} = (A + BD)/(A_0 + B_0D_0) = \gamma' + \delta' D$$

If the inhibitor affects more than one enzyme then, in different ranges of concentration of the inhibitor, the rate of growth may be controlled by different enzymes and each range will have its appropriate equation with different values of γ and δ. In the figure a number of such modes due to phenol (which as an inhibitor follows $D' + En \rightleftharpoons D'En$ since dilution decreases inhibition) have been shown up.

Adding to the medium the product of such a reaction, provided it can penetrate the cells readily, must eliminate control by that reaction; similarly adding some substance from which the cells can derive the product in an alternative way must also eliminate its control, unless the alternative is not adequate to replace the lost production, then the degree of inhibition is decreased, that is, δ is made smaller. Thus trial-and-error additions to the medium may indicate the part of the metabolism affected by each mode, and as modes are eliminated, uncover others which in their turn become the rate controlling reactions.

These phenomena for phenol inhibiting *Klebsiella cloaca* in glucose-mineral salt media are shown in Fig. 1. For the purposes of demonstration phenol was chosen since the literature suggests that it affects more than one part of the metabolism. The bacterial strain must be acclimatized thoroughly to the conditions and the parent culture grown in glucose-deficient medium so that the cells do not encounter harmful conditions nor the inocula contain inhibition-removing materials. Mean generation times can be determined to within 3 per cent and multiple determinations increase the accuracy. The concentrations used for the results shown are the minimum ones to give the maximum effects.

Aerated cultures show two modes, *A* and *B*, and unaerated three modes *A*, *E* and *F*. Adding an unnatural hydrogen-carrier causes *B* to be replaced by *C* and *D*. *A* is eliminated by the addition of glutamate, tryptophan, phenylalanine, casein hydrolysate or peptone. *C* and *E* are diminished or replaced when casein hydrolysate, phenylalanine or peptone is added and may be the same. Additions of leucine had similar but less-effective actions as additions of phenylalanine, whereas no other single amino- or carboxylic-acid had any effect.

The method has been used also with tetracyclines to direct subsequent work into profitable channels. It shows up inhibitions caused by bacteriostatic concentrations, and determinations of γ and δ under defined conditions may be useful for comparison of the various members of this group of antibiotics.

DIMER FORMATION AND GLUCOSE TRANSFER ACROSS THE MEMBRANE OF THE RED BLOOD CELL

By Dr. W. D. STEIN*

Department of Colloid Science, University of Cambridge

GLUCOSE and other sugars appear to cross the human red blood cell membrane by making use of a specific facilitated diffusion system present in the membrane[1-3]. The molecular mechanism of this and other membrane transport systems is obscure, but a number of models has been suggested consistent with the available experimental data. These models[4] involve the presence of 'carriers', 'pores' or enzymes in the membrane, to speed up the transfer of the permeant. No unambiguous criteria exist for distinguishing between these mechanisms, and there is no firm knowledge as to how these postulated mechanisms indeed act. The present article presents a new mechanism for glucose transfer and new experimental results in support of it.

I have recently shown that in the case of glycerol transfer, also across the human red blood cell membrane, there is evidence that the carrier for glycerol is a second glycerol molecule[5]. It appears that the observed facilitation of glycerol transfer occurs as a result of dimer formation between pairs of glycerol molecules, bound at the active centre of a specific catalytic component of the membrane, possibly enzymic in nature. As a result of such dimer forma-

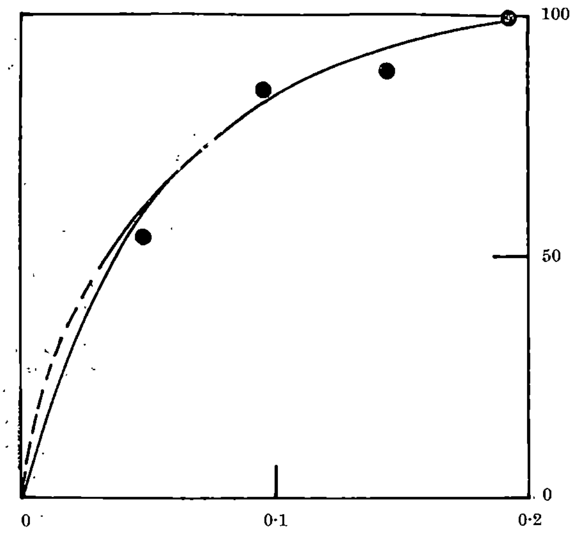

Fig. 1. Glucose penetration into the human red blood cell. Ordinate, initial velocity of glucose penetration relative to velocity at 0·19 *M*; abscissa, glucose concentration in moles per litre. Solid circles, experimental points; dashed line, prediction on monomer theory; solid line, prediction on dimer theory K = 0·05 *M*; β = 0·02 *M*

tion there is a reduction in the total number of the free hydrophilic groups of the pair of glycerol molecules, resulting in a more rapid rate of transfer across the cell membrane. I should now like to present evidence which suggests that glucose transfer, too, must occur by a similar mechanism.

It will be convenient, first, to describe more fully the model I propose for facilitated diffusion. We shall postulate the existence as part of the cell membrane, but exterior to the lipid component of the membrane, of a novel type of enzyme—a 'dimerase'. Such an enzyme has, in common with other enzymes, the property of binding its substrate by non-covalent bonds to form the classical Michaelis–Menten complex. But a dimerase differs from most other enzymes in two ways. First, rather than binding single substrate molecules, it binds pairs of these, that is, it is divalent towards its substrate. Second, the enzyme does not bring about any covalent modification in the substrate; instead, it enables the pair of bound substrate molecules to interact with one another by hydrogen bonds to form dimers. Such dimers will have a reduced number of hydrophilic groups available to form bonds with the water of the aqueous phase and can thus readily enter and cross the lipid regions of the membrane. The dimer is spontaneously dissociated again into monomers when it re-enters the aqueous phase. The 'membrane carrier' is thus the second substrate molecule and the function of the dimerase is simply to concentrate the substrate molecules and to orient these in such a way as to induce dimer formation.

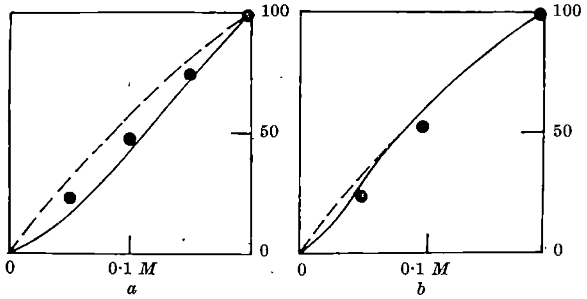

Fig. 2. (*a*) Sorbose penetration into the human red blood cell; (*b*) fructose penetration into the human red blood cell. Units and symbols as in Fig. 1, but with:

K_{sorbose} = 0·5 *M* K_{fructose} = 0·5 *M*

β_{sorbose} = 0·2 *M* β_{fructose} = 0·08 *M*

The evidence that glycerol transfer occurs by such a system has been presented in a previous paper[5]. The method most convincingly demonstrating dimer formation in the case of glycerol transfer fails to distinguish between the dimer and monomer models in the case of glucose, as we shall first discuss. But it will be seen that such a distinction can be made by a new method. (Full details of these experimental methods and the theoretical treatment will be presented elsewhere.)

Fig. 1 presents results for the initial velocity of glucose penetration into the red cell (measured by the photometric method[6]), as a function of glucose concentration (at 24° C. and *p*H 7·4). As a number of authors have demonstrated[4], such results are adequately accounted for on the basis of the classical Michaelis–Menten kinetics, so successfully applied in enzymology. The dashed curve in Fig. 1 (which merges with the solid line above 0·05 *M*) is drawn with these kinetics and a Michaelis constant K = 0·05 *M*. The solid line is computed from the 'dimerase' model, which requires that two substrate molecules be bound at the active centre and that these interact with one another to form the penetrating complex. The relevant constant analogous to the Michaelis constant and referring to the affinity of each of the pair of binding sites with single substrate molecules is β = 0·02 *M*. Clearly no distinction between these two models is possible on the data here. Similarly in Figs. 2*a* and *b* the results for the penetration of sorbose and fructose (which also use the glucose system[1]), at 24° C. and *p*H 7·4 are presented. Again the dashed line is drawn on monovalent theory with, in both cases, a Michaelis constant of 0·5 *M* (chosen arbitrarily to be ten times greater than the constant for glucose). The solid lines are drawn on divalent theory with the constants β = 0·2 *M* for sorbose and

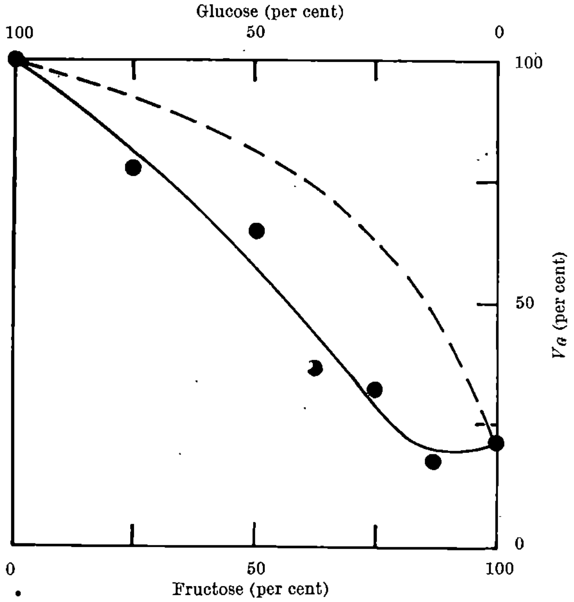

Fig. 3. Entrance of sugar into the human red blood cell from a mixture of glucose and fructose. Total sugar concentration, 0·19 *M*. Ordinate, initial velocity relative to that in 0·19 *M* glucose alone; abscissa, percentage fructose concentration increasing from left to right. Symbols as in Fig. 1. K and β as in Figs. 1 and 2

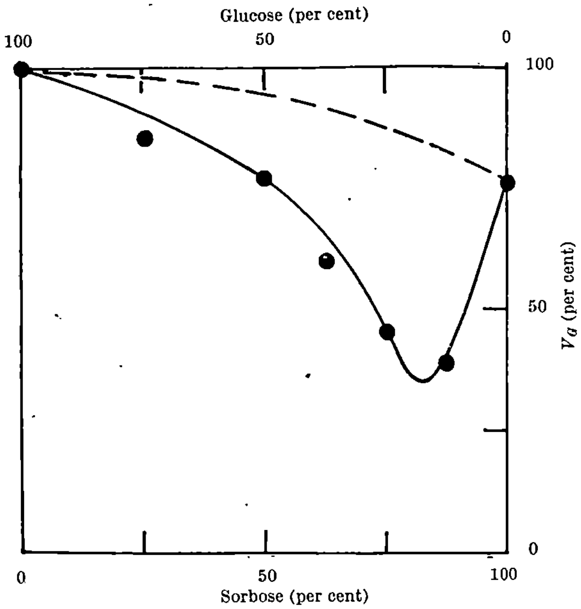

Fig. 4. Entrance of sugar into the human red blood cell from a mixture of glucose and sorbose. Units and symbols as in Fig. 1, but abscissa is 'percentage sorbose concentration'. K and β as in Figs. 1 and 2

0·08 M for fructose (these values were chosen for reasons to be described here). The divalent theory is perhaps marginally better with these values for K and β, but if K is chosen to be very large (in fact, infinite, that is, when the initial velocity is directly proportional to concentration), monovalent theory is as successful as divalent theory, within the experimental error of the results. Clearly such results do not allow us to distinguish between the models suggested but do demonstrate that divalent theory can adequately account for kinetic data of this type. We can, however, devise an unambiguous criterion to distinguish the monomer and dimer models as follows:

Let us investigate how the velocity of transfer varies in a mixture of two sugars (A and B) as the proportion of each sugar is altered. We keep the total concentration of sugar ($A + B$) constant (in the present investigation at 0·19 M) and alter the relative amount of A from 0 to 100 per cent. The experimental results for the pairs glucose/fructose glucose/sorbose and fructose/sorbose are given in Figs. 3, 4 and 5 respectively.

As we alter the relative amounts of A and B, there will always be a particular ratio of A to B at which the amount of A bound to the binding site will be exactly equal to the amount of B similarly bound. This ratio of A to B is given by the ratio of the Michaelis constants K_A and K_B (or β_A and β_B on divalent theory). On monomer theory this equivalence point is of no great theoretical interest; but such is not the case with the dimer theory. For if half the sites binding substrate are binding A, and half are binding B, molecules, the ratios of the dimers formed by any subsequent interaction are $\frac{1}{4}$ AA, $\frac{1}{4}$ BB and $\frac{1}{2}$ AB. In the mixture of A and B, therefore, we have a new species: AEB (E standing for the enzymic binding-site) present in neither of the pure components. Now it may be that such an AEB complex, by virtue of peculiar structural features of the molecules A and B, cannot form the true dimer AB, or that if such a dimer is formed it cannot penetrate the membrane. Then it will follow that at the equivalence point where A and B are equally bound to the binding sites, 50 per cent of the complexes formed will be AEB complexes (heterocomplexes) and will fail to form effective dimers. We would predict, therefore, that in such circumstances, the observed initial velocity of transfer in the mixture would be lower than would be the case for either of the components present alone. Monomer theory predicts no such minimum velocity, the predicted initial velocity never falling below the velocity found for the slower component present alone. For on monomer theory, if A inhibits the binding of B, it itself forms an effective complex with the binding site and a proportion of these complexes must be carried through the membrane to contribute to the observed velocity of transfer. The proportion of these A complexes which penetrate must be independent of the presence of B, if a ternary AEB complex is not postulated.

In Figs. 3 and 4 we have computed the predictions of monomer theory (dashed line) and dimer theory (solid line) for the glucose/fructose and glucose/sorbose systems. K for glucose has been taken as 0·05 M, the value which best fits the data on pure glucose (Fig. 1), while the corresponding constants for fructose and sorbose have been arbitrarily taken as ten times this amount. Clearly from Figs. 2 a and b, the true value of K is a good deal greater than this, but, whatever value is chosen above 0·5 M, only an infinitesimal difference to the prediction on monomer theory will result. The value of the corresponding constant β for glucose of 0·02 M is again taken from the data on pure glucose (Fig. 1). With this value, integral values between 3 and 10 of the ratios of β_{glucose} to β_{fructose} or β_{sorbose} were taken and the prediction on dimer theory computed. The best fit (and hence the lines drawn in Figs. 3 and 4) demand

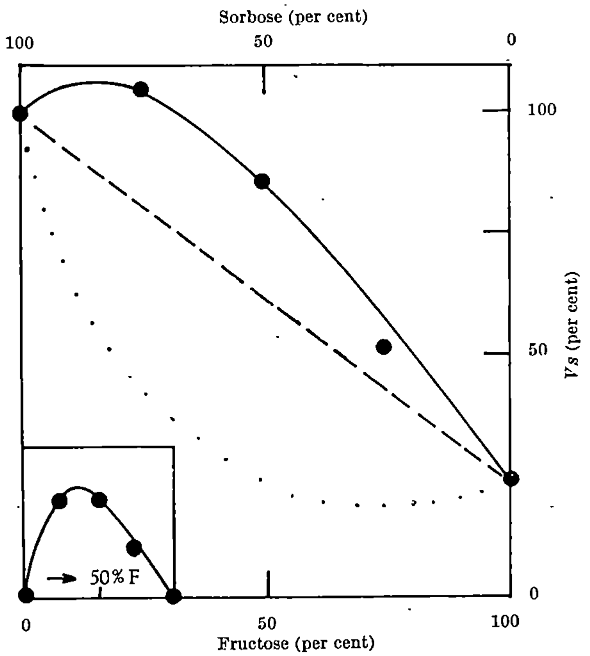

Fig. 5. Entrance of sugar into the human red blood cell from a mixture of sorbose and fructose. Ordinate, initial velocity relative to that in 0·19 M sorbose alone; abscissa, percentage fructose concentration. Symbols as in Fig. 1. K and β as in Figs. 1 and 2, but dotted line is 'prediction on dimer theory where heterocomplexes do not yield effective dimers'; solid line is 'prediction on dimer theory where heterocomplexes do form effective dimers'. Inset: difference between prediction on simple dimer theory and experiment

a ratio of β_{fructose} to $\beta_{\text{glucose}} = 4$ and a ratio of β_{sorbose} to $\beta_{\text{glucose}} = 10$, giving $\beta_{\text{fructose}} = 0{\cdot}08\ M$ and $\beta_{\text{sorbose}} = 0{\cdot}2\ M$. These values for β were then used to compute the solid lines in Figs. 2*a* and *b*. Clearly monomer theory is not consistent with both the experimental procedures of Figs. 1 and 2 on one hand, and 3 and 4 on the other; but dimer theory can very adequately account for all these results.

We have so far considered only the case in which the *AEB* complex fails to form effective dimers. But it is possible that the heterocomplex *AEB* may lead more readily to fruitful interaction than the homocomplexes *AEA* and *BEB*. It is clearly quite possible that *A* and *B* may have a complementary structure such that the dimer *AB* is more readily formed than either *AA* or *BB*. Such a consideration is forced on us by the data of Fig. 5 for the sorbose/fructose system. The dashed line in the figure is the prediction of monomer theory with $K = 0{\cdot}5\ M$ for each sugar. This line is simply the straight line between the points representing the velocities of the pure components. Variations of K above the value $0{\cdot}5\ M$ would lead to only a very small change in this prediction. The dotted line in the figure is drawn on the assumption that the heterocomplex SEF (sorbose–enzyme–fructose) fails to lead to the formation of SF dimers. Clearly this theory is even less effective than monomer theory in accounting for the data. On the inset to Fig. 5 are plotted as solid points the difference between the experimental points of the upper figure and the predicted points of simple dimer theory. The solid line drawn in this inset gives the concentration of the SEF heterocomplex computed with values for β_{sorbose} and β_{fructose} derived from Figs. 3 and 4, on a scale chosen so that the curve passes through the point on the difference curve at 50 per cent concentration. Then the solid line clearly also passes through the remaining points on the difference curve. It is thus the species SEF that must be contributing to the transfer across the membrane. It is possible to derive from the inset curve the interesting result that the species SEF is 1·76 times as effective as SES in leading to dimer formation and subsequent transfer. With this value the upper solid curve of Fig. 5 can be constructed, a curve which adequately accounts for the experimental data. In contrast to the glucose/fructose and glucose/sorbose systems, it would appear, therefore, that fructose and sorbose are in some way complementary structures and, when bound at the 'dimerase', interact with one another more effectively than they would interact with themselves.

It appears difficult to account for these data on monomer theory, but clearly on dimer theory a consistent explanation of all the above experimental data can be presented, with the values for the constants β and $V_{\text{max.}}$ (the maximum velocity of transfer) as given in Table 1 ($V_{\text{max.}}$ refers to the penetration of the dimer, β to the binding of the monomers by the separate sites of the dimerase).

Table 1

Sugars	Affinity constant β (moles/l.)	Maximum velocity (fructose = 1)
Fructose–fructose	0·08	1
Glucose–glucose	0·02	3
Sorbose–sorbose	0·2	8
Fructose–sorbose	—	14
Glucose–sorbose	—	0
Glucose–fructose	—	0

There is other evidence to suggest that the binding site for sugar may bind pairs of substrate molecules. Thus, Lefevre has shown[7] that certain inhibitors of glucose transfer (analogues of phloridzin), possessing two hydroxyl groups, appear to bind in pairs at the glucose binding site, while only one molecule of phloridzin itself is so bound. This evidence is now readily interpretable. (A similar phenomenon is found in the glycerol system[8], where the binding site is monovalent towards the competitive inhibitor 1,3-dihydroxypropane, but divalent towards isopropanol. The 1,3-dihydroxypropane apparently binds across the active centre of the dimerase, a hydroxyl interacting with each of the pair of binding sites for glycerol, while the alcohol binds independently at each of the two binding sites.) Bowyer and Widdas have shown[9], in work on the kinetics of dinitrofluorbenzene inhibition of glucose transfer in the red cell, that the rate of this reaction was second order with respect to both the inhibitor and the membrane sites. This result is readily interpretable if the binding site for glucose is divalent, as the dimerase model requires.

It is perhaps surprising that molecules as large and complicated as glucose can form dimers to any extent. It is possible, however, with both Catalin and skeleton-type molecular models, to make at least one possible dimer between pairs of glucose molecules without conflicting any stereochemical principle. But it is too early to view these artefacts seriously while it is yet uncertain as to how many hydroxyl groups must be involved in the formation of the penetrating dimer.

Such dimerases may have a wider application than simply to the red blood cell facilitated diffusion systems. In particular, the kinetics of the outward transport of arabinose from perfused rat hearts, under conditions of anoxia inhibition[10], may well follow dimer theory, the increase in velocity with concentration being faster than can be accounted for on monomer theory. Also in the case of uptake of amino-acid by ascites cells, a phenomenon similar to that of Fig. 5 has been discovered, the initial rate of uptake of L-tryptophan being increased by pre-incubation with azaserine[11].

Further analysis of these and similar systems may show that dimerases, if they exist at all, are even more widely distributed.

I wish to thank Prof. F. J. W. Roughton for his hospitality in providing me with facilities for this work, and Dr. J. C. Kernohan and Dr. D. A. Haydon for their invaluable help in the development of these ideas.

Note added in proof. It has been pointed out to me that the term 'dimerase' might suggest that the catalytic component involved in facilitated diffusion acts by forming and breaking covalent bonds, as does a true enzyme. There is no reason, however, to think that anything other than hydrogen bond interactions are concerned. I propose, therefore, to refer to such a membrane transfer mechanism as a 'dimerizer'.

EXTRACTION OF HEAT-LABILE ALKALOIDS FROM PLANTS

By Dr. A. R. MATTOCKS

Toxicology Research Unit, Medical Research Council Laboratories,
Woodmansterne Road, Carshalton, Surrey

THE method to be described here has been applied to the separation and subsequent purification of pyrrolizidine alkaloids from plants. It should be generally applicable to any heat-labile compound which is cationic in neutral or weakly-acid solution.

The apparatus is shown in Fig. 1. *A* and *B* are 800-ml. aspirators fitted with rubber bungs and glass connectors as indicated. They rest on a spring balance, *C*, with support from a light stand (not shown) also attached to the balance. The balance is modified by the addition of a spring, *D*, to compensate for the weight of the apparatus. A small mercury switch, *M*, is fitted in place of the pointer. The upper aspirator, *A*, is connected via flexible plastic tubing, T_1, and a T-piece to a water-pump and to an electrically operated air valve, V_1. The latter (Fig. 1, left) consists of a piece of narrow gauge, thin-walled rubber tubing which is normally closed by pressure from a spring-loaded iron plunger. When a current is applied to the solenoid, *S*, the plunger is withdrawn into the solenoid and hence the valve is opened. (This device can be constructed from a discarded motor car trafficator.) The lower aspirator, *B*, contains a triple 'Bunsen' valve, V_2, made by cutting three parallel slits, about 7 cm. long, in a length of thick-walled rubber tubing of approximately 8 mm. outer diameter. The exit tube, *E*, in the form of a syphon, leads into the extraction vessel, *F*, containing the ground plant, *P*, supported on a layer of cotton-wool, *W*. This vessel is either a large inverted bell jar (diameter 20 cm.) holding up to 3 kgm. of plant, or an inverted bottle (Winchester) with the bottom removed, for smaller quantities. It is connected via a column, *G*, containing cation exchange resin, a reservoir, *H*, and a plastic return tube, T_2, to the upper aspirator, *A*. The resin I have used is 'Dowex 50' (200–400 mesh, cross-linkage 8 or 12) in the acid form.

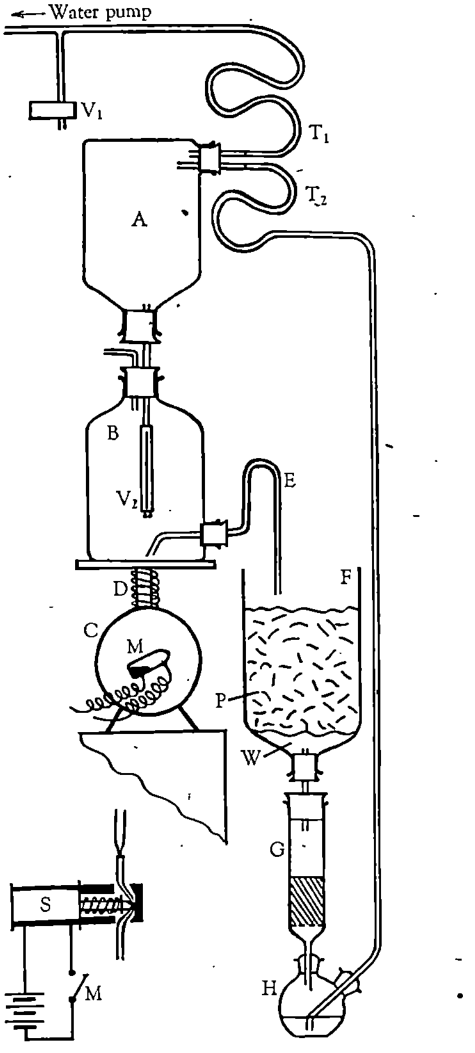

Fig. 1. Right, apparatus for continuous cold extraction (not to scale); left, details of the valve, V_1

For operation, the mercury switch, *M*, is connected via a battery to V_1, and its angle is adjusted so that it reaches the 'on' position when *A* is about three-quarters filled with solvent. The plant, *P*, is soaked in solvent, usually alcohol, and then covered to a depth of a few inches. The water pump is then turned on so as to apply a gentle suction to *A*. The apparatus functions as follows: solvent is drawn through the plant and *G* into *H* and thence into *A*, by the applied suction, which also keeps V_2 closed (it is helpful to moisten V_2 with solvent initially). When *A* is sufficiently filled, V_1 is actuated by the switch *M*, air is admitted through T_1 and the solvent flows into *B* via V_2. *B* is then emptied through *E* into *F*, and, as the weight decreases, *M* is opened, V_1 is closed, and the cycle is repeated. By this discontinuous process, ethanol can be circulated indefinitely at rates between 9 and 14 l./hr.

Alkaloids are removed from the solvent by the resin, but chlorophyll and non-basic substances remain dissolved. The resin is washed briefly with solvent and with water, and the alkaloids are eluted by dilute aqueous ammonia, reduced with zinc and acid to convert N-oxides to the tertiary bases, and extracted from alkaline solution with chloroform. (Though the alkaloids often occur as the weakly basic N-oxides, these are apparently held by the resin as readily as the free bases themselves.) Alternatively, the column can be made basic by passing a solution of ammonia in ethanol. In contrast to previous work with other alkaloids[1], this does not elute the alkaloids, which can then be obtained in more concentrated solution by eluting with water.

Table 1. Extraction of Alkaloids with Ethanol using various Procedures

Plant	Approximate weight of plant extracted (kgm.)	Alkaloid: extraction	Method of isolation	Yield of crude alkaloid (per cent wt.)	Condition of product
Crotalaria retusa	7	Soxhlet (hot)	Conventional (*D*)	0·380	Crystalline with very considerable dark brown gum
Crotalaria retusa	1·1	2 percolations (*A*)	Conventional (*E*)	0·177	Crystalline with moderate brown impurities
Crotalaria retusa	1·4	3 percolations (*A*)	Conventional (*E*)	0·192	Crystalline with moderate brown impurities
Crotalaria retusa	1·1	2 percolations (*A*)	Dowex (*F*)	0·158	Very slightly brown crystals
Crotalaria retusa	1·3	3 percolations (*A*)	Dowex (*F*)	0·150	Very slightly brown crystals
Crotalaria retusa	1·3	3 percolations (*A*)	Dowex (*G*)	0·135	Almost colourless crystals
Crotalaria retusa	0·7	Percolation (*B*)	Dowex (*B*)	0·350	Slightly brown crystals
Heliotropium indicum	1·75	2 cold soakings (4 days) (*C*)	Conventional (*E*)	0·163	Pale brown gum
Heliotropium indicum	5·2	3 soakings (5 days) (*C*)	Conventional (*E*)	0·190	Pale brown gum
Heliotropium indicum	11	2 soakings (5 days) (*C*)	Dowex (*F*)	0·140	Colourless gum
Heliotropium indicum	2	Percolation (*B*)	Dowex (*B*)	0·390	Pale brown gum
Senecio jacobaea	1·8	Percolation (*A*)	Conventional (*E*)	0·065	Dark brown, semi-crystalline
Senecio jacobaea	1·8	Percolation (*A*)	Dowex (*F*)	0·063	Very light brown crystals

A, cold ethanol continuously circulated for several hours; *B*, ethanol circulated continuously through plant and then resin; *C*, plant soaked in cold ethanol for several days with occasional stirring; *D*, the extract concentrated by distilling at atmospheric pressure; the chlorophyll extracted; reduced to convert *N*-oxides to bases; made alkaline with ammonia and extracted with chloroform; *E*, as *D*, but extract concentrated under reduced pressure; *F*, extract passed once through bed of 'Dowex 50'; *G*, extract acidified with conc. sulphuric acid (1 per cent by volume), then passed through resin

An alternative procedure is desirable if the plant already contains decomposition products, as discussed later. In this case the column, *G*, is omitted, and several batches of solvent are circulated through the plant for a few hours each. The combined extracts are then passed once through the resin column.

The dimensions of the resin column are not critical. For extractions of up to 2·5 kgm. of plant we have used a column of 5 cm. diameter, containing about 120 gm. (damp weight) of resin (depth 10 cm.). As a preliminary trial a column of 'Dowex 50' (30 gm. damp weight) was washed with 4 *N* hydrochloric acid, water and ethanol. A solution of the pure alkaloid monocrotaline (1 gm.) in ethanol (1 litre) was passed through the column: the eluate contained no alkaloid. After washing with ethanol and water, elution with a mixture of 10 ml. ammonia (sp. gr. 0·880) and 200 ml. water, and extraction of this with chloroform, gave 100 per cent recovery of crystalline alkaloid.

The details of a series of extractions are given in Table 1. For each species, plants from a single batch were used for all experiments.

The amount of resin needed to extract all the alkaloid from a given lot of plants depends on several factors; some of the resin will react with inorganic cations (for example, *Heliotropium indicum* contains potassium nitrate), and the efficiency may be reduced by the adsorption of dark impurities and some chlorophyll. Some extracts darken the resin more than others. These seem to be from plant materials which have been stored for a long time or dried by heating, and may hence contain basic decomposition products of high molecular weight. In a trial with *Heliotropium indicum*, 40 gm. of fresh resin were treated with an excess of ethanolic plant extract until alkaloid ceased to be absorbed; 4·4 gm. of crude alkaloid (mol. wt. about 300) was then recovered from the resin.

Since inorganic salts are converted to acid by the resin, an experiment was performed with an ethanolic extract from *Crotalaria retusa* to which acid had been added (Table 1). Under these conditions the resin absorbed less alkaloid, but it was almost free from dark impurities. However, much more acid was used than would normally be formed in a continuous extraction cycle.

The resin can be regenerated by washing with 4 *N* hydrochloric acid, but brown and green impurities are best eluted with ethanolic hydrochloric acid. Trials indicate that each use with a crude extract decreases the resin's capacity to absorb alkaloids by up to 25 per cent.

The extraction of pyrrolizidine alkaloids from powdered plant materials by hot ethanol in a Soxhlet-type extractor is unsatisfactory, because much alkaloid may decompose through heating and the products are always contaminated with gummy, dark brown impurities. The concentration of such extracts and removal of chlorophyll is a tedious procedure. Repeated soaking of the plant in large volumes of cold alcohol gives a better quality product, though in lower yield, but very large volumes of alcohol must then be concentrated under reduced pressure.

Continuous percolation for 9–10 hr. is a more efficient method of extraction than several days' soaking in stationary solvent. Subsequent isolation of the alkaloids by means of cation exchange resin has additional advantages. Effectively large volumes of alcohol can be used for extraction, while subsequent concentration is not necessary, and the extraction of chlorophyll is avoided. The alkaloids are not subjected to heat, and brown, gummy impurities are almost absent from the product. When a resin column is included in the continuous cycle, the alkaloids are progressively removed from the plant as in a Soxhlet extraction, with which it is comparable in efficiency.

The main drawback of this method is that the resin is rendered unusable after a few regenerations, and must be discarded.

The use of cation-exchange resin has previously been reported for the isolation of alkaloids for analytical and medicinal purposes[1], and anion exchange resin has recently been used for the large-scale extraction of insulin[2]. The usefulness of the present method is illustrated by the fact that only after extraction in this way could the new alkaloid, indicine, from *Heliotropium indicum*, be readily obtained in crystalline form[3].

Thanks are due to the Tropical Products Council, London, for its help in obtaining supplies of *Heliotropium indicum* and *Crotalaria retusa*.

ROLE OF POLYSACCHARIDES IN STABILIZATION OF NATURAL SOIL AGGREGATES

By Dr. D. J. GREENLAND, G. R. LINDSTROM and Dr. J. P. QUIRK
Department of Agricultural Chemistry, Waite Agricultural Research Institute, University of Adelaide

IT is well known that polysaccharide and polyuronide materials are generally present in soils[1-3], and that in sufficient concentration they are particularly effective in causing aggregation[4,5]. The amounts normally present in soils are small[6]. They are, however, more strongly adsorbed by clay than the humic and fulvic acids as a whole[7]. Furthermore, the humic and fulvic acids are much less effective in stabilizing aggregates than the polysaccharides[3]. It therefore appeared reasonable to conclude that the soil polysaccharides normally played a significant part in the cementing of aggregates. However, a recent examination of the effects of periodate treatment on soil aggregates[8] indicated that in the soils tested the polysaccharides–polyuronides were either not contributing at all to the aggregation, or if they were, then their contribution was complementary to, and dependent on, the effect of other materials. Mehta *et al.*[8] considered that the periodate-borate treatment given to the aggregates would disrupt the polysaccharide–polyuronide molecules, so that if these were the essential cement in the aggregates, then the treatment would cause their breakdown. In fact the periodate treatment did not disrupt the aggregates tested. Aggregates prepared in the laboratory by treatment of soils with various polysaccharides were broken down by the treatment, showing the effectiveness of the technique for the purpose intended.

Although the earlier evidence which suggested that the polysaccharides and polyuronides played an important part in soil aggregation was only presumptive, it appeared desirable to examine the effect of periodate treatment on a further range of soils. It also seemed desirable to examine aggregates from soils that had been under short-term pastures, as well as those that had been under pasture for many years, since it has been shown[9] that long-term pastures produce a much more durable aggregation than short-term ones. It seemed possible that the less-durable aggregation could be due to the polysaccharides–polyuronides. Mehta *et al.*[8] showed only that aggregates from a braunerde under old forest and various other (unspecified) Swiss soils, including two rendzinas, were stable to the periodate treatment.

In the investigation reported here, soils were taken from the permanent rotation trial at the Waite Institute, and from similar red-brown earths and solonized brown (mallisols) and related soils from the lower north of South Australia. The textures of the soils varied from sandy loam to clay loam, their histories from permanent pasture to continuous wheat-fallow cultivation, and their carbon contents 3·6–0·8 per cent. Aggregates (1·0–2·0 mm.) were separated from surface samples (0–3 in.) by gentle hand sieving. These aggregates were carefully made wet on a sintered-glass funnel at 100 cm. water suction to prevent disruption on flooding[11], and transferred to a permeameter similar to that described by Dettmann and Emerson[10]. It was considered that a permeability test would be more likely to reveal differences in aggregate stability than the somewhat drastic 'Yoder' wet sieving technique used by Mehta *et al.*

After the aggregates were transferred to the permeameter they were further wetted at 8 cm. suction. They were then sodium-saturated by passing 3 litres of 0·02 or 0·05 *N* sodium chloride through the permeameter under a head of 3 cm. of solution. Treatment with 0·02 *N* sodium periodate was carried out in the permeameter, followed by 0·10 *N* sodium borate according to the procedure described by Mehta *et al.*[8]. The controls were treated with 0·01 *N* sodium chloride instead of periodate, but otherwise were subjected to the same reagents. Collapse of the aggregates leads to a reduction in permeability, and this was tested by measuring the rate at which 0·01 *N* sodium chloride passed through the beds of treated aggregates. The effect of the periodate treatment was assessed by comparing the permeabilities of the treated and untreated soils at different times (Fig. 1). The results are plotted in terms of the ratio of the rate of flow of solution (P_t) at a certain time after the introduction of periodate (or corresponding salt) to the rate of flow (P_i), immediately prior to periodate treatments.

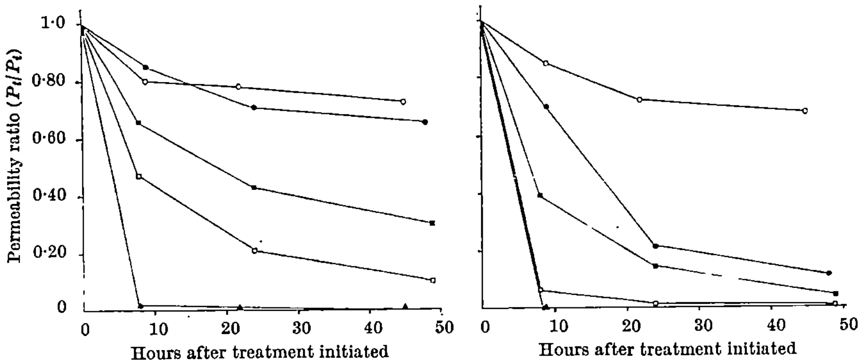

Fig. 1. Change with time in the permeability to 0·01 *N* sodium chloride of beds of aggregates from Urrbræ loam surface soil: left, control aggregates; right, periodate-treated aggregates. Histories of the soils from which the aggregates were taken are: ○, permanent pasture, 3·6 per cent C; ●, fourth year of pasture of 4 year pasture, 2 year wheat rotation, 1·92 per cent C; ■, second year of pasture of 2 year pasture, 1 year wheat rotation, 1·80 per cent C; □, continuous wheat, 1·60 per cent C; ▲, fallow of wheat-fallow rotation, 1·14 per cent C

Only the aggregates from old pasture soils high in organic matter were stable to the treatment. The soils which had been cultivated and then put down to pasture for two or four years showed a very marked decline in permeability on periodate treatment. The leachate from these aggregates contained a noticeably higher content of peptized organic material and clay. The aggregates from the continuously cultivated soils disintegrated considerably even without periodate treatment, so that it was difficult to be certain with these soils whether or not significant changes were produced. Only the results for the soils of precisely known history from the Waite Institute are given in Fig. 1; but the other soils collected from County Victoria fully confirmed these results.

It is concluded that molecules containing *cis*-hydroxyls are most probably involved in stabilizing aggregates in soils from young pastures. It is recognized, however, that periodate may react with *cis*-hydroxyls of molecules other than polysaccharides. However, the polysaccharides are most probably the constituents of soil organic matter involved.

It is possible that the periodate-resistant materials in old pasture soils are fungal hyphæ and mycelia, since Bond[12] has recently shown that in the soils from the permanent rotation trials at the Waite Institute very little of the fungal material is present in the young pastures, but it is very well developed in the older pastures.

NON-RANDOMNESS IN AMINO-ACID 'ALLELES'

By RICHARD V. ECK

Laboratory of Biology, National Cancer Institute, National Institutes of Health, Bethesda 14, Maryland

VARIOUS proposals, general and specific, have been made in the past few years concerning a 'code' by which genetic information might be transferred from the hereditary material (presumably nucleic acids, but possibly nucleoproteins) to proteins such as hormones and enzymes. This relationship is sometimes referred to as a cryptogram, the nucleic acid chain being a 'signal' and the protein chain a coded 'message'. It is frequently assumed that it has another characteristic of cryptograms—a point-to-point relationship of some sort. Particular attention has centred on the discrepancy between the number of different nucleotide links in nucleic acids (four) and the number of different amino-acid links in proteins (twenty). If a nucleic acid sequence occurred 'at random' (with no limitation on which nucleotide could occur at any particular place), it would contain exactly two bits of information per link ($2^2 = 4$). Similarly, a completely unconstrained protein chain would contain 4·3 bits per link ($2^{4\cdot3} = 20$). Since these numbers are incommensurable, it is obvious that a point-by-point relationship of any sort must require that one or both of the chains contain redundancy or constraint.

An 'overlapping' code was first proposed by Gamow[1] in which each link in the protein chain would be determined by three adjacent links of the nucleic acid chain, the next protein link being determined by the last two of these three and the one following, etc. This code effectively reduced the amount of information in the protein chain to two bits per link. Any particular amino-acid would be determined partly by one corresponding nucleotide, and partly by the context of the immediately adjacent links. This would 'permit' a maximum of $4^5 = 1,024$ tripeptides, and 'prohibit' the occurrence of the rest of the $20^3 = 8,000$ mathematically possible tripeptides. This situation was disproved by Brenner[2], who showed that more published information already existed than could be fitted into such a limited pattern.

Since then, various proposals have been made concerning 'non-overlapping' codes, in which any protein sequence would be free to occur. One of these would have three adjacent nucleotide links to determine each amino-acid link independently of the next three. The nucleotide chain would be three times as long as the protein chain, and each amino-acid link would have six bits of information with which to be encoded. Considerable mathematical ingenuity has been exerted to develop patterns which would, in effect, dispose of the excess information, so that any random sequence of nucleotides would determine one unique sequence of amino-acids[3,4]. Another proposal would have some of the information come from a single nucleotide link, and the rest from some other unknown source[5,6]. I suggest that the unknown source might simply be the nearby links. (Brenner's analysis applies only to overlapping triplets. It would be very difficult and probably inconclusive to use his method to disprove longer overlapping codes, given the limited amount of data at present available.) However, Yčas failed to find statistical constraints on the frequency of occurrence of dipeptides. He considers this to be good evidence against an overlapping code and suggests that, in the case of a virus, the additional source may be the viral host[5].

If detailed chemical evidence were available for the link-by-link structure of some moderately long nucleic acid chain, and of the specific protein determined by the same chain, one might try to solve the cryptogram in a simple, direct way. There seems some reason to expect that such data will eventually become available, for example, from some simple virus. At present, however, there is very little evidence concerning the details of nucleic acid chains.

It is obvious that if a non-overlapping code of any sort (in which one amino-acid link contains no information concerning other links) were the basic mechanism, the code could not be solved (in fact, no information about it can be derived) by a study of the protein sequence data alone. An overlapping code, however, could, in principle, be completely solved in terms of four code numbers representing the four nucleotide bases. Chemical evidence from nucleic acids would then be needed to determine which nucleotide corresponds to each number. A code which is partly overlapping and partly determined by some other source of information might be solved to some limited extent.

I consider that the overlapping hypothesis has not been definitely disproved, and that it has several attractive features—one of which is the theoretical possibility of solving it, if it exists.

Spurious statistical constraints might be imposed on the published protein sequences by a variety of possible causes. Conversely, if constraints fundamentally exist, apparent randomness might be superimposed on them. However, if one assumes (1) that such confusion will not completely obscure and existing underlying pattern, and (2) that constraints will involve adjacent linkages (whatever else they may also involve), a general approach to the cryptogram is possible.

The published data on amino-acid sequences can be sorted, tabulated and arranged in a great variety of ways. (The simplest of these is to count and tabulate the dipeptides.) Any such manipulation will produce some sort of pattern. Tests can then be made to determine whether these patterns are more regular or more extensive than could reasonably be expected by chance. If one finds such evidence of non-randomness, it would always be possible to suggest some 'just so' explanation not requiring a code. Even so, an accumulation of several independent types of non-randomness, all of them predicted by the overlapping code, and not readily explained otherwise, would strengthen the hypothesis. Eventually, this procedure should make possible the development of the detailed structure of the code, when enough sequence information is available.

The statistical evidence of non-randomness presented here does not use the entire mass of amino-acid sequence data, but only that part which has been reported as alleles[7] or which seems to be confidently interpretable as alleles.

Examples of 'alleles' as used here are the various hæmoglobins, in which one amino-acid difference has been found to correspond to a difference in a single gene[7]. Also included are all apparently homologous proteins which differ only at particular links, such as the insulins from various species[8,9]. Allele pairs are included only if they are flanked on both sides by identical amino-acids. This eliminates many cases for which there might be presumptive justification, but no strong evidence, such as has been suggested for matching the two chains of insulin, etc.[6]. Two different amino-acids occurring at one locus are counted as one pair of alleles. Three at one locus produce three pairs, four produce six pairs, etc. A tabulation of all available cases yields 74 allele pairs. One of these (alanine : serine) occurs eight separate times, two occur four times, six thrice, five twice and 30 others occur only once. Thus, of the 74 there are 44 different pairs.

The question whether this distribution could occur by chance is approached as if the sample of 74 pairs had been drawn by lottery from the theoretical population of $\frac{20 \times (20-1)}{2} = 190$ possible pairs. One must first take into account the obvious inequality in frequency of the various amino-acids. Some are much more common than others. If they were all of equal frequency, the probability is 1/190 that any two pairs drawn at random would be duplicates. Using the reported frequency of the various amino-acids, this probability was computed to be 1/121.

In the 74 pairs, there are $\frac{74 \times 73}{2} = 2{,}701$ possible comparisons, each one of which (with trivial exceptions) has an equal chance to be a duplication. The number of duplications expected by chance is therefore: $\frac{2{,}701}{121} = 22$. Using this same method, every possible comparison being a countable instance, the duplications in the tabulated data are counted. An allele pair which occurs twice represents one duplication. A pair which occurs three times represents three duplications, etc. The total number of duplications in the data is 63. Since the 2,701 opportunities for duplication would not influence one another if the 'lottery' were truly random, the distribution would be binomial (within practical limits). The probability is infinitesimal that 63 cases could occur by chance in a binomial distribution where 22 were expected ($t = 6{\cdot}5$).

Various tests were done, in which certain of the original data were discarded on grounds that they might possibly introduce some bias. When the above calculations were repeated on these reduced bodies of data, the results were essentially unchanged.

The above calculation can be inverted, to find the effective size of the population of pairs from which the sample of 74 must have been drawn to give 63 duplications. Instead of the 190 expected by chance, this is computed to be 67, with 95 per cent fiducial limits between 52 and 87.

We conclude that these reported amino-acid alleles are not a random sample of the amino-acids found in all protein sequences reported. The same pairs are found repeatedly, far beyond their expected chance frequency. It is conceivable that some unknown cause may have biased the sample, but what this may have been is not obvious. On the other hand, this is exactly what would be expected from an overlapping code; given a particular context of surrounding links, not all possible amino-acids are 'permitted' to occur.

A full account of the mathematical calculations, and a more extensive discussion of the general approach, are being prepared for publication elsewhere.

I wish to thank Dr. Norman Shapiro, of the Computation and Data Processing Branch, U.S. National Institutes of Health, for his helpful criticism of the mathematical treatment.

LETTERS TO THE EDITORS

RADIOPHYSICS

Effect of External Conditions on the Phase of Radio Signals

THE emissions at 16 kc./s. from the Post Office *GBR* transmitter at Rugby are in the form of interrupted continuous waves and are used for purposes which include the international co-ordination of standards of frequency and time and studies of propagation[1-3] by comparing the phase of the received signals with that of a local reference source. The relative observed phase of the carrier wave will change, due to changes in the rates of the controlling reference oscillators, to varying radio propagation and to phase changes in the transmitter. Some investigations have been made of the latter by comparing the phases of the aerial current and the carrier source.

We have found that phase aberrations can be caused by the following:

(1) Detuning of the low-decrement aerial by changes of weather conditions and by aerial sway. Throughout November and December 1960, phase shift was recorded during typical weather including gales and icing conditions. Slow changes of phase of 20° or more were observed on several occasions, and once a change of up to 60° in a 2-hr. period would have occurred but for manual re-tuning, which was carried out when the phase had changed some 20°. Aerial sway produced fluctuations of 12° with periods of 1–2 min. Throughout the period of observation the aerial circuit was slightly out of tune (more than 7° shift in phase) for 32 per cent of the time and noticeably out of tune (more than 13° shift) for 2·2 per cent.

(2) Fluctuations in the inductance of the aerial tuning inductors caused by mechanical forces between coupled turns set up by the current. The natural period of the fluctuations is about 3 c./s., but their magnitude is largely determined by the nature of the keyed signals. During the mark signals of normal telegraph traffic, we have observed a random fluctuation of about 7°. The seconds pulses of the time signals cause only a small phase variation from pulse because the off/on ratio has a constant value of 9. A gradually increasing current up to the maximum of 800 amp. under conditions of continuous mark produces a change of 8° corresponding to a change of inductance of 0·07 per cent.

(3) Phase changes in the amplifiers during a mark. The transient electrical and thermal effects in the class *C* amplifiers produced a phase shift of about 30° during the build up of the mark, which takes about 20 msec. to reach 90 per cent amplitude in the aerial. At the end of the mark the aerial, being unloaded by the amplifier, oscillates freely and the phase of the aerial current changes by more than 360° during the decay.

With methods of measurement at present in use, only phase changes under heading (1) would be likely to be observed at a distance. Accurate frequency comparisons are made after integrations of phase during multiples of 24 hr. to remove the diurnal propagation effect[3], but this could include a phase error due to changes of aerial tuning which might amount to 60°, equivalent at 16 kc./s. to 10 μsec. or a little more than 1×10^{-10} in 24 hr. Automatic aerial tuning and other phase-correcting devices now being actively considered, besides keeping power more constant, would reduce this possible error. It would also hold more constant the over-all response of the transmitter to transients and enable more accurate determinations to be made of epoch from time-signal transmissions.

GEOPHYSICS

Age Measurements on Antarctic Rocks (Queen Maud Land)

WE wish to report here the results of absolute age measurements carried out on rocks from the Sör-Rondane Mountains. These mountains, extending from 23° E. to 28° E. in Queen Maud Land, were explored in 1958 in the course of the Belgian Antarctic Expedition led by Gaston de Gerlache[1]. Preliminary accounts of the geology and of the petrography of this region have been published[2,3] already.

We have measured rubidium–strontium ages on biotites obtained from various types of rocks : 'intrusive' granite and diorite, gneiss and migmatites, granitic and pegmatitic veins. The procedures for the determination of rubidium-87 and strontium-87 were similar to those described by Aldrich *et al.*[4]. The isotopic ratios were measured with a 33-cm. radius of curvature mass-spectrometer equipped with an electron multiplier. The analytical error of the concentrations is between 1 and 3 per cent, resulting in an uncertainty of ± 15 million years in the calculated ages. The analytical data and the resulting age appear in Table 1. The geographical names refer to the map of the Sör-Rondane Mountains, published by the Norsk Polarinstitutt, during 1957.

The results indicate that the biotites are all the same age, ~ 475 million years, which corresponds in the stratigraphic scale to a Lower or Middle Ordovician age.

Ravitch and Krylov[5] carried out argon–potassium measurements on rocks occurring in the mountains situated west of our region. Their data yield ages ranging from 410 to 500 million years by using the values: $\lambda_\beta = 4 \cdot 72 \times 10^{-10}$ yr.$^{-1}$ and $\lambda_e = 5 \cdot 85 \times 10^{-11}$ yr.$^{-1}$ for the decay constants of potassium-40.

On the other hand, Nicolaysen *et al.*[6] report rubidium–strontium ages of ~ 515 million years for biotites from pegmatites and charnockitic gneiss occurring near Lützow-Holm Bay, on the eastern limit of Queen Maud Land.

Our data around 475 million years refer clearly to the last major metamorphic episode in Queen Maud

Table 1. RUBIDIUM–STRONTIUM AGES OF BIOTITES

Location	Source rock	Rubidium (p.p.m.)	Radiogenic ^{87}Sr / Total ^{87}Sr	Age (m. yr.)
Romnoesfjellet	Porphyroblastic granite	563	0·42	478
Romnoesfjellet	Pegmatite vein in granite	1,108	0·91	465
Småhausane, 1,180	Quartz diorite	139	0·56	458
Småhausane, 1,180	Diorite	328	0·39	457
Nordtoppen, 1,100	Biotite gneiss (xenolith in diorite)			
	Fine fraction	1,477	0·92	476
	Coarse fraction	1,459	0·89	481
Nordtoppen, 1,100	Coarse biotite crystals from xenolith in diorite	786	0·59	493
Strandrufjellet	Biotite gneiss	545	0·56	455
Strandrufjellet	Fine-grained granite (anatectic ?)	1,329	0·90	483
Bautaen	Fine-grained granite (anatectic ?)	1,282	0·93	506
Trillingane	Amphibole biotite gneiss	371	0·50	471
Trillingane	Leucocratic pegmatite	842	0·60	474

λ rubidium-87 = $1·39 \times 10^{-11}$ yr.$^{-1}$, rubidium-87 = 0·283 gm./gm. rubidium

Land. They confirm the very large extension of this episode, which has been recorded from 165° E. (ref. 7) to 10° E. along the Antarctic coast.

Biotites are known to be very sensitive to metamorphism and to keep record only of the last metamorphism, therefore very little can be said about the age of the intrusive bodies, the migmatites and the pegmatites occurring in Queen Maud Land, in relation to the $\sim$500 million years old metamorphic episode.

In order to solve these problems, more measurements should be carried out not only on biotites but also on minerals like feldspars, muscovites or zircons, which preserve pre-metamorphic ages better than biotites[8,9].

We wish to thank Miss E. Jäger (Mineralogisches Institut, Berne), who kindly made available to us her calibrated strontium and rubidium spikes.

GEOCHEMISTRY

Microstructural and Chemical Identity of the Bear Creek and Narraburra Iron Meteorites

METALLOGRAPHIC examination of small specimens taken from the Bear Creek (*Nin.* 352·1γ) and Narraburra (*B.M.* 1927, 1264) iron meteorites reveals a remarkable similarity of microstructural detail. This similarity of structure is matched by the analytical results of Brown *et al.*[1], who place both bodies in the same gallium–germanium group and report the following detailed analyses for Bear Creek and Narraburra respectively: nickel, 10·14 and 10·22; cobalt, 0·51 and 0·59; chromium, 1·2 and <1; copper, 154 and 157; gallium, 15 and 8·2; germanium, 25 and 29. The values for nickel and cobalt are percentages, the other values are p.p.m.

The object of the present communication is to propose that the two meteorites are fragments of the same original mass and have been subject to similar histories.

By comparison with the majority of finest octahedrites both specimens show the following anomalous structural features: acicular structure in both Widmanstätten and plessitic kamacite; bainitic structure in the larger areas of taenite; absence of a marked and continuous taenite border along the interface of coarse plessite fields, coupled with a tendency for small rounded schreibersite crystals to be present as satellite bodies in the kamacite around taenite regions instead of actually in the kamacite – taenite interface. These features are well shown in the Bear Creek photomicrograph published, as Fig. 2, Plate 37, of Perry's monograph[2].

Though it is not, as yet, possible to give a comprehensive account of the thermal history which produced this anomalous structure, the metallographic indications are of a heat treatment or series of heat treatments applied to a normal fine octahedrite. Laboratory experiments involving a single heating cycle have not so far reproduced this type of structure, but speculation may reasonably be directed to the possibility of a series of heating and cooling cycles, such as might arise by frictional heating of a body repeatedly in non-circular orbit about the Earth. This mechanism of heating is to some extent supported by the fact that the 500-lb. Bear Creek meteorite was found in the United States while the 71-lb. Narraburra was found in Australia. Such a wide geographical separation of chemically identical material, when considered in relation to the anomalous details of the microstructure, suggest the fragmentation of a captured satellite meteorite as a more plausible explanation than two separate and isolated falls. Published photomicrographs of Smith's Mountain in Perry's monograph[2] (Fig. 1, Plate 38; Fig. 2, Plate 41) suggest that this may be a third member of the same group, but detailed analytical values for Smith's Mountain are not available.

Thanks are due to Dr. Max Hey for the loan of specimens from the British Museum.

PHYSICS

Recoil-Atom Reactions at Low Temperature

CHEMICAL effects attending transformations of the nuclei of atoms in solids have been observed in a large number of systems[1]. Such effects are attributed to nuclear recoil, inner shell ionization followed by an Auger cascade, or nuclear charge change, for example in β-decay. Atoms which have transformed may be found in their original chemical form[2] or in altered

§ Single determination.

chemical states. The percentage of radioactive atoms found in the original chemical form has been called the 'retention' by Libby[2]. A recoil atom of the latter type may be considered a defect in the crystalline lattice, and in analogy with thermal annealing reactions of defects, for example interstitial atoms, produced by heavy particles of γ-ray bombardment[3], the application of heat to crystals containing recoil atoms frequently changes the observed distribution of chemical species[1]. In general, annealing reactions of recoil atoms tend to restore those atoms to their original ('parent') chemical form. Recoil reactions following slow neutron capture are known as Szilard–Chalmers reactions, after the discoverers of this effect[4].

In work on radiation damage in solid-state physics, it has been found desirable to provoke the damage, and to measure it, at very low temperatures, in order to preserve the original distribution so far as possible. Annealing reactions may take place even below liquid-air temperature, indicating activation energies of only a few tenths of an electron volt. The corresponding situation in chemical, for example Szilard–Chalmers, systems is experimentally more difficult, since in general one would wish to carry out some sort of chemical analysis, perhaps involving dissolution of the crystal containing the recoil atom, at low temperatures.

We wish to report here experiments in which we have done this. For example, we have analysed neutron-irradiated alkali chromates by dissolution in aqueous solutions at −55° C., and sodium bromacetate in methanol at −60° C. The aqueous solutions were eutectic mixtures of 33·7 gm. of lithium chloride to 100 gm. of water, freezing at about − 70° C. The lithium salt was found to be inert in affecting the distribution of chromium recoil atoms between the tri- and hexa-valent oxidation states. We have thus been able to irradiate crystals with neutrons at the temperature of dry ice (−78° C.) and analyse them without allowing them to warm up. Complete experimental details will be published elsewhere.

In Tables 1 and 2 are presented retention[2] data obtained by these low-temperature techniques, including the complete thermal history of the specimens. Each figure is the average of two or more independent determinations, unless otherwise noted.

Table 2. RETENTION OF RECOIL BROMINE-80M and 82 ATOMS in $BRCH_2COONA$ IRRADIATED WITH NEUTRONS

Irradiation		Storage		Dissolution		Retention (per cent)

* Sample transferred from the reactor following irradiation to dry ice in less than 30 sec.

Similar experiments have been carried out with potassium and ammonium chromates; here, too, lower retentions are observed for low-temperature conditions. For example, potassium chromate, which has a room-temperature retention of 60·5 per cent (ref. 5), shows a retention of about 47 per cent when irradiated and stored at dry-ice temperature, and dissolved at − 55° C. These experiments will also be more fully reported elsewhere.

It is surprising to note that, despite annealing effects which are important at + 55° C., one can obtain almost the same retention in sodium bromacetate by irradiating at room temperature (+ 25°) and rapidly quenching in dry ice, as by irradiating at dry-ice temperature. This demonstrates that there is little effect of the ambient temperature on the recoil-chemistry, for this compound. Similar effects have been found for bromine-80m and 82 recoil atoms in potassium bromate, and for bromine-80m formed by (*n*, 2*n*) reactions in sodium bromacetate.

It is evident from the results in Tables 1 and 2 that, in general, retention values are only significant in terms of the thermal history of the irradiated specimens. One might even say that it is probably impossible to measure 'intrinsic' retentions as meaningful quantities, since one cannot carry out chemical analyses at indefinitely low temperatures, as would be necessary. One always will observe the 'intrinsic' retention increased by a variable amount which depends on the temperature and time of irradiation, storage and analysis. Uncertainties in these unknown increments thus make dangerous any attempt to correlate retention data with recoil energies derived from spectra of neutron-capture γ-rays or with chemical compositions or to use mechanical ('billiard ball') models to explain retention values observed in crystals.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

Melting and Polymorphism of Indium Antimonide at High Pressures

THE change of electrical resistivity with pressure of indium antimonide has been studied by Keyes[1] up to 12,000 atmospheres and recently by Gebbie *et al.*[2], who extended measurements to 70,000 atmospheres. The resistivity measured at room temperature, according to them, shows an initial increase with pressure and drops several orders of magnitude at 30,000 atmospheres. This sharp drop in resistance was attributed by Gebbie *et al.* to melting, with the indium antimonide changing from a state of semiconduction in the crystal to metallic conduction in the liquid phase. A melting curve, based on the pressures giving a drop in resistivity at temperatures of 150°–800° K., was presented by them. The plotted points exhibit a wide scatter and the authors mention that the latent heat of melting calculated from the melting curve slope, namely 27 cal./gm., compares unfavourably with the experimentally determined value of 47·2 cal./gm. Hence it appeared to us that the melting curve of indium antimonide should be investigated again.

A piston-cylinder apparatus was used for generating high pressures. In this device, a tungsten carbide piston advances into a 'Carboloy' high-pressure chamber 0·5 in. in diameter and 2 in. long. The sample was sealed in a length of platinum tubing, ½ in. × ⅛ in., which was placed inside the talc-sheathed graphite furnace, which serves both for heating the sample and transmitting pressure to it. The absorption of latent heat accompanying melting was detected by differential thermal analysis. The sample temperature and the differential temperature were recorded simultaneously on a strip-chart recorder. The record of differential temperature analysis shows the latent heat accompanying melting as a break in the slope, or reversal of trend. Thus the melting point can be determined accurately. The high-pressure apparatus and the experimental techniques have been described in detail by Kennedy and Newton[3]. Semiconductor grade polycrystalline indium antimonide supplied by the Indium Corporation of America was used. Kennedy and Newton used platinum containers for the melting-point determination of both indium and antimony and have found platinum an inert container for both metals.

Volume-change of transition was used to locate the lowest five points of Fig. 1, because of the small heat of transition and the advantage in accuracy in intersecting a phase-boundary at a high angle. Powdered indium antimonide was intimately mixed with silver chloride and the mix was compressed into a pellet of the shape and dimensions needed to fill the high-pressure chamber. A heating tape was wound on the steel supporting-ring of the 'Carboloy' core. In this way, a temperature of nearly 200° C. at the sample site could be reached. Ram pressure and piston displacement were recorded on an x–y recorder. Piston friction was eliminated by a piston rotation method[4] and wall-friction was reduced by a 0·001 in. lead-foil wrapping. A change of state is revealed by a break in the pressure versus displacement curve.

Fig. 1 shows the melting curve of indium antimonide obtained in the present investigation. It will be seen that the melting point goes down until a pressure of 19·4 kb. is reached and rises thereafter with increasing pressure. By inserting the initial value of the slope of this melting curve in the Clausius–Clapeyron equation and using the known volume contraction on melting ($\Delta V/V_{\text{solid}} = 0{\cdot}13$), the latent heat is calculated to be 49·0 cal./gm., which is in good agreement with the experimentally determined value of 47·2 cal./gm.. To make doubly certain of the existence of melting above 300° C. at 40 kb., a special run was made in which a pure sample was compressed to 40 kb. at room temperature, and then heated. A thermal rest was encountered at 380° C., exactly as in the run on a sample of complicated pressure-temperature history.

Below 335° C., application of pressure transforms indium antimonide to another solid phase. We designate this new high-pressure form indium antimonide II, the normal form indium antimonide I.

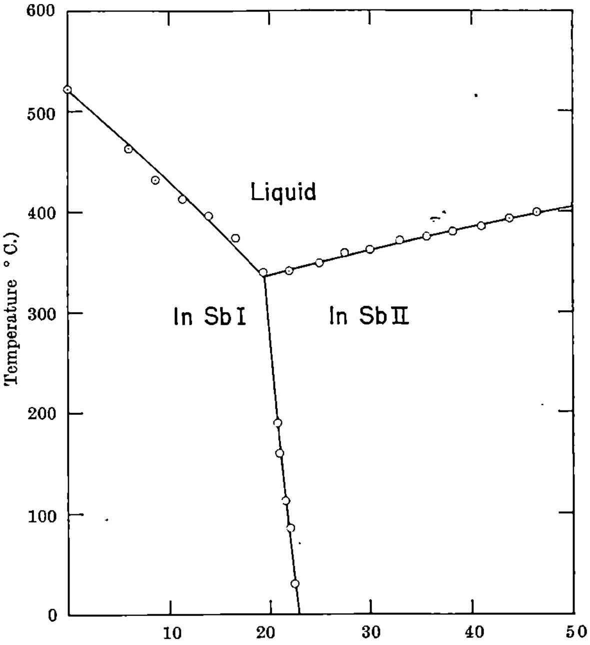

Fig. 1. Phase diagram of indium antimonide

The solid–solid boundary was located by using the volumetric method briefly mentioned earlier. This boundary intersects the melting curve at 335° C. and 19·4 kb. The solid–solid transition has a large change in volume associated with it, and an estimate from measured displacement in transition gives $\Delta V/V \approx 20$ per cent, which is probably a minimum. It was found that a rise in temperature of 150° produced a great increase in the sharpness of the transition as recorded volumetrically. This is almost certainly due to higher transition velocity at higher temperature. The transition was so sluggish at room temperature that the pressure of transition could not be determined with nearly the precision at 80° C. This effect probably accounts for the very high-pressure values for drop in resistivity obtained by Gebbie *et al.* at 150° K.

It is well known that the intermetallic compounds formed among group III and V elements have properties resembling the corresponding members of the group IV elements. Indium and antimony occupy positions in the III and V group, sandwiching tin, which is the corresponding member of the fourth group IV. We may therefore expect indium antimonide to exhibit properties analogous to tin. Tin has two forms, grey tin and white tin, designated respectively α and β. White tin transforms to grey tin below 13° C. The latter has diamond structure and is a semiconductor while the former has a body-centred tetragonal lattice exhibiting metallic properties. The change-over from grey to white tin is accompanied by a large reduction in volume, amounting to 27 per cent. The transition in indium antimonide is strongly reminiscent of transformation from grey to white tin both in regard to the change from a state of semiconduction to metallic conduction and the large reduction in volume accompanying it. We believe from these considerations that the transformation which takes place in indium antimonide at high pressure is similar to the grey-white tin transition: indium antimonide I having zinc-blende structure corresponding to grey tin transforms to indium antimonide II having the structure of white tin.

A New Photometric Technique using a Variable Shutter Device

THE present standard of accuracy in spectrophotometric measurement is unsatisfactory, partly because of the limitations of conventional techniques. In the measurement of spectral transmission of coloured filters, for example, the precision obtainable from commercially available instruments is limited to ± $1/10^3$ of full-scale reading, while the accuracy depends, *inter alia*, on the linearity of a detector-amplifier system or an attentuator-comb. This is found to be inadequate and an alternative approach to the problem is suggested.

In our proposed technique the quantity measured is, effectively, time, while the detector is used as a null indicator. The steady light flux passing through the filter to be measured is compared with the mean flux contained in the same beam when the filter is replaced by a repetitive shutter, the 'open to shut' time-ratio of which can be varied. This ratio is adjusted to make the mean flux reaching the detector the same in the two cases. The transmission factor of the filter, τ, is then obtained by measuring, r, the 'open to shut' time-ratio of the shutter $\left(\tau = \dfrac{r}{1+r}\right)$.

Three major considerations are: (1) The photocell system adopted must average the pulsed flux correctly, in other words, it must obey Talbot's Law[1]; it need not, however, exhibit d.c. linearity. (2) Since variable shutters of the type required are not available, one must be devised. (3) The timing measurement must be capable of very high accuracy and precision.

As a result of recent work we have been able to show that Talbot's law is obeyed closely by a vacuum photocell, provided the rate of repetition of the pulses is high enough. This is because the 'fatigue' processes producing non-linearity in photocells have a relatively long time constant. This result was foreshadowed by the work of Carruthers and Harrison[2] and Stiles[3], who showed that some cells which were markedly non-linear when used under steady-state conditions did in fact obey Talbot's Law to their limit of accuracy when the light was interrupted at a frequency of a few cycles a second. Preston and Gordon-Smith[4] have suggested that 'fatigue' effects may be caused by the accumulation of a quasi-static electron charge on insulating surfaces inside the photocell: such a process might have a time constant of hundreds of seconds.

As yet the ideal variable shutter does not exist, although some commercial types of high-speed shutter have operating times shorter than 10^{-8} sec. so that the prospect of developing a suitable type for our purpose appears hopeful. Since the shutter ratio could be measured for each transmission reading, it need not retain its calibration for long periods, nor is absolute constancy in operation essential, since the time-ratio measuring technique gives a mean value.

In order to test the possibility of making an accurate time-ratio measurement, we have successfully used a rotating sector disk interrupting a light beam at a very small image to 'imitate' a shutter. Although this 'shutter' was non-ideal, in that the occulting of the image by the sector edge took an appreciable time compared with the repetition period, it was possible to measure it with the same precision as with the most precise d.c. photometry.

Two sectors, having transmissions of 1·5 per cent and 3 per cent respectively, were measured (*a*) by a high-precision laboratory method of d.c. photometry, using a photometer similar to that described by Jones and Sanders[5], and (*b*) by using a simple timing technique developed this year. The transmission values obtained by these methods agreed to within the experimental tolerances (± $1/10^5$ of full scale reading), and these values were found to correspond closely with the results of direct measurement of the sector angles.

We conclude, therefore, that the new method is already capable of the same accuracy as the best conventional photometry and that, suitably developed, its potential precision and accuracy are much higher.

CHEMISTRY

Determination of Uranium as Pyrophosphate

WITH reference to the communication in *Nature* of June 24, p. 1188, on this subject, the following extract from Soddy's *Chemistry of the Radio-Elements*, published 1911, p. 33, may be of interest.

"This pouring of a solution of uranium containing a complex mixture of other constituents into excess of an alkaline carbonate is always a valuable first step in the separation of the uranium, and when the latter element is the only one being separated or estimated, it affords a ready means of obtaining the whole of the uranium in the filtrate in a state of approximate purity. For analytical estimations it is almost always an advantage to add some ammonium sulphide to complete the precipitation of the iron. Any suitable method can then be employed for the separation and estimation of the uranium in the filtrate. One of the most commonly employed is, after acidification and removal of the carbon dioxide, to add microcosmic salt (sodium ammonium hydrogen phosphate), to neutralize as nearly as possible with ammonia without causing a permanent precipitate to form, and then to add a considerable excess of sodium thiosulphate. Boiling for ten minutes brings down the whole of the uranium as phosphate with a bulky sulphur precipitate which settles and filters excellently. After washing, the precipitate is ignited at a dull red-heat and weighed as the 'green phosphate', a body which has been found empirically to correspond with 68·55 per cent of uranium, and which is far less hygroscopic than the pyrophosphate. When pure it dissolves completely in concentrated nitric acid, but when impure the solution is more difficult. Evaporation of this solution and ignition leaves the yellow pyrophosphate $(UO_2)_2P_2O_7$, which contains 66·81 per cent of uranium. The conversion of the 'green phosphate' in the crucible into the yellow pyrophosphate affords a check on the estimation, but the latter body is excessively hygroscopic and difficult to weigh. (For further details, Brearley's *Analytical Chemistry of Uranium* should be consulted.)"

The slight variations in percentage of uranium quoted may probably be due to difference in the atomic weights used. It would appear from this that the "green phosphate" coincides closely with the precipitate obtained by Wright, Hayes and Ryan.

F. M. Brewer

Inorganic Chemistry Laboratory,
South Parks Road,
Oxford.

We thank Dr. Brewer for directing our attention to the reference in Soddy's publication. The passage quoted would seem to be a recapitulation of Brearley's work, published in 1903, with which we are acquainted.

It would appear also that Soddy has erroneously quoted the "green phosphate" as being formed at "dull red-heat" whereas Brearley states that the "pure yellow form" is obtained at "low redness". He attributes the formula $(UO_2)_2P_2O_7$ to the yellow residue. If the ignition is carried out at a higher temperature (at no time does he quote a precise temperature) then the green residue is obtained. Brearley does not assign a formula to the green phosphate, but states that it contains 68·55 per cent uranium.

We have confirmed that treatment with nitric acid yields the yellow form, which is hygroscopic. Thermogravimetric data would lead us to believe at present that stoichiometric $(UO_2)_2P_2O_7$ (66·67 per cent uranium) is never obtained by direct ignition. A yellow-green non-hygroscopic form containing 67·2 per cent uranium has been obtained by ignition at temperatures between 500° C. and 800° C. So far, only the green phosphate (68·21 per cent uranium), obtained by ignition at temperatures in excess of 950° C., has been studied in any detail. The original communication was intended to direct attention to the presence of both tetravalent and hexavalent uranium in the green product.

Differences in atomic weights between 1903 and the present day would not explain the apparent differences in uranium content.

Role of Pressure Gradients in obtaining Minimum Time in Gas Chromatography

Although a great deal of attention[1-5] has been focused on obtaining separations in the least possible time, the theory of minimum-time operation has not been developed for inlet/outlet pressure ratios greatly exceeding unity. Such a theory does not immediately seem widely applicable since most rapid separations made with an outlet pressure of one atmosphere do not require an inlet pressure greatly exceeding one atmosphere. This conclusion is incorrect, however, since a search for the optimum values of all parameters reveals that the optimum outlet pressure is very close to zero in all circumstances. Furthermore, the difference in minimum retention times found with an outlet pressure of one atmosphere and zero is large enough in many cases to be significant in obtaining more rapid analyses.

The apparent or measured plate height, $\hat{H}$, is related to the inlet/outlet pressure ratio, P, as follows[6]:

$$\hat{H} = \frac{9}{8} H_0 \frac{(P^4-1)(P^2-1)}{(P^3-1)^2} + \frac{3}{2} C_l v_i \frac{P(P^2-1)}{(P^3-1)} \qquad (1)$$

where C_l is the mass transfer term for the liquid, v_i the inlet gas velocity, and H_0 is the sum of all plate height terms remaining constant throughout the column. Although the theory is applicable to both packed and capillary columns, the equations below are derived specifically for capillary columns in which $H_0 = B/pv + C_g pv$.

Following the method of reference 5, modified by the inclusion of the appropriate P terms, the time required for the elution of the first peak of a pair is :

$$t = \frac{N}{R}\left[\frac{3}{4} \frac{H_0}{v_i} \frac{(P^4-1)}{P(P^3-1)} + C_l\right] \qquad (2)$$

where N is the number of plates required for separation and R is the ratio of zone to gas velocity. This equation can be used to optimize a wide spectrum of variables. Its use is somewhat complicated by the dependence of v_i on P with N fixed. It can be proved, however, that with any fixed inlet pressure, p_i (even if this is the optimum value for atmospheric outlet), a separation can be accomplished in the least possible time if the outlet pressure, p_0, is zero (in practice, near zero). The corresponding separation time, t, and column-length, L, may be written :

$$t = (N/R)(3H_0/4v_i + C_l) \qquad (3)$$

$$L = N(9H_0/8 + 3C_l v_i/2) \qquad (4)$$

Following this, the inlet pressure can be optimized. Its best value is $p_i = \rho p_c$, where the critical pressure, $p_c = (6/r_0)(\eta D_{g1} N)^{1/2}$, is the smallest inlet pressure capable of giving a separation. The quantity ρ is obtained from a graph of the function, $\rho^2 = 3 + 8s/3\rho$, where $s = C_l/C_g p_c$. The capillary radius has been written as r_0, the viscosity as η, and the diffusion coefficient of solute at unit pressure as D_{g1}. The inlet velocity may be obtained, once p_i is known, from the equation:

$$v_i = \left[\frac{2D_{g1}(\rho^2-1)}{C_g p_i^2 + 4C_l p_i/3}\right]^{1/2} \qquad (5)$$

If one elects to maintain an outlet pressure of one atmosphere, the time t becomes:

$$t = \frac{NC_l}{R}\left[\frac{S_1(\rho S_1/s + 1)}{(S_2\rho^2 - S_1)} + \rho S_1/s + 1\right] \qquad (6)$$

where $S_1 = 3(P^4-1)/4P(P^3-1)$ and $S_2 = 3\ (P^3-1)/4P^3$. The minimum value of t is obtained numerically by substituting various values of P into (6).

A comparison of minimum times can now be made between atmospheric and vacuum outlet. Typical capillary parameters are chosen as follows: $C_g/C_l = 10^{-6}$, $D_{g1} = 10^5$, $\eta = 10^{-4}$, $r_0 = 10^{-2}$, all in C.G.S. units. First, assume that easy separation requires 10^3 plates. The least time obtainable with $p_0 = 10^6$ dynes/cm.² (very close to one atmosphere) has been obtained from (6) as $t = 2{\cdot}08NC_l/R$. The corresponding P is approximately 1·08. With a vacuum outlet, the minimum $t = 1{\cdot}26NC_l/R$ and $p_i = 2{\cdot}30 \times 10^5$ dynes/cm.² ($\simeq 0{\cdot}25$ atm.). Thus the time required with atmospheric outlet is 1·66 times larger than the vacuum outlet time.

Assume that a more difficult separation requires $N = 10^5$. With $p_0 = 10^6$ dynes/cm.², the best parameters are $t = 2{\cdot}90NC_l/R$ and $P = 1{\cdot}8$. With $p_0 = 0$, the best parameters are $t = 2{\cdot}51NC_l/R$ and $p_i = 1{\cdot}34 \times 10^6$ dynes/cm.² ($\simeq 1{\cdot}3$ atm.). The time ratio in this case is 1·15.

The above examples show that time for analysis can be reduced by operating the outlet at very low pressures. The reduction in time depends on a number of factors. As shown above, it is least for very large plate requirements. This is true since the inlet pressures approach one another for very large plate requirements, and there is very little difference in the average performance of the columns. The reduction in time increases, also, with s, a measure of the relative mass transfer resistance in the gas phase compared with the liquid phase. In the examples above, the two terms are assumed equal ($s = 10^{-6}$) at atmospheric pressure.

Inhibition of Ultrasonic Decolorization of Rhodamine *B* in Presence of Organic Substances

Ultrasonic waves obtained from Mullard's high-frequency ultrasonic generator type *E*-7562 with a barium titanate transducer having a frequency of 1 Mc./sec. were passed into the aqueous solution of rhodamine *B* and it was found that the solution was decolorized after some time. These waves were found to decolorize aqueous solutions of congo red, chrysoidine, aniline blue and brilliant green also[1]. 20 ml. of an aqueous solution (0·0064 gm./l.) of rhodamine *B* and 5 ml. distilled water in a Jena glass bottle were held vertically above the transducer and the position so adjusted as to produce maximum fountain inside the vessel on passing the ultrasound. When, however, 20 ml. of the same solution and 4 ml. of distilled water were taken and 1 ml. of methyl alcohol, ethyl alcohol, *n*-propyl alcohol, *n*-butyl alcohol, diacetone alcohol, acetone, dioxan or ether were added separately, and the mixtures exposed to ultrasonic radiation under the same conditions as before, very little change in colour was observed, even when the time of exposure of the solutions containing these substances was almost doubled (Table 1). The colorimetric readings were recorded on a Klett Summerson photoelectric colorimeter using a No. 54 filter, which covers a range of 520–580 mμ. Readings for the dye solution exposed without adding any organic substance are shown in the second column (blank).

Table 1

		Colorimetric readings in presence of:							
Exposure (min.)	Blank	Methyl alcohol	ethyl alcohol	*n*-propyl alcohol	*n*-butyl alcohol	Diacetone alcohol	Acetone	Dioxan	Ether

Virtanen and Ellfolk[2] noted that the ultrasonic oxidations caused by cavitation may be inhibited by substances with a high vapour pressure. Oxidative nitrogen fixation in an ultrasonic field is inhibited by more than 50 per cent by volatile substances such as aliphatic fatty acids, aldehydes, alcohols and aromatic hydrocarbons. Bresler[3] observed that by the addition of substances of high vapour pressure, such as ether or ammonia, the breakdown of the cavitation bubbles is prevented, and the luminescence of luminol otherwise produced by ultrasonic vibrations is prevented. Mellaerts[4] has reported that water treated with ultrasonic waves exhibits a non-uniform luminescence. This luminescence can be suppressed by the presence of some substances with high vapour pressure, for example, ether and acetone. In our case also, the substances added are of high vapour pressure and they prevent the breaking of the cavities and hence the inhibition of the decolorization of rhodamine *B* solution.

We thank the Ministry of Scientific Research and Cultural Affairs, India, for a scholarship to one of us (Sheo Prakash).

Viscosity-Temperature Relationships for Dilute Solutions of High Polymers

Investigations of the viscosities of dilute solutions of cellulose derivatives[1,2] over a range of temperature have shown that the pre-exponential term A and the apparent activation energy of viscous flow Q in the viscosity-temperature relationship:

$$\eta = Ae^{Q/RT} \qquad (1)$$

where η is the viscosity, depend on both the concentration c of the polymer and its molecular weight M. $(Q - Q_0)$, where Q_0 is the value for the solvent, is generally a linear function of c in the range 0·1–0·4 gm./dl. and is a function of M. The value of A

Table 1. VALUES OF $(Q-Q_0)$ AND $(A-A_0)$ FOR 1 PER CENT SOLUTIONS OF POLYMERS

Polymer	$\bar{M}_n$	Solvent	$(Q-Q_0)$ (k.cal.)	$(A-A_0)$ ($\times 10^5$)
Polyvinyl acetate	148,000	acetone	0·3	2·6
		chloroform	0·3	9·6
		dioxan	0·2	2·0
Polymethyl methacrylate	121,000	acetone	−0·16	11·0
		toluene	−0·1	9·6
		benzene	nil	4·9
Polyisobutylene	90,000	cyclohexane	0·16	3·0
Ethyl cellulose, 48·4 per cent ethoxyl content	119,000	ethyl methyl ketone	3·7	−10·9
		butyl acetate	3·6	− 8·3
		benzene	3·8	− 7·8
Cellulose nitrate, 12·2 per cent nitrogen content	132,000	acetone	1·4	3·3
		butyl acetate	4·25	− 8·0
Cellulose nitrate, 13·8 per cent nitrogen content	130,000	acetone	4·0	−21·5
Cellulose triacetate	107,000	chloroform	1·4	− 9·6

generally decreases with increase of both *c* and *M* and $-\log A$ is a linear function of *c* and a more complex one of *M*.

Extension of such work to dilute solutions of other polymers shows that the variations in *A* and *Q* obtained when flexible, less polar polymers are used differ markedly from those obtained for comparable solutions of cellulose derivatives. Table 1 gives values of $(A - A_0)$ and $(Q - Q_0)$ for 1 per cent (w/v) solutions of fractions, of similar number average molecular weight, of polyvinyl acetate, polymethyl methacrylate and polyisobutylene. Estimated values for 1 per cent solutions of fractions of ethyl cellulose[1], a cellulose nitrate with 12 per cent nitrogen, a cellulose nitrate with 13·8 per cent nitrogen and cellulose triacetate are also given. Values of $(Q - Q_0)$ for the cellulose derivatives are all positive and about ten or more times greater than those for the other polymers, which may be positive, zero or negative. Values of $(A - A_0)$ for the other polymers are all positive, in contrast to the negative values associated with all the cellulose derivative systems with the exception of the 12·2 per cent nitrogen nitrate in acetone.

Reasons for such differences are not clear, but they may be connected with differences in chain flexibility and extension. Chains of cellulose derivatives are stiff, adopting extended forms in solution, even in thermodynamically poor solvents[3]. Chains of the other polymers are flexible and adopt much more coiled forms in solutions. Stiff, extended chains, which are likely to overlap at the concentrations considered, might be expected to cause greater interference with flow, leading to larger values of $(Q - Q_0)$ than less-extended flexible chains. The reasons for negative values of $(Q - Q_0)$ for polymethyl methacrylate in acetone and toluene are also not clear, but such negative values might be related to solvent power. Intrinsic viscosities for the fraction of polymethyl methacrylate in acetone and toluene at 25° C. are 0·26 and 0·29 respectively, that for the fraction in benzene being 0·39. Acetone and toluene may be regarded as poor solvents in which the chains are tightly coiled, and such coiling may, in some way, lead to a reduction in *Q* as *c* increases.

In terms of rate theory[4]:

$$\eta = (Nh/V)e^{-\Delta S/R}e^{Q/RT} \qquad (2)$$

where *N* and *h* are the Avogadro number and Planck's constant, *V* the molar volume of the liquid and ΔS the entropy of activation of viscous flow. From equations (1) and (2):

$$A = (Nh/V)e^{-\Delta S/R} \qquad (3)$$

In the dilute solutions considered, *V* will differ little from the value for the solvent and the value of *A* should depend largely on that of ΔS. If this were so, flexible chains presumably would cause a decrease and stiff chains an increase in ΔS. From equation (3):

$$-\log A = -\log (Nh/V) + \Delta S/R \qquad (4)$$

With cellulose derivatives[1,2] $-\log A$ is generally a linear function of *c*, so that ΔS may increase linearly with concentration.

Although the reasons for such marked differences between the two types of polymers are not clear, the view that they are connected with chain flexibility and extension is supported by the differences between the values of $(Q - Q_0)$ and $(A - A_0)$ for the two cellulose nitrates in acetone. Chain stiffness and extension of cellulose nitrate have been shown to increase with increasing degree of substitution[5]. The exponent *a* in the Mark–Houwinck equation:

$$[\eta] = KM^a \qquad (5)$$

is 0·80 at 25° C. for the 12·2 per cent nitrogen nitrate in acetone[2]. This value is the upper limit for flexible chains[6], suggesting some degree of flexibility and coiling. The value of *a* at 25° C. for the 13·8 per cent nitrogen nitrate in acetone is 0·92 (ref. 5), implying much more extended and stiffer chains. The value of $(A - A_0)$ for the nitrate with 12·2 per cent nitrogen is positive, like those for the flexible chain polymers, and the value of $(Q - Q_0)$, although comparatively large, is considerably less than that for the 13·8 per cent nitrogen. The value of the exponent *a* at 25° C. for the 12·2 per cent nitrate with 12·2 per cent nitrogen in butyl acetate is 0·91, and the value of $(Q - Q_0)$ is much larger than that for the same nitrate in acetone, while that of $(A - A_0)$ is negative.

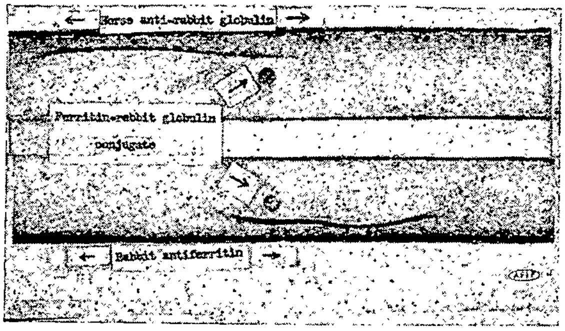
BIOCHEMISTRY

A New Two-Stage Method for Cross-linking Proteins

THE combination of two different proteins with each other via covalent bonds is useful for certain immunological work[1-4]. This type of chemical reaction requires a bifunctional compound which, by stepwise coupling first with one and then with the other protein molecule, will form a bridge between them. Among the compounds used for this purpose have been *bis*-diazotized benzidine[1] and difluorodinitrobenzene[2]. Howard and Wild[3] developed a method consisting of three steps: one protein was coupled with *bis*-diazotized benzidine at acid *p*H, the second protein was coupled with a derivative of



Horse anti-rabbit globulin
Ferritin-rabbit globulin conjugate
Rabbit antiferritin

Fig. 1. Immunoelectrophoresis of a crude ferritin–rabbit globulin conjugate prepared by the use of BDD. (Precipitin arcs were stained with amido black)

pyrrole at basic *p*H, and then the products of both additions were coupled with each other.

The recently introduced method of labelling antibodies with electron-dense protein ferritin[4] created a need for a coupling reagent that would be efficient and also mild enough to preserve the antibody activity. Singer[4] used for this purpose *m*-xylylene di*iso*cyanate, but he had to take precautions to avoid inactivation of antibodies by this reagent. The use of toluene 2,4-di*iso*cyanate (TDI) improved the coupling efficiency[5], but did not remove the risk of adversely affecting the antibody. The use of diazonium coupling would be preferable, since this is a mild reaction that has relatively little effect on antibody activity[6].

In my laboratory the attempted use of *bis*-diazotized benzidine for the above purpose was not successful, possibly because its reaction with ferritin proceeded too fast, leaving an inadequate number of free functional groups for subsequent coupling with immune globulin[7]. The use of *bis*-diazotized 3,3′-dimethoxy derivative, dianisidine (BDD), however, gave the desired result. The *o*-methoxy group is known to slow down the diazonium coupling ten-fold[8], whereas Pearse[9] showed that BDD reacts at acid *p*H with only one end, while at alkaline *p*H both diazonium groups react.

A solution of 160 mgm. ($2{\cdot}8 \times 10^{-4}$ m.mole) ferritin and 80 mgm. (5×10^{-4} m.mole) rabbit globulin in 7 ml. 0·1 *M* citrate buffer, *p*H 5·0, was treated at 4° with 1 ml. aliquot of a solution of 6·7 mgm. ($2{\cdot}8 \times 10^{-2}$ m.mole) dianisidine and 3·8 mgm. ($5{\cdot}5 \times 10^{-2}$ m.mole) sodium nitrite in 10 ml. of 0·017 *N* hydrochloric acid. The solution was stirred in the cold for 2 hr., and then dialysed overnight against 0·08 *M* borate, *p*H 9·4, and finally against neutral saline. The crude product gave the immunoelectrophoretic pattern shown in Fig. 1. The component of intermediate mobility, which reacted with both antiferritin and anti-rabbit globulin, is the conjugate; the slow component is the uncoupled globulin, and the fast component the uncoupled ferritin. The three components were separated by means of continuous-flow electrophoresis[7]. The middle fraction was then concentrated (by dialysis against 30 per cent polyvinylpyrrolidinone) and dialysed against neutral saline.

A conjugate prepared by the use of BDD from globulin containing antibody against tobacco mosaic virus was more homogeneous when tested by 'Millipore' filtration and viewed under the electron microscope, and it had a higher antibody activity than a similar conjugate prepared with TDI (Hartman, R. E., personal communication). Another conjugate, prepared by means of BDD from globulin containing Forssman antibody, had a hæmolysin titre twice as high as did one obtained by the use of TDI. The use of BDD avoids any loss of protein by precipitation during and after the reaction; by making the medium monophasic, it also facilitates the control of the degree of coupling.

A Biochemical Effect of Deuterium

AMONG the naturally occurring steroid hormones and metabolites the androgens are unique in that 3-hydroxy-5α-androstanes exhibit high hormonal activity, the 3α-hydroxy (axial) compounds being highly active while the 3β-hydroxy (equatorial) compounds are much weaker androgens. It is known from both chemical and microbiological work[1] that the 3α-alcohols are oxidized more readily to the corresponding 3-ketone than are the 3β-alcohols, in accordance with the thermodynamic prediction. It is further known that enzymic oxidation of 3-hydroxy-5α-androstanes occurs in mammalian tissue, in particular in the liver. This suggests the possibility that *in vivo* these compounds are oxidized in various degrees to the even more potent androgens, the 3-keto-5α-androstanes, and that, in fact, the 3-alcohols may be androgenically inactive *per se*.

To test this hypothesis, 3α-deutero-17α-methyl-5α-androstane-3β,17β-diol (I) (m.p. 213–214°, α_D −13°), prepared by the lithium aluminium deuteride reduction of 17α-methyl-5α-androstan-17β-ol-3-one (III), was assayed in the castrated-rat in parallel with the corresponding 3α-hydrogen-17α-methyl-5α-androstane-3β,17β-diol (II) (m.p. 213–214°, α_D −14°). Should the activity of these compounds depend on oxidation to the 3-ketone with loss of the 3α-hydrogen or 3α-deuterium as the rate-determining step, then, in accord with the primary deuterium isotope effect[2], the 3α-deutero compound (I) should be oxidized more slowly and consequently would be expected to exhibit lower androgenic activity than the 3α-hydrogen compound (II).

Male albino rats were castrated at 22–24 days of age, and, beginning on the day of surgery, the compounds were injected subcutaneously once daily for seven consecutive days. The vehicle was an aqueous suspending medium consisting of sodium chloride (0·9 per cent), polysorbate 80 (0·4 per cent), carboxymethylcellulose (0·5 per cent) and benzyl alcohol (0·9 per cent), and the daily dose was contained in 0·5 ml. Twenty-four hours after the last injection the rats were killed with ether and the ventral

$$* \text{ Tissue ratio} = \frac{\text{mgm. of tissue}}{\text{gm. of body-weight}}$$

prostate, seminal vesicles, and levator ani were removed and weighed wet after blotting.

Compound II was 3·36 (+1·64; −1·10 ($P = 0{\cdot}95$)) times more active than the deutero compound I on the basis of the ventral prostate and 4·65 (+1·67; −1·25 ($P = 0{\cdot}95$)) times more active on the basis of response of the seminal vesicles (Table 1), demonstrating that in the rat oxidation to the 3-ketone is an important, if not the sole, factor contributing to androgenicity of 3β-hydroxyandrostanes.

In the chicks' comb assay, by local inunction[3], no significant difference could be established between the activities of I, II and III. When the potency of compound II was assigned a value of 1, the relative potency of compound I was 1·03 (+0·51; −0·33 ($P = 0{\cdot}95$)) and that of compound III was 1·04 (+0·46; −0·32 ($P = 0{\cdot}95$)). This indicates that in this species either the 3β-hydroxy-androstanes are active *per se* or more likely that oxidation to the 3-ketone in the comb is rapid and essentially complete.

It was of interest that we could not establish any difference in androgenic activity between testosterone and 17α-deutero-testosterone in the castrated rat by either the oral or subcutaneous route, nor could Bollinger and Wendler[4] increase the anti-inflammatory activity of hydrocortisone by conversion to the 11α-deutero analogue.

Separation of Linear from Branched Polysaccharides by Precipitation as Iodine Complexes

A MAJOR problem in studying polysaccharides is the isolation of individual polysaccharides from mixtures. In connexion with work on hemi-cellulose *B* it was observed that a solution of this polysaccharide in aqueous calcium chloride was partially precipitated by adding iodine–potassium iodide, and thus a separation of polymer types may have occurred.

Whistler and Lauterbach[1] have indicated that corn-cob hemi-cellulose (xylose 65·2 per cent, arabinose 13·3 per cent, glucuronic acid 9·8 per cent, galactose 2·9 per cent, glucose 8·6 per cent) contains three components: polymer I (xylose 89·4 per cent, arabinose 10·6 per cent, glucuronic acid 1 per cent), polymer II (not characterized, but probably a glucan), and polymer III (xylose 59·1 per cent, arabinose 21·9 per cent, glucuronic acid 11·3 per cent, galactose 7·6 per cent). A 200 mgm. sample of purified hemi-cellulose *B* prepared according to these authors was dissolved in 20 ml. of aqueous calcium chloride (specific gravity 1·3). On addition of 2 ml. of iodine solution (3 gm. iodine and 4 gm. potassium iodide in 100 ml. water) a dark blue complex precipitated which was separated by high-speed centrifugation (20,000*g*). The clear supernatant solution was decanted and the excess iodine destroyed by adding sodium thiosulphate. Pouring the solution into four volumes of ethanol resulted in precipitation of a polysaccharide consisting of uronic acid, galactose, arabinose and xylose residues, the galactose, arabinose and xylose being in the ratio of 1: 2·7: 7·9. This is essentially the same as the ratio 1: 2·9: 7·8 obtained by Whistler and Lauterbach for polymer III, a highly branched polysaccharide. The amount of precipitate available was too small to determine uronic acid by evolution of carbon dioxide.

The blue iodine complex decomposes when suspended in water. From it may be regained a polysaccharide consisting of glucose, a trace of uronic acid, arabinose and xylose residues. The ratio of arabinose/xylose is 1: 8·4, similar to the ratio found by Whistler and Lauterbach (1: 7·8) for polymer I, essentially a linear polysaccharide. The glucose in the iodine precipitate may represent a degraded cellulose. In this case, it appears that the linear polysaccharides are precipitated by iodine, and the branched ones remain in solution.

There are numerous references in the literature to reaction of iodine with hemi-celluloses to give blue complexes ('amyloid reaction'). This reaction is usually ascribed to the presence of glucose residues.

However, a purified, glucose-free hemi-cellulose *A*, as described by Whistler and me[2] can be partially dissolved in calcium chloride solution and gives a heavy blue-black precipitate with iodine.

It was of interest to see whether iodine precipitates other polysaccharides from a solution of calcium chloride. Ivory nut, mannan, which is described as a linear polymer[3], was quantitatively precipitated. Guaran, a chain of mannose units with galactose side-chains[4], and a highly branched mannan from bakers' yeast[5], remained in solution when treated with iodine as described. Therefore, it appears that reaction with iodine in a solution of calcium chloride discriminates between linear and branched polysaccharides and may be a useful means of separating and characterizing these materials.

I thank Prof. R. L. Whistler for providing a sample of pure guaran.

Effect of 5-Fluorouracil on Hepatic Induced Increase of Tryptophan-Pyrrolase

THE competitive inhibition of tryptophan-pyrrolase, adaptive formation by ethionine[1] and preferential incorporation of valine-^{14}C into the enzyme protein after injection of the inducing agent[2] would indicate that this increase of enzymic activity is brought about through the synthesis of a new enzyme protein.

Poznanskaia[3], on the contrary, is of the opinion that such increase is a result of some activation of preformed proteins; while, according to Straub[4], the liver contains a large amount of inactive enzyme.

Recent investigations have demonstrated that purine and pyrimidine analogues are capable of inhibiting protein synthesis, by interfering with the metabolism of nucleic acid. It has been demonstrated in particular that induction of β-galactosidase in micro-organisms may be inhibited by either 8-azaguanine or[5,6] 5-fluorouracil.

Thus the use of these antimetabolites provides a valuable means of elucidating the mechanism of induced increase in liver tryptophan-pyrrolase.

So far, experimental researches in this direction yielded contradictory results.

In animals given an LD_{50} of 8-azaguanine and 6-mercaptopurine, Lee[7] found a net increase in tryptophan-pyrrolase; Feigelson, Dashman and Margolis[8], on the contrary, did not find any modification when non-toxic amounts of 8-azaguanine were used. Only recently, Kwam and Parks[9], treating adrenalectomized rats with 8-azaguanine, obtained a significant inhibition of glucose-6-phosphatase induction by hydrocortisone, and on tryptophan-pyrrolase induction by the substrate.

In our work we used 5-fluorouracil as antimetabolite because of the capacity of this compound of producing particular and noticeable inhibition of protein synthesis.

Control + tr.	5	9	23·6 ± 3·1	0·05
5-FU + tr.	6	9	18·9 ± 4·7	

The 5-fluorouracil was administered intraperitoneally in one dose (25 mgm./100 gm.) to groups 2 and 6; daily for 3 days to group 4.

Activity of tryptophan-pyrrolase was assayed 5 hr. after the L-tryptophan administration (100 mgm./100 gm.) in groups 3 and 4, and 4 hr. after in groups 5 and 6. Twenty hours before death, no food was given to the animals of all groups.

Table 2. EFFECT OF 5-FLUOROURACIL ON INDUCTION OF HEPATIC TRYPTOPHAN-PYRROLASE
(The 5-fluorouracil was administered during the decreasing phase of the substrate-induced tryptophan-pyrrolase curve)

Treatment	Group No.	No. of animals	μMoles kynurenine/gm. liver wet wt./hr.	*P*
Control + tr.	1	2	24·4 ± 1·0	
5-FU + tr. (FU 4 hr. after the 1 tr. injection)	2	2	19·1 ± 2·2	0·05
5-FU + tr. (FU 13 hr. after the 1 tr. injection)	3	2	20·9 ± 2·9	0·05

Tryptophan-pyrrolase activity was assayed 4 hr. after the second intraperitoneal administration of L-tryptophan (100 mgm./100 gm.). The second injection (100 mgm./100 gm.) was always made 17 hr. after the first administration, when the enzyme-level was returned to basal values.

5-fluorouracil appears to exert at least two distinguishable effects: it interferes with the normal synthesis of ribonucleic acid and inhibits the formation of thymidilic acid[10].

Male Sprague–Dawley albino rats weighing about 200 gm. were used for the experiments. The 5-fluorouracil was administered in one dose simultaneously with the tryptophan or daily for three days, the final injection being given together with the enzyme inducer.

Activity of tryptophan-pyrrolase was determined according to the method of Knox and Mehler.

Since the experiments of Feigelson, Feigelson and Fancher[12] showed an increased incorporation of inorganic phosphorus-32 into ribonucleic acid during the period following the maximal increase in tryptophan-pyrrolase, experiments were made, in which 5-fluorouracil was administered during that period and the enzyme formation was again induced afterwards.

As shown in Tables 1 and 2, 5-fluorouracil at the dosages used causes a limited but significant inhibition of enzyme induction, practically independent of the time of administration.

As the toxicity of 5-fluorouracil hinders the use of greater dosages, in order to obtain an increased inhibition we tried another experimental device.

Campbell and Kosterlitz[13], Munro and Clark[14], found that when rats are fed on a protein-free diet there is a breakdown of ribonucleic acid, which is resynthesized when the rats are again fed on a normal diet. It would therefore seem probable that, if rats were given a normal diet after a period of protein depletion, there would be a greater incorporation of 5-fluorouracil into ribonucleic acid with consequent greater inhibition in induction of tryptophan-pyrrolase, if this was really an *ex novo* protein synthesis controlled by ribonucleic acid.

The results in Table 3 demonstrate that this really happened. So far as the kinetic relationships between enzyme synthesis and ribonucleic acid metabolism are concerned, the results obtained do not reveal any modification in metabolism of ribonucleic acid either contemporary with or subsequent to the maximum increase in enzyme synthesis.

Table 3. EFFECT OF 5-FLUOROURACIL ON INDUCTION OF HEPATIC TRYPTOPHAN-PYRROLASE DURING PROTEIN REFEEDING

Treatment	No. of animal	Refeeding period days Rat's wt. (gm.)		µMoles kynurenine/gm. liver wet wt./hr.	*P*
		0	2		
Control + tr.	5	167	182	21·9 ± 4·1	0·001
5-FU + tr.	7	166	171	12·3 ± 2·8	

Rats fed on protein-free diet for 13 days were then given for 2 days a normal diet. During protein refeeding the second group daily received intraperitoneally 10 mgm./100 gm. of 5-fluorouracil.

Tryptophan-pyrrolase activity was assayed 5 hr. after the L-tryptophan injection (100 mgm./100 gm.). Food consumption was always the same for the two groups of rats.

Though the variability of response of single animals consequent on 5-fluorouracil stress makes advisable a more exact check, nevertheless these results agree with the observation that even marked changes in rate of synthesis of an enzyme would not necessarily require changes in synthesis of ribonucleic acid[15].

Furthermore, experiments of protein refeeding of rats previously depleted of protein would probably prove that inhibition of synthesis of tryptophan-pyrrolase occurs at the microsomal ribonucleic acid level.

Munro and Clark[14] found, in fact, that when the ribonucleic acid is reduced by feeding rats on a protein-free diet, loss of ribonucleic acid is essentially confined to the microsome fraction. When proteins are administered again, the microsomal ribonucleic acid is regenerated and in the presence of 5-fluorouracil we may well find the formation of a 'fraudulent' ribonucleic acid that hinders protein synthesis in general and largely inhibits synthesis of this specific protein tryptophan-pyrrolase.

5-fluorouracil was kindly given to us by F. Hoffmann-La Roche et Cie, Basle.

Collagen Fractions in the Skin of New-Born and Adult Rats

SINCE the early works on the soluble fractions of collagen were published, two fundamental theories have been put forward claiming that probable precursors might be found either in the neutral salt-soluble collagen or in the acid-soluble collagen. At present Jackson[1], and Gross[2], seem to have modified the earlier approach on the ground that the various solutions used for extraction differ only in their capacity to split the cross-linkings between the fibre chains. This points to the conclusion that the earliest precursors are to be found in the solutions of the weakest ionic strength that still keep their extraction capacity.

Jackson[3] observed that a protein fraction soluble in distilled water, obtained by treatment of carrageenin granuloma with 0·2 *M* sodium chloride *p*H 7·4 and in which hydroxyproline was present, was greatly increased during the first days of the development of the granuloma, predominating even over the other soluble fractions. On the other hand, Green and Lowther[4] found very little hydroxyproline in the same fraction when compared with high levels of proline. They reported also that distilled water could extract large amounts of protein proline from the granuloma with very little hydroxyproline.

These experimental facts might be connected with certain theoretical considerations based on the possible origin of the collagen hydroxyproline from proline[4], which lead to the assumption that the earliest precursors might be low molecular weight proteins or peptides with little hydroxyproline, if any, and with a high content of proline[5].

In the course of a work on the variations in total collagen content and its various soluble fractions in rat skin from embryonic to adult stages, some comparative results were found. They confirm the presence of this water-soluble fraction, rich in proline, in normal skin. Jackson's fractionation method[3], with slight modifications, was applied together with extractions of fresh skin with distilled water. The fractions were purified but not as thoroughly as in the original method. In this way the following observations were made:

(*a*) As was expected, a considerable increase of 'total' proline (Pr) and hydroxyproline (HPr) soluble in hot water at 1 atm. pressure with age represented

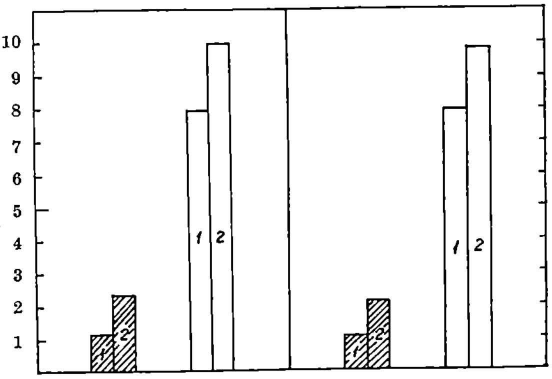

Fig. 1. Unfractionated rat skin. Left, 'total' proline and hydroxyproline; right, protein proline and hydroxyproline. Hatched areas, 22 one-day-old males (6·8 ± 0·4 gm.), 12·9 per cent dry defatted tissue; unshaded areas, 12 two-month-old males (2·8 ± 10 gm.), 26·8 per cent dry defatted tissue. 1 = HPr; 2 = Pr

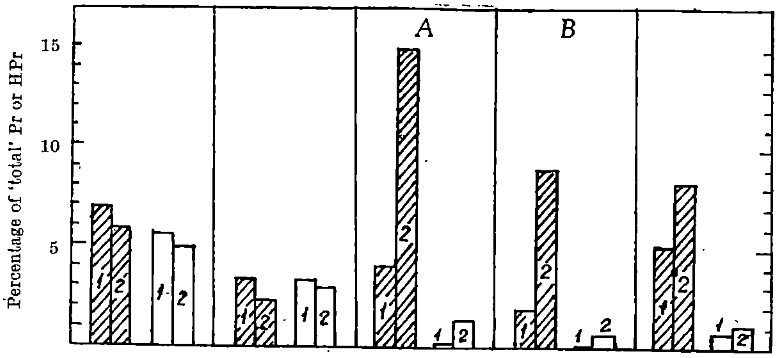

Fig. 2. Soluble collagens and water-soluble proteins. Hatched areas, one-day-old rats; unshaded areas, two-month-old rats. Left to right: neutral salt-soluble collagen (III); acid-soluble collagen (IV); water-soluble proteins (V); free amino-acids (VI). 1, HPr; 2, Pr

almost entirely by the protein fractions was found (Fig. 1). Multiplying the protein HPr content by 7·46 (ref. 6), 8·2 per cent and 58·6 per cent of collagen for the new-born and the adult rats respectively were obtained.

(*b*) Comparing both ages, no very significant differences between the acid- and neutral-soluble fraction percentages of 'total' Pr and HPr were found. The neutral salt-soluble collagen was slightly predominant over the acid-soluble collagen in new-born rats as well as in adult rats (Fig. 2).

(*c*) On the other hand a remarkable increase of the water-soluble fraction extracted with sodium chloride, *p*H 7·4, in 1-day-old rats was also observed. The most significant percentage of the soluble protein Pr corresponds to this fraction, being higher than that of the other soluble fractions (Table 1, V*A*). It showed a very high Pr/HPr ratio in both ages under study (Table 1).

Table 1. Pr/HPr Ratios of the Different Fractions

No.	Fraction	1 day-old rats	66-day-old rats
I	Total proline and hydroxyproline	1·99	1·26
II	Protein proline and hydroxyproline	1·90	1·24
III	Neutral salt-soluble collagen	1·80	1·05
IV	Acid-soluble collagen	1·30	1·10
V*A*	Water-soluble proteins extracted with sodium chloride *p*H 7·4	7·80	14·50
V*B*	Water-soluble proteins extracted with distilled water	8·50	13·50
VI	Free proline and hydroxyproline	3·30	1·50
VII	Insoluble collagen	1·15	1·15

Theoretical values of fibrillar collagen, 1·10–1·25.

(*d*) The distilled water also extracted a protein fraction with a high Pr/HPr quotient (Table 1, V*B*). In terms of Pr contents there is an almost four-fold increase in 1-day-old rats in comparison with 66-day-old rats, which is far greater than that corresponding to the water-soluble proteins extracted with sodium chloride *p*H 7·4 (Fig. 2). This is highly suggestive if we consider that the distilled water is the least effective agent in breaking up the fibres already laid down, extracting only the pre-existing material in soluble form.

(*e*) The 'total' Pr/HPr ratio in new-born rats is far greater than in adult rats due to the increase of the water-soluble fractions (Table 1). The same happens with the neutral salt-soluble collagen and in a smaller degree with the acid-soluble collagen. An attempt to investigate this ratio after an adequate purification process will be made in order to find out if differences in the chemical composition of these two soluble fractions could really exist.

(*f*) Free amino-acids, especially Pr, are increased in young rats (Fig. 2).

(*g*) The Pr/HPr ratio of insoluble collagen is the same in both ages, indicating no changes in fibrillar collagen composition (Table 1).

These preliminary observations are to be completed with the results obtained in other stages of development, together with the fractionation of water-soluble proteins. The data will be compared by labelling the various fractions of normal skin in connexion with autoradiographic and electron microscopical work in order to determine their biological significance.

Inhibition of β-Glucuronidase by Oral Administration of D-Glucosaccharo-1,4-Lactone

Levvy[1] showed that D-glucosaccharo-1,4-lactone was a very powerful inhibitor for β-glucuronidase. Recently, Boyland *et al.*[2] suggested that the oral administration of D-glucosaccharo-1,4-lactone should be effective in the prevention of bladder cancer. It is probable that D-glucosaccharo-1,4-lactone, when administered *per os*, would, even though the lactone ring may partly be opened, yet more or less inhibit the tissue β-glucuronidase. In that event, as a result of inhibition of hydrolytic action of the enzyme, excretion of glucuronide compounds in urine would be increased. The present work has shown that the orally administered D-glucosaccharo-1,4-lactone actually caused an inhibition of liver β-glucuronidase.

D-glucosaccharo-1,4-lactone was administered orally to mice (*CF*-1 strain). At various time-intervals after administration, animals were stunned and killed and the liver immediately removed and homogenized in two volumes of isotonic potassium chloride solution with Potter–Elvehjem type of glass homogenizer. The homogenate was immediately run in the *p*H 5·0 (*M*/10 acetate buffer) incubation mixture[1] containing phenolphthalein glucuronide, and incubated for 1 hr. at 37° C. The activity of the β-glucuronidase was assayed by measuring the product of hydrolysis, phenolphthalein, by the method of Fishman[4].

Activities of mice liver β-glucuronidase measured 30 min. after oral administration of various doses of D-glucosaccharo-1,4-lactone are shown in Table 1.

Table 1. ACTIVITY OF MICE LIVER β-GLUCURONIDASE 30 MIN. AFTER ADMINISTRATION OF D-GLUCOSACCHARO-1,4-LACTONE

Dosage (mgm./kgm.)	Activity (per cent)*
Control	100
50	83·0
100	72·0
200	48·1
400	40·7
800	24·4

* Mean percentage of 5 mice.

As shown in Table 2, the enzyme was most strongly inhibited when tested 30 min. and 1 hr. after oral administration of D-glucosaccharo-1,4-lactone. After several hours, the enzyme activity was almost normal.

Table 2. ACTIVITY OF MICE LIVER β-GLUCURONIDASE AT VARIOUS TIME INTERVALS AFTER ORAL ADMINISTRATION OF D-GLUCOSACCHARO-1,4-LACTONE (400 MGM./KGM.)

Time after administration	Activity (per cent)*
Control	100
30 min.	40·8
1 hr.	37·3
2 hr.	81·6
4 hr.	94·9
6 hr.	87·4

* Mean percentage of 5 mice.

The enzyme was not strongly inhibited after administration of other sugar lactones such as glucuronolactone and gluconolactone (Table 3).

Table 3. ACTIVITY OF MICE LIVER β-GLUCURONIDASE 30 MIN. AFTER ORAL ADMINISTRATION OF SOME SUGAR LACTONES

Compound and dosage	Activity (per cent)*
Control	100
Glucuronolactone 1,000 mgm./kgm.	90·4
Gluconolactone 1,000 mgm/kgm.	95·3
Potassium saccharate 1,000 mgm./kgm.	85·8
D-Glucosaccharo-1,4-lactone 800 mgm./kgm.	24·4

* Mean percentage of 5 mice.

Similar results were obtained in experiments on the β-glucuronidase of rat liver and kidney, and in experiments in which *o*-aminophenol glucuronide was used as substrate instead of phenolphthalein glucuronide.

These results suggest that D-glucosaccharo-1,4-lactone would have some effect on the detoxication mechanism *in vivo*.

Karunairatnam and Levvy[3] reported that the administration of a large dose of saccharic acid to mice did not influence liver regeneration after damage or normal growth in infant animals.

Incorporation of 5,10,15 ^{14}C-Farnesol Pyrophosphate into *Phycomyces* carotenoids

CELL-FREE extracts of *Phycomyces blakesleeanus* incorporate farnesol pyrophosphate labelled with carbon-14 into non-saponifiable lipids. Separation of these compounds on magnesium oxide-'Hyflo-Supercel' columns demonstrate that the carbon-14 is associated with crystalline β-carotene, purified ergosterol and fractions containing phytoene, phytofluene and lycopene. It has been reported several times that a great portion of the activity associated with the non-saponifiable compounds is lost on recrystallization[1]. As a consequence, the separated saturated fractions in this experiment are indicative only.

In the present experiment, 2-^{14}C-mevalonic acid and adenosine triphosphate were incubated with the soluble portions (30–60% ammonium sulphate saturation) of rat liver extracts to yield ^{14}C-farnesol pyrophosphate[2]. After separation and purification, the pyrophosphate was incubated with cell-free extract of *Phycomyces blakesleeanus* prepared as reported previously by Yokoyama *et al.*[3].

The *Phycomyces* incubation mixture contained adenosine triphosphate, reduced diphosphopyridine nucleotide, triphosphopyridine nucleotide, glucose-phosphate, manganine, sodium fluoride, and flavine adenosine dinucleotide. As a comparison, mould extracts of the same preparation were incubated with 2-^{14}C-mevalonic acid, and combinations of P-P farnesol and mevalonic acid. As the time of incubation was rather long (19 hr.) the preparations were checked before and after incubation for microbial contamination.

The β-carotene was isolated by chromatography and recrystallized to constant specific activity. The ergosterol was separated on similar chromatographic columns, eluted and precipitated as the digitonide. The digitonide was split with pyridine, and the ergosterol reprecipitated prior to counting. Unlabelled carrier was added to both compounds during purification.

The other compounds were collected as crude fractions after chromatography; they were then rechromatographed twice but not crystallized. Thus, they do not necessarily represent the minimum activity to be found in the components identified. The phytofluene is, in the circumstances of this experiment, relatively pure. The phytoene band, however, is likely to contain several high-counting contaminants. The lycopene band may contain some residual sterols.

The separated components were dissolved in toluene and sealed in counting vials. These were exposed to ultra-violet light (8–10 hr.) until completely bleached. Scintillating phosphors were added by injection through the vial caps, and the samples counted in a Packard 'Tri-Carb' counter. Appropriate controls were run to correct for quenching.

Table 1 gives the activities of the various fractions isolated, as well as the active materials added to the incubation medium.

It is apparent from Table 1 that farnesol pyrophosphate is more efficiently incorporated into β-carotene than is mevalonic acid. The fact that the efficiency of incorporation increases when a pool of 5 carbon fragments is supplied to the mixture indicates that the condensing unit is larger than 15. The general results of the experiment confirm the identity of precursors

Table 1
c.p.m.

Compound isolated	2-^{14}C-Mevalonic acid	^{14}C-Farnesol-P-P	^{14}C Farnesol-P-P inactive mevalonic acid
β-Carotene	8	69	131
Ergosterol	13	33	34
Phytoene	164	7,709	12,149
Phytofluene	26	735	1,485
Lycopene	24	222	112

in both sterol and carotenoid synthesis. Previous reports substantiate mevalonic acid as obligatory intermediate in the carotenoid synthesis. The findings indicated here would agree with this and would continue the identity through the C-15 level. Presumably the condensing unit for the formation of the C_{40} chain would be a C_{20} compound made from the condensation of farnesol pyrophosphate with an additional C-5 unit (possibly isopentenol pyrophosphate).

The ergosterol produced by the extract incorporates activity from both mevalonic acid and farnesol-P-P, but more efficiently from the latter. No increase in activity was shown when mevalonic acid was added, which would be as expected. The lack of stimulation in this case coupled with the increases noted in the carotenes would tend to confirm that the differentiation of the two pathways would occur at the C-15 to C-20 level.

As in most other reports on carotene synthesis, there is very high incorporation of activity in the phytoene fractions; the significance of these has not been established, since it has not yet been possible to crystallize phytoene or phytofluene. The activity is thought to reside in high-counting companions rather than in the carotenoids themselves.

This investigation was supported in part by a research grant from the National Institutes of Health.

Isolation and Fractionation of some Damselfly Pigments

THE imagines of *Ischnura elegans* are found in great numbers around some ditches and pools during the months of May–September. The females, especially, of this species exist in various colour forms, some of which experience changes in colour[1,2].

Two layers of granules situated immediately below the cuticle are concerned in the production of the different colours of the thorax[2]. The outer layer consists of small granules, while the inner layer consists of larger granules of varying sizes which are generally much darker in colour than the smaller ones, the different colours exhibited depending on the variation in thickness of the layers and the colour, distribution and density of the granules. The greatest numbers of both types of granules are present in the blue forms. The blue, being a structural colour based on the Tyndall effect, contrasts sharply with the orange and darker pigments of the granules themselves[2].

Ommochromes are found in a variety of insect eye cells and epidermal cells as granules responsible for pigmentation[3,4]. The isolation and structure of the ommochrome pigments, consisting of two major types, ommatines and ommines, have been extensively studied by Butenandt and his colleagues[4–7]. They are biosynthesized from tryptophan[6], through kynurenine and 3-hydroxykynurenine[4–6], and the latter compound is a characteristic constituent of acid hydrolysates of ommochromes, its presence being considered good evidence that the pigment is an ommochrome[4,5].

The granule pigments were isolated and their properties compared with those of samples of ommochrome pigments, namely rhodommatine and ommatine *D*, since ommochromes have been found as pigments (eye) of certain Odonata (including *Agrion mercuriale*[4]), and also with those of melanin prepared by enzymic synthesis, since the ommochromes and melanin have a common biosynthetic pathway as far as shikhimic acid.

One at least of the granule pigments is considered to belong to the ommochrome group, while evidence for the other is equivocal.

The extraction procedure followed that of Butenandt and his colleagues[4–7]. Three species of blue damselfly were extracted separately for comparison. The procedure was the same in each case.

The thoraxes of the damselflies, with wings removed (seventy *Ischnura elegans*—blue; twenty *Agrion pulchellum;* seventy *Enallagma cyathigerum*), were crushed in a small macerator (M.S.E.) with methanol (3 × 30 ml.) containing 2 per cent concentrated hydrochloric acid. The methanol was gassed with sulphur dioxide (3 min.) before use. The residue was centrifuged off between each extraction and each port-wine coloured extract was distilled under vacuum. The brownish-red residues, after distillation, were extracted with aqueous $M/15$ disodium hydrogen phosphate. The centrifuged extracts were green in colour. The brownish-red residues from this extraction were dissolved in concentrated hydrochloric acid (21 ml.) and an equal volume of distilled water was added. The mixtures were stored at −20° C. overnight and the precipitates were washed with acetone (5 × 5 ml.) and dried in air (yields: 2–10 mgm.).

In paper electrophoresis ($M/40$ sodium tetraborate solution: Whatman No. 54; 8 hr.; 12 V./cm.; 5 m.amp.) dinitrophenol-glycine and dinitrophenol-ethanolamine markers (fast and slow respectively) were used. The crude methanolic-hydrochloric acid extracts were found to contain three pigments distinguishable by paper electrophoresis: a faster moving mauve pigment, an orange pigment remaining with the slow marker, and a green pigment falling between the two. However, though the mauve pigment behaved in a similar fashion to rhodommatine, the latter appeared as a salmon-coloured pigment in the borate buffer. This mauve pigment was found to correspond to the red precipitate, while the orange pigment was found, together with the green pigment, to be concentrated in the $M/15$ disodium hydrogen phosphate extract. The latter pigment may have been chlorophyll.

The orange pigment was isolated by electrophoretic separation (Whatman 3*MM*; borate buffer), elution with methanolic hydrochloric acid (2 per cent) and distillation under vacuum.

The mauve pigment, isolated by a procedure for obtaining purified ommochromes, was found to be associated with protein (paper chromatography of acid hydrolysate; ninhydrin detection). When this pigment (2 mgm.) was hydrolysed with $6N$ hydrochloric acid (2 ml.) by refluxing for 10 hr., 3-hydroxykynurenine was found to be present (ascending paper chromatography; solvent, *n*-butanol/acetic acid/water: 12/3/5; Whatman No. 4 paper; dip detection by Ehrlich as well as 0·25 per cent potassium ferricyanide, followed by 0·25 per cent sodium dithionite).

Under the same conditions both the rhodommatine and ommatine *D* samples gave 3-hydroxykynurenine, as would be expected.

The orange pigment, similarly treated, gave equivocal responses to 3-hydroxykynurenine tests. (Even after alcoholic precipitation of a gum-like material, substances present in the hydrolysate of the orange pigment made chromatographic identification difficult.)

The mauve pigment behaves, on electrophoresis, in a similar fashion to rhodommatine and probably belongs to the ommochrome class: its solubility, its behaviour during isolation and the presence of 3-hydroxykynurenine in its acid hydrolysates are good evidence for this grouping. The character of the orange pigment, although originally suspected to be xanthommatine on the basis of colour, solubility and mode of isolation, remains in doubt.

Melanin, prepared by the action of mushroom polyphenoloxidase[8] (acetone precipitate) on tyrosine hydrochloride[9], gave no 3-hydroxykynurenine on acid hydrolysis and differed from the isolated granule pigments in appearance and solubility.

The large dark granules, in 5μ sections and in uncut integument, dissolve easily in methanolic hydrochloric acid (2 per cent) to give a reddish-brown solution. They do not appear to be soluble in $M/15$ disodium hydrogen phosphate, unlike the small orange-coloured granules in sections. These small granules do not pass into solution with phosphate buffer from intact integument even after the large ones have been removed with methanolic hydrochloric acid. This would imply that the matrix affects their solubility or dispersion. Medium-sized granules were present in damselflies where the blue colour was being formed, though they were not observed in older flies. One explanation is that these medium-sized granules are precursors of the large ones, another is that later they are obscured by the larger granules. Differential solution of the large (and possibly medium) granules from intact integument with methanolic hydrochloric acid yielded material which gave $6\ N$ hydrochloric acid hydrolysates containing 3-hydroxykynurenine. Solution of the remaining small granules + matrix in concentrated hydrochloric acid yielded material, the $6\ N$ hydrochloric acid hydrolysate of which gave a negative response to 3-hydroxykynurenine tests. These histochemical tests seem to link the large granules with the mauve pigment and the small orange ones with the orange pigment.

The mauve pigment isolated from *I. elegans*, *A. pulchellum* and *E. cythigerum* appears to belong to the group of Butenandt's ommochrome pigments and differs from melanin.

We thank Prof. F. W. R. Brambell for his interest and encouragement, Prof. W. C. Evans for his hospitality to one of us (P. M. L.), and Dr. A. B. Acton for his advice and suggestion of the problem. We are grateful to Prof. A. Butenandt, Munich, for the generous gift of rhodommatine, ommatine *D* and 3-hydroxykynurenine, and also to Dr. L. M. Henderson, Oklahoma State University, for his gift of 3-hydroxykynurenine. We are indebted to the Department of Scientific and Industrial Research for a postgraduate studentship (P. M. L.) and the University of Wales for an I.C.I. fellowship (C. B. C.).

Lipids of the Common Pea (*Pisum sativum* L.) with Special Reference to the Occurrence of Galactolipids

IT has been firmly established that the lipids of most seeds consist almost entirely of triglycerides[1]. The lipids of leaves, on the other hand, are much more complex and contain considerable amounts of wax and phospholipids[1] in addition to a cold acetone-soluble fraction amounting to some 50–70 per cent of the total lipids[2]. This acetone-soluble fraction has been generally assumed to consist mainly of triglycerides along with lesser amounts of unsaponifiable matter and free fatty-acids. In the light of recent work, however, it appears that leaves contain not more than minor amounts of triglycerides, their place being taken by galactolipids[3,4]. The identification of galactolipids as the main lipid fraction involved in the early stages of photosynthesis suggests a relationship between the occurrence of chlorophyll and of galactolipids[5], and is in keeping with their presence in leaves and their apparent absence in seeds. In this regard it was thought instructive to examine the leaves, pods and seeds of the common pea (*Pisum sativum* L.) as the seeds in this instance contain relatively little oil, much of which is non-glyceridic in nature[6], and in addition the seeds contain some chlorophyll or chlorophyll-like pigments.

Using techniques previously described[2,4] it was found that the total lipids present in the leaves, pods and seeds taken at a stage when the pods were full and still green comprised respectively 10·3, 2·4 and 4·8 per cent of the tissues dried to constant weight at 100°. The corresponding values for the acetone-soluble fractions were 7·4, 1·3 and 1·8 per cent while those for the non-dialysable lipids from these fractions were respectively 4·4, 0·7 and 0·4 per cent.

Examination of the non-dialysable fractions (which include all the galactolipids present) showed that whereas in the leaves the values for galactose and glycerol indicated that the fraction consisted mainly of galactolipids, as previously found for other leaves, in the pods and seeds the galactose contents were considerably lower.

The relative contents of chlorophyll-like pigments, as measured by the blue colour of the acetone extracts using a Lovibond tintometer, indicated that the leaves contained much more of these pigments than did the seeds, and in general the amounts of galactolipids calculated from galactose contents followed approximately those of the chlorophyll-like pigments.

In agreement with Wagenknecht[6] we have been able to demonstrate that the acetone-soluble lipids of pea seeds are comprised largely of triglycerides. Whereas, however, Wagenknecht[6] considered that the sugars associated with this fraction are solely contaminants, our present work as well as earlier work[2–4] support the view that the sugars are combined in the lipid molecule.

The present results confirm that galactolipids are the main acetone-soluble lipids in leaves, but in addition indicate the presence of trace amounts of triglycerides in these tissues. Moreover, while triglycerides are the main component of seed lipids it is now shown that in some seeds, at least, traces of galactolipids may also be present. The work in this field is being continued.

Isolation of a New Antioxidant from Oats

The antioxidant properties of oatmeal are well known[1] and have been ascribed to phospholipids[2]. Oats are also rich in tocopherols[3] which function as antioxidants. We now report the isolation of an active antioxidant from oats which belongs to neither of these classes.

Whole oat kernels were freed from most of their oil by soaking in light petroleum (boiling point below 40° C.) for several days. A crude preparation of the antioxidant was obtained by extracting the defatted kernels with diethyl ether. This was purified by precipitation from solution in diethyl ether by the addition of light petroleum followed by chromatography on columns of silicic acid.

The purified antioxidant is almost colourless, melting point 85° C., soluble in most organic solvents, but insoluble in light petroleum and water. It has the properties of a phenol, dissolves in aqueous alkali to give a bright yellow solution and gives a green colour with ferric chloride, which suggest the presence of a free catechol nucleus. It has a characteristic ultraviolet absorption spectrum with a principal maximum at 331 mμ (in ethanol), E(1 cm., 1 per cent), 440. Analysis of two specimens gave: C, 69·9, 69·7; H, 8·4, 8·9; OCH_3, 3·8, 4·1 per cent molecular weight by Barger's method, 700; no nitrogen or phosphorus was found. On alkaline hydrolysis caffeic acid, ferulic acid and a neutral substance were obtained apparently in equimolecular proportions.

The neutral component was crystallized from ethyl acetate giving colourless needles, melting point 105° (found: C, 76·9; H, 13·1; M, 290). It formed an acetate, melting point 70°, and on oxidation with chromium trioxide in acetic acid gave an acid melting point 114°. The infra-red absorption spectrum with bands at 1,716 cm.$^{-1}$ (C=O stretching) and at 3,300 and 1,055 cm.$^{-1}$ (OH stretching and bending respectively), for which we are indebted to Dr. M. J. Fishwick, of the Low Temperature Research Station, Cambridge, suggests that it may be a keto-alcohol.

Table 1. ANTIOXIDANT ACTIVITIES MEASURED IN ARBITRARY UNITS/MGM.*

Substance	Antioxidant activity (units/mgm.)
Purified oat antioxidant	30
Caffeic acid	90
Ferulic acid	14
Neutral component	0
Propyl gallate	30
Butylated hydroxytoluene	30

* The increase in induction period (hr.) when 100 mgm. of an oat oil (petroleum-soluble) was oxidized in oxygen in the presence of 1 mgm. of a test sample, was a measure in arbitrary units of the activity of the latter.

The results in Table 1 show the antioxidant activity of the new substance and its constituent parts as measured by a recording oxygen apparatus[4]. For comparison, the corresponding figures for the two synthetic antioxidants, *n*-propyl gallate and butylated hydroxytoluene, are also included. The results suggest that the activity of the antioxidant is largely related to its caffeic acid content.

Work is in progress to elucidate precisely the structure of this natural antioxidant and to determine the extent to which it is present in wheat and other cereals.

This investigation is being financed in part by the U.S. Department of Agriculture under the authority of U.S. Public Law 480, 83rd Congress.

Effect of Adrenalectomy on the Activity of Enyzmes of the Urea Cycle in Rat Liver

The procedures for the estimation of enzymes of the urea cycle reported by Brown and Cohen[1] have made it possible to study quantitatively the effect of hormones on the individual reactions of the urea cycle. These authors have recently shown that, in rat liver, the condensing enzyme of the arginine synthetase system is rate-limiting and will thus be a pacemaker for the whole system[2]. It is at such rate-

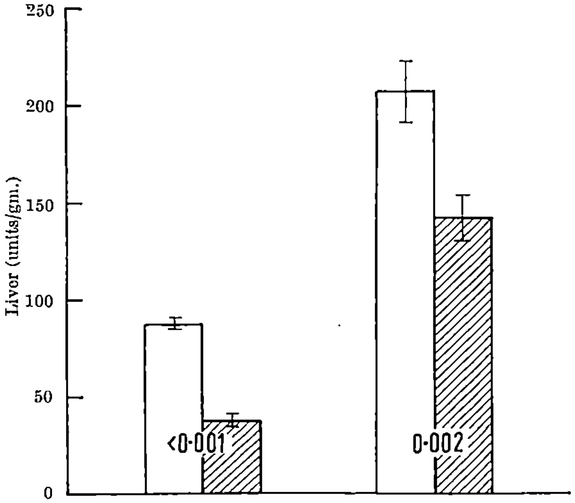

Fig. 1. Effect of adrenalectomy on the activity of rat liver arginine synthetase (left) and argininosuccinase (right). The open columns represent the mean values for 6 control rats, the hatched columns the mean values for 6 adrenalectomized rats. The vertical lines represent twice the standard error of the mean and the figures across adjacent columns are values for Fisher's *P*. The enzyme activities were determined 10 days after adrenalectomy by the method of Brown and Cohen (ref. 1). The control rats were pair-fed with the adrenalectomized rats which were maintained on 1 per cent sodium chloride in the drinking water. A unit of enzyme activity is defined as that amount which catalyses the production of 1 µmole urea/hr. under the assay conditions

limiting reactions that metabolic control might be exerted, and it therefore seemed of particular interest to measure the activity of this enzyme under conditions where there is a marked change in nitrogen metabolism and the production of urea.

The experiments of Long *et al.*[3] and many others (see Young[4]) have clearly established that adrenalectomy in rats causes a decreased nitrogen excretion and depressed gluconeogenesis from protein. Further, it has been shown that liver arginase is markedly depressed in adrenalectomized rats (Fraenkel-Conrat *et al.*[5], Folley and Greenbaum[6]). The experiments reported here are concerned with the effect of adrenalectomy on the activity of liver argininosuccinase and the arginine synthetase system as measured by the method of Brown and Cohen[1]. The arginine synthetase system is, in effect, a measure of the activity of the condensing enzyme forming argininosuccinate since the two succeeding enzymes, argininosuccinase and arginase, are present in excess. The results of these experiments are shown in Fig. 1.

Adrenalectomy caused a marked fall in the activity of the arginine synthetase system to a value less than half that of the pair-fed control rats. Liver argininosuccinase activity was also significantly reduced in adrenalectomized rats; but the magnitude of the effect was smaller—the enzyme activity was approximately 64 per cent of the control value. A similar pattern of change was found when the enzyme activities were expressed as total units in the liver and total units/100 gm. body-weight. The potential rate of urea synthesis may be calculated from the activity of the rate-limiting enzyme of the arginine synthetase system, and this is found to show a close correlation with the observed rate of urea production. Long *et al.*[3] found that the nitrogen excretion of adrenalectomized rats was approximately 34 per cent lower than that of control animals, a value confirmed in the present experiments.

Liver arginase was measured by the method of Folley and Greenbaum[7] and showed the usual marked depression in activity; the mean values for control and adrenalectomized rats are, respectively, 27×10^3 and 47×10^3 units/gm. liver. These results emphasize again the great disparity in the relative activities of different enzymes of the urea cycle.

Cohen *et al.* have already studied the effect of thyroxine on enzymes of the urea cycle in regenerating rat liver[8]. It would be interesting to know how the urea-cycle enzymes change under conditions where there is a negative or positive nitrogen balance as in rats treated with adrenal steroid or growth hormone, and this work will be extended to include such measurements.

I am indebted to Dr. R. G. Westall for a generous supply of argininosuccinate. This work was supported in part by a grant to the Medical School from the British Empire Cancer Campaign.

RADIOBIOLOGY

Decreased Urinary Excretion of 2-Aminoethanol by Irradiated Human Beings

PREVIOUS reports have described an increase in the urinary excretion of certain amino-acids by accidentally irradiated human beings[1] and by patients receiving radiation therapy[2]. This communication concerns the previously unreported finding of a decrease in urinary aminoethanol in human beings following total-body radiation.

Patients selected for radiation treatment were suffering from far-advanced neoplastic disease, resistant to conventional therapy. Total-body radiation was administered in a multiple-source cobalt-60 irradiator, which delivers a uniform air dose at rates up to 30 r./min.

Complete urine collections were obtained daily from each patient before and after irradiation. Aliquots were stored at −15° until they were analysed. Aminoethanol was determined by high-voltage electrophoresis on paper using a pyridine/acetic acid/water (1:10:89) buffer, *p*H 3·6, and a commercial apparatus[3]. (A potential of 30 V./cm. was applied for 90 min. at −3°.) By this method, aminoethanol is clearly separated from all other ninhydrin-reacting substances. Quantitative determination was by elution and colorimetric comparison with standards run simultaneously. Analysis for phosphorylaminoethanol was carried out in the same manner except that a pyridine–acetic acid buffer at *p*H 6·0 was used.

Among normal subjects and patients with various forms of cancer, the urinary excretion of aminoethanol, although variable, was never less than 10 mgm. a day. Following total-body radiation, the urinary content of aminoethanol decreased to undetectable concentrations, that is, less than 0·4 μgm./ml., in all six patients who were exposed to single doses in the range of 300–900 r. The results in one patient of this group are shown in Fig. 1. Aminoethanol virtually disappeared from the urine in this individual on the fourth and fifth days following irradiation. The other cases exhibited this effect for varying periods ranging from one to six days during the first week post-irradiation. The effect was more prolonged following higher doses. In all six cases aminoethanol re-appeared in the urine by the twelfth day.

In contrast, urinary aminoethanol was decreased but not absent following irradiation in one patient given 225 r. (single exposure) and in each of four patients who received multiple 100 r. exposures at two- to three-day intervals to a total dose of 500 r.

Changes in the excretion of aminoethanol were not observed in patients undergoing major surgery or in cases of body burns.

Phosphorylaminoethanol was not detected in the urine of any of the cases studied.

The mechanism responsible for the observed alteration in aminoethanol excretion following irradiation is open to speculation. Renal effects cannot be ruled out since analysis of plasma was not performed. A possible clue to the mechanism is offered by the finding of Kretchmar[4] that free serine disappeared from the urine of accidentally irradiated men. The metabolism of serine is closely related to that of aminoethanol. Both compounds are constituents of cephalins and plasmalogens. It is felt that the observations reported here may point to further investigations.

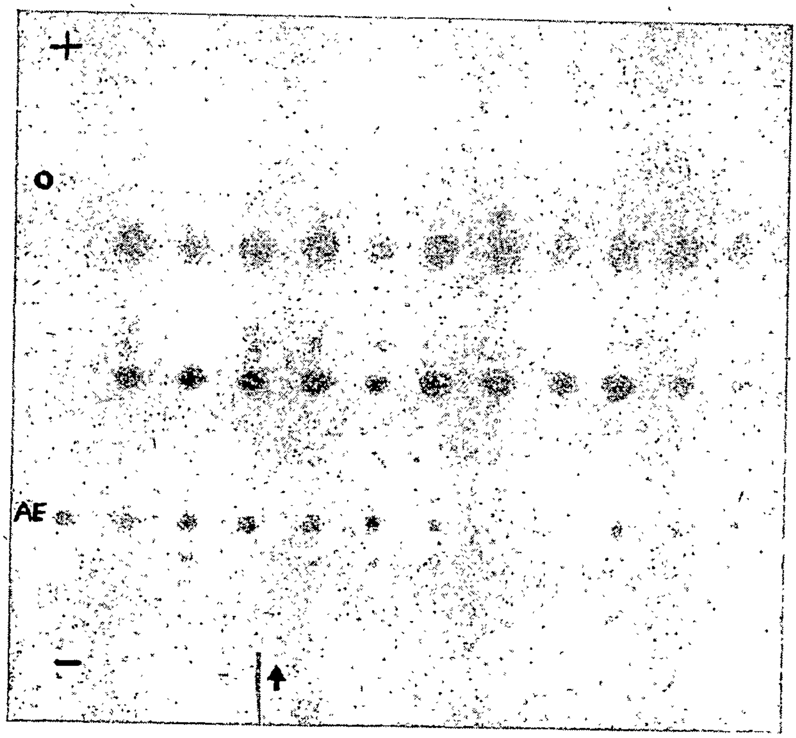

Fig. 1. Electropherogram, stained with ninhydrin, of samples of urine collected daily from a patient who received 300 r. (air dose) total-body radiation at the beginning of the fourth day (arrow). 15-μl. samples were applied in spots along line *O*. A standard (*AE*) containing 0·1 mgm. aminoethanol per ml. was run simultaneously at the far left. Note the virtual disappearance of aminoethanol in the urine excreted on the fourth and fifth days following irradiation

Radiation Damage to Proteins

Physicochemical work shows that ionizing radiations cause fragmentation and aggregation of protein molecules[1–3]. When protein molecules are degraded there is a variety of products and also many amino-acids are degraded. However, the mechanisms by which these changes occur are still obscure. In our experiments, we define the radiation damage to cytochrome *c*, hæmoglobin, catalase, and egg albumin in terms of radiation-lability of amino-acids and loss of biological properties of the three hæmoproteins. The amino-acid pattern of scission products and insoluble protein aggregates was also determined.

If aggregates are formed by protein-protein cross-linkage or by denaturation of native molecules one would expect that the amino-acid pattern of insoluble aggregates would be similar to that of original protein. Also, if scission products arise by random cleavage at the most radiation-labile amino-acids into large polypeptide chains, then these scission products and the original protein should have similar amino-acid patterns except for destruction of the most radiation-labile amino-acids.

In our experiments, 0·1 per cent solutions of proteins were anaerobically exposed to 0·6–2-MeV. γ-irradiation; the dose-range varying from 10^5 to 5×10^7 rads[4]. Insoluble aggregates were separated by centrifuging and filtration. Soluble protein was precipitated using 5 per cent trichloroacetic acid (TCA) and thus separated from scission products. These three fractions were hydrolysed and amino-acids were determined by two-dimensional paper chromatography. Protein which did not receive any irradiation served as the control.

Cystine, methionine, histidine, phenylalanine, tyrosine, threonine and serine were most susceptible to radiation damage. Rank in terms of radiation-lability, however, varied with the protein. These amino-acids were degraded even at lower radiation doses ($< 10^6$) in contrast to other amino-acids, such as aspartic acid, glutamic acid, lysine and alanine, which were among the most stable. Loss of biological properties of the hæmoproteins cannot be attributed to destruction of any specific loci as the proteins are modified considerably and several amino-acids degraded by ionizing radiations. Although the mechanisms are different, ionizing radiation may be compared with active carbonyl-amine browning and lipid peroxidation reactions in which amino-acids are degraded. The same amino-acids are labile except for greater losses of lysine and arginine in the latter two reactions[5-7].

As a function of radiation dose, the survival of amino-acids in the TCA-precipitable protein declined, indicating degradation of original protein. The amino-acid pattern of scission products and/or insoluble aggregates was totally different from that of original protein or TCA-precipitable protein at a particular radiation dose. This suggested that denaturation or polymerization was not the only cause of formation of insoluble protein aggregates, and that hydrolysis induced by radiation was not the mechanism of fragmentation.

Radiation-lability of sulphur amino-acids in the proteins merits special attention. These amino-acids give rise to volatile products responsible for some undesirable flavour in irradiated foods and are a site for localization of radiation damage[8]. Fission of cystine and cysteine gives rise to hydrogen sulphide and alanine. Analogous to this reaction is the formation of CH_3SH and α-amino butyric acid from irradiation of methionine.

PHYSIOLOGY

Splitting of Serum Albumin during Electrophoresis on Paper

The existence in human and animal serum of protein constituents which migrate during electrophoresis at rates faster than that of albumin has been widely reported in the literature by investigators using moving boundary electrophoresis[1] and electrophoresis on paper[2-5] and in hydrolysed starch-gels[6,7]. Using *tris* buffer (*p*H 8·9), which consists of *tris*-(hydroxymethyl)aminomethane, ethylenediamine tetraacetic acid (EDTA) and boric acid, Aronsson and Grönwall[8] reported not only an enhanced separation of the protein constituents of human serum and the appearance of a pre-albumin component, but also a partial splitting of the albumin peak during electrophoresis in *tris*/boric acid buffers.

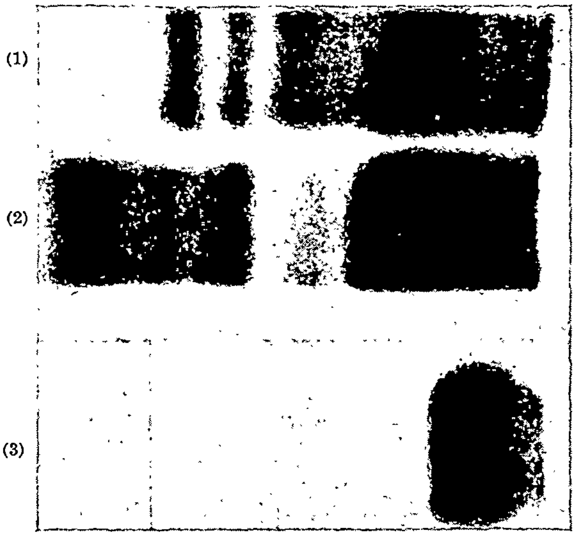

Fig. 1. The splitting during electrophoresis in *tris* buffer (*p*H 8·9) of (1) fœtal sheep serum albumin; (2) pregnant sheep serum albumin; and (3) crystalline bovine plasma albumin

In this Laboratory serum from maternal and fœtal sheep was examined at different stages of gestation by means of electrophoresis on paper using the *tris* buffer described by Aronsson and Grönwall[8]. Separation of the serum protein constituents was carried out in an air-tight 'Perspex' box, the buffer troughs of which were connected by gel bridges to silver/silver chloride electrodes immersed in saturated potassium chloride solution. The serum samples were applied to the paper after the current had been passed through the strip for at least 1 hr. Electrophoresis was continued for 18 hr. at room temperature, using a current density of 0·5 m.amp./cm. width of strip and a potential gradient across the paper of 3·2 V./cm. The paper strip was then dried at 115° C. for 15 min. and was stained with a bromocresol-green reagent. The stained paper was washed free of excess dye, and, after drying in air, was permanently blued by spraying with a 4 per cent solution of sodium carbonate.

In these conditions of electrophoresis a splitting of the serum albumin of fœtal, pregnant and normal adult sheep was observed. The degree of separation of the two components varied somewhat from one electrophoresis run to another, but nevertheless the two components always appeared as quite distinct entities. A third component was frequently detected lying between the two main components, but this material of intermediate mobility was not usually a well-defined band. It appeared to arise from a further splitting of the faster-moving of the two main components. In Fig. 1 are shown examples of the splitting of sheep serum albumin and the results of electrophoresis of crystalline bovine plasma albumin (Armour) under the same conditions, when this latter material showed the presence of three components. The electrophoretic patterns obtained with human serum showed a distinct band moving ahead of the main albumin component. Sheep serum albumin and crystalline bovine plasma albumin moved as single components during electrophoresis in veronal buffer, *p*H 8·6.

The splitting of sheep serum albumin reported is being investigated further.

Urinary Inhibitors of Hyaluronidase

In connexion with the recent discussion on the relationship between urinary hyaluronidase and diuresis between Ginetzinsky and Berlyne[1], some observations of ours may be of interest.

We have investigated hyaluronidase activity in urine, in serum, and in various kinds of tissue extracts by a somewhat modified viscometric method[2]. One essential feature of this method is that flow-time is read every 1 or 2 min. A plot of flow-time against reaction time gave, for most urine samples, approximately a straight line in contrast to the characteristic curved shape obtained with samples of pure enzyme.

We could reproduce the rectilinear curves by adding to the enzyme solution small quantities of various hyaluronidase inhibitors, for example, chondroitin sulphate, polyœstradiolphosphate ('Estradurin *R*', H. Lundbeck and Co., Copenhagen) and partly degraded hyaluronic acid.

Gibian[3] showed that the influence of inhibition in serum samples could be suppressed by diluting the samples. We have been able to confirm this observation[2] and have found that in human sera a dilution of about 1: 30 (that is, about 1: 200 in the reaction mixture) seems sufficient to eliminate the inhibition.

In Table 1 are given the results of similar dilution experiments with two normal adult night urine samples and it is seen that the inhibition is not with any certainty suppressed completely in even more dilute solution. Since the absolute activity in urine is much lower than in serum, it is impossible to get results with a dilution technique in anything but the most concentrated urine samples.

It will be necessary, therefore, to find a convenient way to separate enzyme and inhibitor in urine, and we have tried with some promise of success a 'Sephadex' filtration[4]. 4 ml. of a normal adult female night urine was poured on a 45 ml. 'Sephadex' *GR*-75 column and was washed through with acetate-buffer (pH 4·6). Hyaluronidase activity is found in the very early fractions, as shown in Fig. 1, where proteins of high molecular weight would be expected to occur. In similar filtration experiments on the same column with serum, tissue extract, and U.S.P. standard hyaluronidase, the activity was found in very nearly the same range of fractions, that is, in advance of hæmoglobin, for example. This was contrary to our expectations from prior knowledge of the molecular weight of hyaluronidase, and it seems to indicate an aggregation in this particular buffer milieu.

A, Female; *B*, male. 1, dilution of sample in reaction mixture; 2, hyaluronidase-like activity (*H*-factor activity) in arbitrary units (ref. 2); 3, *H*-factor activity converted to equivalent concentration of U.S.P. reference hyaluronidase standard in international units per litre of reaction mixture by means of a calibration curve (ref. 2); 4, *H*-factor activity expressed in international units per ml. of urine.

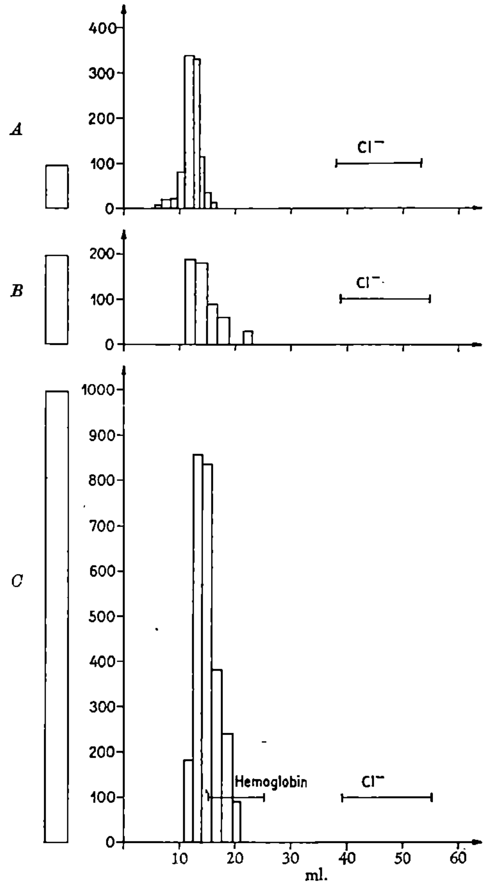

Fig. 1. 'Sephadex' filtration of 4 ml. of *A*, an undiluted night urine sample from a normal adult female; *B*, serum diluted 1 : 34 with acetic acid/acetate buffer pH 4·63, 0·07 M (from an adult normal female person); *C*, kidney cortex extract, diluted 1 : 34 with the same buffer (from a kidney removed *postmortem* from a male person with normal kidney function). Abscissa: Effluent from column in ml. Ordinate: Activity of *H*-factor expressed as international units U.S.P. reference hyaluronidase standard per litre of urine (undiluted) and of serum and kidney cortex extract (diluted 1 : 34). The columns to the left represent the activity recorded in a 4-ml. sample before the 'Sephadex' separation

The integrated activity of the active fractions corresponds to nearly 4 ml. of the most active fraction and is about 3·5 times the activity inferred from the untreated sample. Much of the inhibiting substances, therefore, must have gone into other fractions. In diluted serum the integrated activities of the fractions amounted to 1·4 times that of the directly measured activity and in kidney cortex extract to 1·2 times.

We feel that much of the work on hyaluronidase in urine under varying diuretic conditions will have to be done again in such circumstances that the enzyme is freed from inhibitors before the activity is measured. Until such material has been provided, further discussions of the interesting theories of Ginetzinsky would be unrewarding.

Fructose and Lactic Acid Metabolism in the Perfused Liver of Premature Lambs

Recently, Andrews *et al.*[1] obtained evidence from perfusion studies of the inability of the liver of the fœtal sheep to utilize fructose. However, in lambs a removal of fructose from the perfusate occurred in preparations made from the fifth neonatal day onwards. It was of interest to ascertain whether premature birth could influence the time of onset of hepatic fructose metabolism.

The lambs were delivered from Welsh Mountain sheep by Cæsarean section under spinal anæsthesia. The umbilical cord was stretched to induce constriction of the vessels and ligated immediately. Respiratory movements began at once. After preliminary drainage of the nasopharynx, the animals were dried and stimulated generally by rough towelling: within 1–2 hr. all the lambs were capable of standing voluntarily. The animals were kept together in a pen at room temperature (15–20° C.) and maintained in good condition after birth on a 3–4 hr. feeding regimen of cow's milk administered via an 'Ingram' teat (Holborn Surgical Instrument Co., Ltd.).

Table 1 shows data on the conceptual age, age at the time of perfusion, milk consumption and body-weights. After the initial drop in body-weight, all the animals achieved or surpassed their weight at birth by the third or fourth day.

The lambs were anæsthetized with intravenous thiobarbitone and the perfusion of the liver was carried out by a technique similar to that reported in ref. 1, using fresh heparinized or stored defibrinated blood. In different preparations the perfusate volume varied from 320 to 380 ml. and the rate of flow was between 70 and 150 ml./min. The portal pressure was maintained at 11–15 cm. water. The liver weight ranged from 66 to 111 gm. Thermometers placed between the lobes of the liver registered 40–42° C. Fructose was determined by the method of Chinard *et al.*[2]; glucose by the method of Huggett and Nixon[3]; and lactic acid by the method in ref. 1.

Table 1. Data for the Premature Lambs at Cæsarian Section and at the Day of Liver Perfusion

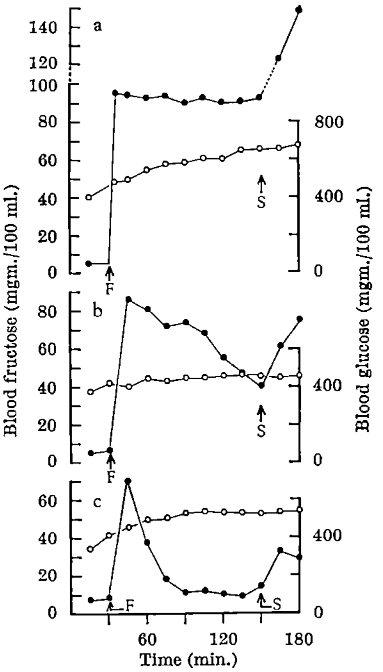

Fig. 1. Fructose and glucose concentration in the perfusion fluid of livers from prematurely delivered lambs. At *F*, 500 mgm. fructose and at *S*, 500 mgm. sorbitol added. Response : 6 days (*a*), 7 days (*b*) and 9 days (*c*) after Cæsarian section

Under the conditions of the experiments, there was no evidence of fructose utilization in premature lambs of 5 and 6 days neonatal age (conceptual age 147 and 148 days) over a period of 2 hr. (Fig. 1*a*), whereas it had been shown before that a rapid removal of fructose occurred by the fifth day after birth in lambs delivered normally at term (148 ± 2·6 (*S.D.*) days) (Young, G. B., personal communication). With premature lambs of 9 and 13 days neonatal age (conceptual age 151 and 155 days), however, a rapid uptake of fructose occurred with the fructose-levels returning to basal values after 60–75 min. (Fig. 1*c*). In premature lambs of 7 and 8 days neonatal age and 148 and 147 days conceptual age, respectively, a slow utilization of fructose was apparent (Fig. 1*b*). With all preparations the concentration of glucose in the perfusate increased; there was also prompt conversion of sorbitol to fructose, as was to be expected from previous results.

In five preparations the lactic acid was estimated and all showed an ability to take up lactic acid from the perfusate (Fig. 2). The rise in lactic acid concentration in the terminal perfusion period may have been due to deterioration of the preparation. However, the rise may be associated with the addition of sorbitol to the perfusate since the enzymic conversion of sorbitol to fructose involves the reduction of diphosphopyridine nucleotide (DPN) to reduced diphosphopyridine nucleotide (DPNH). It is, therefore, conceivable that the DPNH/DPN ratio may be affected in such a way as to bring about an increase in the rate of conversion of pyruvate to lactate such that lactic acid accumulates. The lactic acid-levels encountered were similar to those found before in perfused lamb livers and were considerably lower than those found in fœtal liver preparations (122–140 days conceptual age).

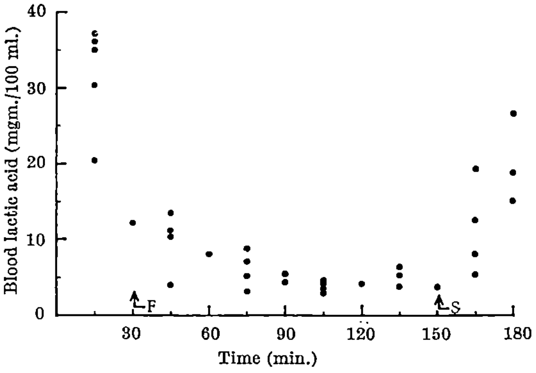

Fig. 2. Pooled values for the lactic acid concentration in the perfusate of livers obtained from prematurely delivered lambs. At *F*, 500-mgm. fructose and at *S*, 500 mgm. sorbitol were added to each of the five preparations

Hers[4] found that fructokinase was absent from the fœtal liver of the sheep, and therefore the onset of fructose uptake by the liver may well be due to the development of this enzyme system. The presence of a ketose reductase (sorbitol dehydrogenase) in the fœtal liver is in keeping with the conversion of sorbitol to fructose by these preparations. A number of other enzyme systems are known to develop at birth[5,6], but so far as is known the effect of premature delivery has not been investigated.

The results presented here suggest that conceptual age is an important factor in determining the onset of hepatic metabolism of fructose, but there may be some acceleration of the process by premature delivery.

Electrolyte Retention produced by the Antialdosterone *SC* 5233

Kagawa[1] reported that the spirolactone *SC* 5233 (3-(3-oxo-17β-hydroxy-4-androsten-17α-yl)propionic acid lactone) possessed weak cortexone-like activity in addition to its well-known antagonistic action towards cortexone and aldosterone. This weak cortexone-like (agonist) activity was estimated at 0·1–0·2 per cent that of cortexone. Reported here are some effects of *SC* 5233 on electrolyte excretion in normal and adrenalectomized rats which cannot be explained purely on a weak agonist activity.

In all experiments male Wistar rats were used the weights of which were approximately 120 gm. Bilateral adrenalectomy or a sham operation was performed under ether anæsthesia and the adrenalectomized animals were maintained on 1 per cent sodium chloride in the drinking water. On the day of the experiment the animals were uniformly hydrated with normal saline (25 ml./kgm.) and the drug injected beneath the skin; they were then placed in single cages suitable for the collection of urine. The response of the animals to *SC* 5233 (5 mgm./rat) was measured in experiment 1 on the first, fourth and eighth days after the operation. As the response of the animals was greatest on the eighth day, the animals in experiment 2 were dosed as in experiment 1, but the response was only measured on the eighth day after the operation. Similarly, in experiment 3 the animals were dosed with cortexone (10·0 μgm./rat) on the first, fourth and eighth days after operation, but urine was collected only on the eighth day.

Table 1. Comparison of the Effects of *SC* 5233 (5 mgm./rat) injected beneath the Skin on Electrolyte Excretion in Sham-Operated and Adrenalectomized Rats on the First, Fourth and Eighth Days after Operation

	8	7·8 ± 0·03	7·9 ± 0·02	7·6 ± 0·07	7·9 ± 0·18

The results of experiment 1 are given in Table 1 and are illustrated in Fig. 1. In the graphical illustration the mean results for the three days of the animals treated with *SC* 5233 are expressed as a percentage of those obtained in the control animals. Injection beneath the skin of *SC* 5233 (5 mgm./rat) produced no consistent alteration in the fluid excretion of the sham-operated rats, nor was there any marked alteration in the excretion of sodium and chloride or *p*H of the urine. However, retention of potassium was observed on the fourth and eighth day in these animals. In the adrenalectomized animals *SC* 5233 produced a progressive decrease in the fluid, sodium, potassium, and chloride excretion and a rise in urinary *p*H. There was no alteration of the endogenous creatinine excretion induced by *SC* 5233 in either the sham-operated or adrenalectomized animals. The results of experiment 2 (Table 2*a* and *b*) were similar to those obtained in experiment 1. Analysis of the plasma did not show any marked alteration in the

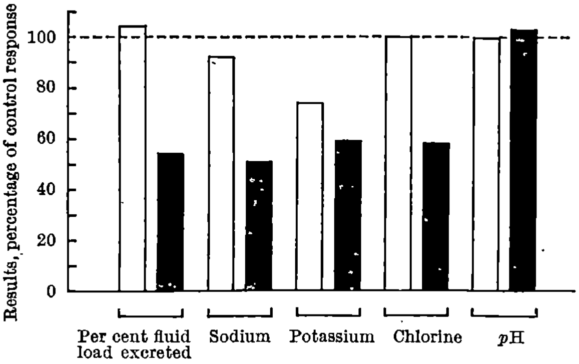

Fig. 1. Effect of the subcutaneous injection of *SC* 5233, 5 mgm./rat, on fluid, sodium, potassium and chloride excretion and urinary *p*H. Results are averages for the three experimental days and expressed as a percentage of the results obtained in the control animals, that is, 100 = control value. □, Sham-operated rats; ▨, adrenalectomized rats

sodium or potassium concentrations, although there was some suggestion of an increase in the plasma sodium concentration in both sham-operated and adrenalectomized animals. In experiment 3 (Table 3) injection beneath the skin of cortexone 10·0 μgm. per rat decreased sodium and increased potassium excretion; the adrenalectomized rats retained sodium and extruded potassium more than the sham-operated animals.

The experimental results show that *SC* 5233 does not possess a weak cortexone-like activity on repeated administration. Subcutaneous doses of cortexone and *SC* 5233, which produce similar degrees of sodium retention, produce opposite effects on potassium excretion. Cortexone will cause a rise in plasma potassium concentration, which has recently been shown to be an important factor in the mechanism of potassium extrusion produced by these substances[2]. The continued administration of *SC* 5233 did not produce an alteration in plasma potassium concentration. The fact that *SC* 5233 does not show a weak cortexone-like activity on potassium excretion, but does show this activity with regard to sodium excretion, would suggest that *SC* 5233 ought theoretically to be less complete in its anti-mineralocorticoid activity on potassium than on sodium excretion. There is clinical evidence that *SC* 5233 produces changes in sodium with little or no change in potassium excretion, both in the normal individual and in the Addisonian patient maintained on cortexone[3].

Table 2, *a* and *b*. COMPARISON OF THE EFFECTS OF *SC* 5233 (5 MGM./RAT) INJECTED BENEATH THE SKIN ON ELECTROLYTE EXCRETION AND PLASMA ELECTROLYTE-LEVELS IN SHAM-OPERATED AND ADRENALECTOMIZED RATS (EIGHTH DAY AFTER OPERATION)

Recently Mills *et al.*[4] have shown in the normal individual that 'Aldactone' will produce some measure of antagonism to the sodium-retaining properties of cortisol, but none towards its kaliuretic effect.

In these experiments the potassium retention, which is not attributable to any alteration in plasma potassium concentration, is most probably the result of an increase in the proximal tubular re-absorption of sodium. This would lead to a decrease in the amount of sodium available for the distal tubular exchange of sodium for potassium or hydrogen-ion. The fact that *SC* 5233 is effective in antagonizing the retention of sodium produced by cortexone and aldosterone would suggest tentatively that sodium-retaining steroids may exert part of their action on sodium excretion by an effect on the proximal tubule.

Electron Transport System and Phosphoproteins of Mitochondria

IN previous papers[1] it was shown that phosphoprotein turnover and mitochondrial swelling went hand in hand, and that inhibition of one was associated with inhibition of the other. It was also shown that mitochondrial contraction and protein phosphorylation were closely associated.

In the present communication we give results which suggest strongly that phosphoproteins may accept phosphorus directly from some component of the oxidative phosphorylation system, and we show that the phosphoprotein fraction studied is identical with that studied by other workers[2,3] in ascites and brain.

Isolated mitochondria incubated in 0·125 *M* potassium chloride or 0·25 *M* sucrose containing inorganic phosphorus labelled with phosphorus-32 take up the tracer rapidly and incorporate it into adenosine triphosphate (ATP) and phosphoprotein. No other insoluble component is labelled. Table 1 shows the conditions for the experiment. Inorganic phosphorus was present at a concentration of 10^{-4} *M*, and swelling of the mitochondria was prevented by the inclusion of ethylenediamine tetraacetic acid (EDTA), both in the reaction medium and in the sucrose used for homogenizing and washing the particles. It can

Table 1. EFFECT OF DNP AND ANTIMYCIN *A* ON PHOSPHOPROTEIN TURNOVER

Exp. No.	Compound	Specific activity c.p.m./μmole phosphorus in presence of Nil	DNP (10^{-4} *M*)	Antimycin *A* (2 μgm./ml.)
1	Alkali-labile phosphorus	175,000	41,500	—
	ATP	1,100,000	1,080,000	—
2	Phosphorus-serine	1,860	430	—
	ATP	22,000,000	21,050,000	—
3	Phosphorus-serine	1,624	—	142
	ATP	21,800,000	—	18,000,000

Mitochondria equivalent to 600 mgm. liver were suspended in 2·0 ml. 0·125 *M* potassium chloride containing 0·02 *M* trihydroxymethylaminomethane hydrochloride buffer, *p*H 7·2. Phosphorus-32 was added as a solution giving 10^{-4} *M* phosphorus final concentration, with 2×10^6 c.p.m. in experiment 1 and 56×10^6 c.p.m. in experiments 2 and 3. The phosphorus–serine determinations were done as described by Heald (ref. 3), carrier phosphorus–serine being added before hydrolysis. The alkali-labile phosphorus was estimated as described by Judah (ref. 1). Temperature, 20°. Time, 30 min.

be seen from the results that 2:4-dinitrophenol (DNP) and 'Antimycin *A*' powerfully inhibit uptake of phosphorus-32 into phosphoprotein. This was measured both by determination of alkali-labile phosphorus and by determination of the radioactivity of phosphorylserine after partial acid hydrolysis and chromatography, as descibed by Heald[3], and by Kennedy and Smith[2]. There is no doubt as to the identity of the fraction inhibited. Other inhibitors such as cyanide, amytal, and azide give similar effects. It is to be noted that none of them affects the level and turnover of intramitochondrial ATP.

In further experiments, it was found that reduction of the electron transport chain by the addition of substrate and by anærobiosis also reduces phosphoprotein turnover (Table 2). This is in agreement with Wadkins and Lehninger's findings[4] that reduction of the carriers inhibits the ^{32}P-ATP exchange reaction. Though Table 2 shows that intramitochondrial ATP is unaffected by reduction of the carriers, the turnover of added ATP is inhibited in our systems, in confirmation of Wadkins and Lehninger[4].

As previously reported, several antihistamine drugs also inhibit phosphoprotein turnover, but have no effect on oxidative phosphorylation. In particular, the drug 'Benadryl' (diphenhydramine hydrochloride) inhibits phosphoprotein turnover by 60–80 per cent but has little effect on the ^{32}P-ATP exchange reaction or on oxidative phosphorylation. This would seem to rule out the possibility that phosphoproteins participate directly in the oxidative phosphorylation reaction. The participation of such compounds, though unlikely, is not ruled out by their low specific activity as compared to that of ATP. Rabinowitz and Lipmann[5] have shown that phosphorylation of ADP by labelled phosphoprotein gives rise to ATP of specific activity many times higher than that of the parent phosphoprotein. This indicates a considerable lack of homogeneity of the phosphorus groups in the latter.

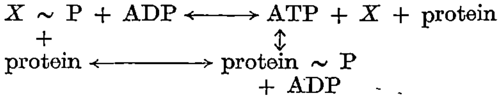
Table 2. EFFECT OF REDUCTION ON PHOSPHOPROTEIN RADIOACTIVITY

System	C.p.m. in phosphoprotein	Specific activity c.p.m./μmole phosphorus of mitochondrial ATP
Oxidized	2,300	$8{\cdot}1 \times 10^6$
Reduced	1,400	$8{\cdot}6 \times 10^6$

The system was as described in Table 1. Reduction of the mitochondrial system was effected by addition of potassium cyanide, 2×10^{-3} *M*, and glutamate, 5×10^{-3} *M*.

It is curious that turnover of mitochondrial ATP is unaffected by the inhibitors. The existence of ^{32}P-ATP exchanging systems insensitive to mitochondrial DNP, however, has been described by Chiga and Plaut[6].

A possible mechanism for the reaction of phosphoproteins is shown in the following reaction, in which they form part of a cyclical system:



$$\begin{array}{lcl} X \sim \mathrm{P} + \mathrm{ADP} & \longleftrightarrow & \mathrm{ATP} + X + \text{protein} \\ + & & \updownarrow \\ \text{protein} & \longleftrightarrow & \text{protein} \sim \mathrm{P} \\ & & + \mathrm{ADP} \end{array}$$

where $X \sim \mathrm{P}$ is an intermediate of the system.

Odour Receptors

WHILE there is evidence[1] that the odour of any compound is related to low-frequency molecular vibrations which give rise to infra-red absorptions in the 15–20μ region of the spectrum, and to Raman shifts below 600 cm.$^{-1}$, there is at present no information concerning the nature of the receptors of these energies. Yet it is quite clear that the olfactory epithelium must contain molecules capable of interacting with the odorant in the nasal space. Moreover, unless the interaction between odorants and receptors occurs within the epithelial cells, which is most unlikely, due to the rapidity of reception of odour and the tremendous variability in solubility of compounds with similar smells, the receptors must be located on the interface between the epithelial cells and the air cavity. Working on this basis, we have attempted to investigate the nature of compounds specifically located on this interface.

It has been known for many years[2] that the soft vascular mucous membranes of the olfactory areas are yellow, whereas non-olfactory areas are not. These yellow areas are known to contain carotenoids[3]. Considering the embryological similarity of the olfactory area and the retina, together with the known function of carotenoids and haplocarotenoids in vision[4], we have carried out experiments to test the hypothesis that the olfactory area contains protein-bound carotenoids which are the molecular receptors of odours.

The heads of freshly killed cows were opened to expose the olfactory regions. These were wiped with petroleum ether to remove excess mucus and melanin, and were then carefully scraped with a scalpel to collect the uppermost tissues. The material collected was pooled into a 2 per cent digitonin solution which was extracted with ether to remove free carotenoids. The absorption spectrum of both the digitonin solution and the ether extract was determined. The extract gave absorption peaks at a variety of wave-lengths in the visible and the ultra-violet regions. From an examination of the spectrum the presence of free α- and β-carotene and of vitamin A was deduced.

The digitonin solution was treated with acetone, which liberates carotenoids from combination with proteins. The mixture was shaken with ether and the ether fraction separated, dried *in vacuo*, and the resulting solution examined spectroscopically. The solution possessed absorption maxima at 445 and 475 mμ. The untreated digitonin solution possessed a weak absorption maximum at about 420 mμ and this was no longer detectable in the spectrum of the acetone-treated residue.

These results indicate that the olfactory epithelium contains free carotenoids and free vitamin A, and also protein-bound carotenoids the chromophore of which is removed by acetone treatment. By analogy with the protein-bound haplocarotenoids of the retina, the rhodopsins, it seems reasonable to assume that protein-bound carotenoids of the olfactory epithelium are the receptors of energy from olfactant molecules entering the nasal cavity. The mechanism of interaction is, of course, obscure, but the known ability of carotenoids to exist in numerous *cis–trans* forms[5], together with the knowledge that the only action of light on rhodopsins is to induce a geometrical isomerization[6], suggest that the exchange of energy from an olfactant molecule to an olfactory protein-bound carotenoid involves a similar molecular change.

This hypothesis suggests that, as animals are not able to synthesize carotenoids, an animal raised on a carotenoid-free diet will have impaired olfactory abilities.

Supporting evidence comes from clinical experience. One of us (R. B. D.) has treated a series of 56 patients with uncomplicated anosmia by intramuscular injection of large doses of vitamin A. Of these patients, 50 recovered olfaction in part or completely. This therapeutic effect may be ascribed to some interaction of carotenes and haplocarotenoids in the olfactory areas.

These experiments and clinical results will be published in more detail elsewhere.

We are grateful to the Wellington Meat Export Co., Ltd., for providing the animal materials and for helpful assistance.

PHARMACOLOGY

Histidine Decarboxylase and Growth

Kahlson[1,2] has presented evidence of a relationship between activity of histidine decarboxylase and growth or wound-healing in rat tissues. In particular he has shown that the developing liver of the fœtal rat has much higher histidine decarboxylase activity than the normal liver of adults. Telford and West[3] have shown that the enzyme of the liver of the fœtal rat has an optimum *p*H of 6·5 compared with 8·0 for that of the adult. They have also found that the activity of histidine decarboxylase of adult rat liver is very low unless benzene is added to the incubation medium. The enzyme of the liver of the fœtal rat, on the other hand, is not activated by benzene. Low histidine decarboxylase activity in fœtal rabbits and guinea pigs has recently been reported (ref. 4).

We have carried out some experiments to determine the histidine decarboxylase activities of liver and kidneys of fœtal, young, and adult guinea pigs. Saline extracts (4·0 ml./gm. tissue) were prepared from the tissues in the usual way, and incubations were carried out as described in ref. 5. The reaction was stopped after 200 min., and the histamine produced was assayed on the atropinized guinea pig ileum.

The results, which are given in Table 1, show that the histidine decarboxylase activities are low in the liver and kidney of fœtal guinea pigs, and that they rise just before or just after birth to the adult-levels.

When incubations of fœtal guinea pig liver extracts were carried out in the presence of benzene, the histamine production was increased two- to four-fold, as occurs with adult tissues. The histidine decarboxylase activity of fœtal and adult guinea pig liver was measured over the range *p*H 8–10 in steps of 0·5 *p*H unit using *M*/20 borate buffer ; the maximum rate of histamine formation with both fœtal and adult liver occurred at *p*H 9.

All these results are in complete contrast to those observed with the rat.

We have also prepared extracts of regenerating rays of starfish (*Asterias rubens*), extracts of normal rays being used as controls. In no case was histidine decarboxylase activity detected.

Weiss and Matoltsy[6] reported that wounds made in the skin of chick embryos before the tenth day of incubation failed to heal, while those made in embryos after the twelth day of incubation healed normally. We have examined extracts of chick embryos for histidine decarboxylase activity. In each case whole embryos were used, but the disproportionately large eyes were omitted. Neither at the eighth nor at the seventeenth day of incubation was any histidine decarboxylase activity detectable over the *p*H range 6·4–8·2. No histidine decarboxylase was detected in the livers or kidneys of chicks one day after hatching.

Table 1. HISTIDINE DECARBOXYLASE ACTIVITIES IN LIVER AND KIDNEY OF FŒTAL, YOUNG AND ADULT GUINEA PIGS

	Animal weights (gm.)	Histamine (μgm./ml.) formed in incubation medium	
		Liver	Kidney
Fœtal guinea pigs	9·5–23	0·6–0·08	—
,, ,, ,,	48–68	0·1–0·2	0·1–0·4
Young ,, ,,	108–147	0·4–0·5	2·2–3·1
Adult ,, ,,	400–900	0·51 ± 0·21	2·6 ± 0·7

The results do not indicate any general relationship between histidine decarboxylase activity and growth.

We are grateful to Dr. J. D. B. MacDougall and Dr. A. J. Matty for the supply of eggs and starfish, respectively, and we acknowledge the award of research fellowships from Smith, Kline and French Laboratories (D. M.) and the Medical Research Council (J. D. R.).

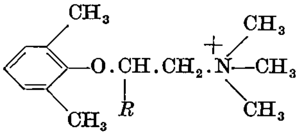
Adrenergic Neurone-blocking Agents related to Choline 2,6-Xylyl Ether Bromide (*TM* 10), Bretylium and Guanethidine

Several compounds have been shown to block transmission at peripheral adrenergic nerve terminals without antagonizing the effects of adrenaline and noradrenaline. They include the quaternary ammonium salts choline 2,6-xylyl-ether bromide (*TM* 10) (I)[1,2], bretylium (III)[3,4], and related substances[3,5–7]. The two compounds named have been shown to act by preventing the release of the adrenergic transmitters at the nerve endings[4,5]. Guanethidine (IV) also blocks peripheral adrenergic mechanisms. Its action, like that of reserpine but in contrast to that of bretylium[8], is associated with marked depletion of peripheral stores of catechol amines[9,10]. This depletion is accompanied by depression of the sympathomimetic responses to tyramine and amphetamine[11], which apparently act by releasing peripheral catechol amines[12]. Responses to tyramine and amphetamine are also affected by bretylium; but only when the drug has been administered for several weeks does the degree of depression equal that seen 24 hr. after guanethidine[13,14]. Whether the depletion of catechol amines is responsible for the adrenergic nerve blockade caused by either drug is uncertain. Depression of the responses of the nictitating membranes of cats to sympathetic nerve stimulation follows rapidly after intravenous injection of guanethidine, but depression of equivalent responses to tyramine is slight at this time and becomes prominent only after several hours[14]. Similarly, the depletion of catechol amines by guanethidine[10] is relatively slow in onset.

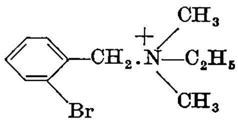
It is therefore possible that guanethidine may have a fundamentally similar action to that of the quaternary blocking agents. Compounds with either a guanidine or quaternary ammonium group are highly basic and would exist almost exclusively in the cationic form at physiological *p*H. These groups could have similar influences in governing pharmacological action.

To enable this possibility to be examined, guanidine derivatives such as V–VIII (for which patents are pending), which bear an obvious relationship to the *TM* 10 and bretylium series of drugs, were synthesized. The screening methods previously described[3,6] then showed that these compounds, too, are powerful adrenergic neurone-blocking agents.

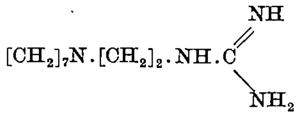
Among the most potent are *BW* 467*C*60 (V; R=H; $R^1=R^2=CH_3$) and *BW*392*C*60 (V; R=Cl; $R^1=R^2=CH_3$). They are about twice as active as guanethidine when tested by their relaxant action on the nictitating membranes of cats and are as effective by the oral route as they are parenterally. Their blocking action on peripheral adrenergic nerves is highly specific but is preceded by a brief sympathomimetic effect when high doses are given. Like bretylium[4] and guanethidine[11], they increase the pressor and nictitating membrane contracting effects of adrenaline and noradrenaline. *BW* 392*C*60 resembles bretylium rather than guanethidine in that it does not readily inhibit the responses of the nictitating membrane and blood pressure of cats to tyramine given 24 hr. later, and does not markedly lower the pressor amine contents of the spleens of cats even when 10 mgm./kgm. doses are injected daily for 6 months. In contrast, *BW* 467*C*60 resembles guanethidine by greatly depressing the responses to tyramine and amphetamine within 24 hr. after administration, and by greatly lowering the pressor amine content of the hearts and spleens of cats in experiments where the drug was injected daily for 6 months (shorter periods have not yet been investigated). However, under the conditions we have used so far, the inhibitory action of *BW* 467*C*60 on responses to tyramine was less than that shown by guanethidine in doses that produced similar degrees of adrenergic nerve blockade. The pharmacological properties of these two compounds



(I; R=H) *TM* 10
(II; R=CH_3)

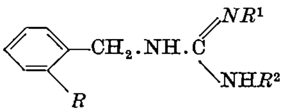


(III) Bretylium

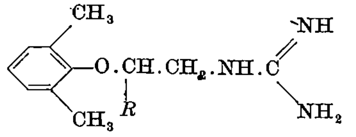


$$[CH_2]_7N.[CH_2]_2.NH.C\begin{array}{l}/\!\!/NH\\ \backslash NH_2\end{array}$$

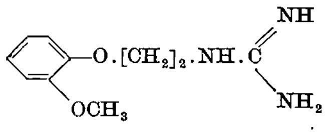
(IV) Guanethidine



(V; R=H, CH_3, Cl, Br, NO_2; R^1 and/or R^2=H, CH_3 or C_2H_5)



(VI); R=H)
(VII; R=CH_3)



(VIII)

are still being studied and will be published in detail elsewhere; but it is of general interest that they have already shown properties that appear to relate the effects of bretylium to those of guanethidine.

A particularly close analogy between quaternary ammonium blocking agents and related guanidine derivatives was found in the phenoxyethyl compounds. *TM* 10 (I) produces a number of powerful muscarine-like actions[1] that are shown to only a small degree by the β-methyl substituted derivatives (II)[7]. Similarly, in the guanidine series, adrenergic neurone-blocking and muscarine-like properties were shown by compound VI, but only the former effect was obvious with the substituted derivative VII. *N*-methyl substitution in these compounds has been accompanied by loss of adrenergic neurone-blocking activity.

HÆMATOLOGY

Cytochemistry of *L*1210 Cells

A DIFFERENCE in the respiratory behaviour of sensitive and 6-mercaptopurine-resistant *L*1210 mouse leukæmia cells has been noted by me[1]. Sensitive cells incubated *in vitro* in a Warburg apparatus had a net average gas output of 1·3 (range 1·1–1·8) μμl./cell/hr., whereas the cells resistant to mercaptopurine had a net average gas output of 0·1 (range 0·5 to minus 0·15) μμl./cell/hr.

A possible interpretation of these results is that the sensitive cells have a much more active glycolytic metabolism than the cells resistant to mercaptopurine. Active glycolysis would cause the production of lactic acid, which, reacting with the bicarbonate in the medium, would liberate carbon dioxide and give a high net gas output. In order to obtain more information on this aspect of the metabolism of the two cell strains, cytochemical tests of their succinic and lactic dehydrogenase activities were carried out. Amethopterin-resistant cells were examined along with the mercaptopurine-resistant cells and those of a strain sensitive to both agents. Cytological and cytochemical investigations with some of the commonly used techniques were also carried out.

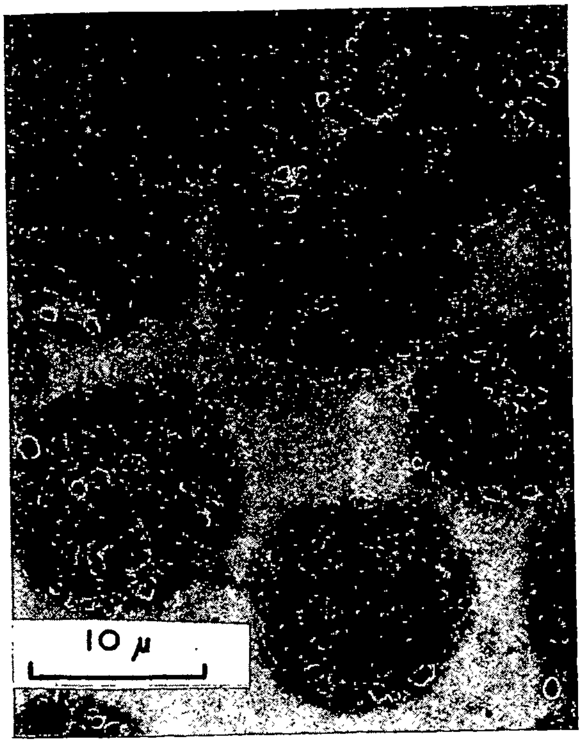

Fig. 1. Sensitive *L*1210 cells showing four-plus lactic dehydrogenase activity

Smears were made from the ascitic fluids of mice which had been inoculated intraperitoneally with one or other of the three cell strains. These were stained by May–Grünwald–Giemsa, periodic acid–Schiff, sudan black, alkaline phosphatase, peroxidase and Feulgen techniques using standard methods. Smears were stained for activity of succinic dehydrogenase using the technique in ref. 2 and for lactic dehydrogenase activity by a suitable modification of the same method.

Five separate specimens of the sensitive and amethopterin-resistant *L*1210 cells and four of the mercaptopurine-resistant *L*1210 cells were examined at intervals of at least a month. The results were consistent in each strain of cell. May–Grünwald–Giemsa stained smears showed no morphological differences between the three strains; each was composed of large pleomorphic leukæmic blast cells having mitotic indices ranging from three to twelve a thousand.

All three strains were negative with the periodic acid–Schiff, alkaline phosphatase and peroxidase stains. Vacuoles in the cytoplasm of all three stained a light grey by the sudan black technique; they did not have the intense positivity found in granulocytes. The Feulgen technique showed up the fine nuclear chromatin pattern and the nucleoli were prominent. Again no differences could be detected between the three cell strains.

The results of the dehydrogenase-staining techniques are given in Table 1. Each smear was assessed semi-quantitatively from one plus to four plus. In the one-plus smears an occasional cell contained a

Table 1. Dehydrogenase Activities of L1210 Cells

	Sensitive	Mercaptopurine-resistant	Amethopterin-resistant
Succinic dehydrogenase activity	+ + or +	+ or 0	+ or 0
Lactic dehydrogenase activity	+ + + + or + + +	+ or 0	+ or 0

few positively stained granules, whereas in the four-plus smears the majority of the cells showed many positive granules (Fig. 1). The sensitive cells were found to have a much greater lactic dehydrogenase activity than the resistant cells, a fact which lends support to the idea that they have a more active glycolytic metabolism. The former also had a greater succinic dehydrogenase activity, but the difference was less marked. The results suggest that sensitive cells may be generally more active in their respiration than the resistant cells.

The fact that sensitive and resistant L1210 cells have differences in respiratory metabolism which can be demonstrated cytochemically suggests that a similar examination of human leukæmic cells would be worth while. If cytochemical differences could be found between sensitive and resistant cells, they would be valuable for predicting the effect of therapeutic agents on human leukæmias.

I am grateful to Dr. L. Law for providing the resistant strains of L1210 cells, to Dr. S. R. M. Bushby and Miss M. Barnett for maintaining them and supplying me with inoculated mice, to Miss T. Minett for technical assistance and to the Lady Tata Trust for a grant-in-aid.

Hæmoglobin 'Bart's' and the Sickling Phenomenon

While examining the hæmoglobin of hydrops and erythroblastosis fœtalis, in an attempt to correlate fœtal disease with hæmoglobin 'Bart's', five consecutive cases (four in Indonesia and one in Malaya) were found in which fœtal hydrops and erythroblastosis were associated with this type of hæmoglobin[1,2]. Four of these cases were examined in detail, and the sickling phenomenon was noted in the abnormal erythrocytes; the amounts of the abnormal fast-moving hæmoglobin were very high, and formed by far the major component. A small amount of hæmoglobin H was detected in all four specimens; no hæmoglobin S was detected in any of them. Hæmoglobin 'Bart's' is now believed to be identical with the Fessas and Papaspyrou type of hæmoglobin[3–5].

In order to eliminate the possibility of false sickling[6], tests on the abnormal erythrocytes were carried out simultaneously with control tests of normal erythrocytes on the same slide. The abnormal erythrocytes, when left on a slide under a cover-glass, without sealing, or when left between two cover-glasses, were found to sickle in 1–1½ hr.; after 24 hr. most of these erythrocytes were sickled (Fig. 1). If the blood were stored under paraffin for 24 hr., sickling was not seen on immediate examination, but appeared after the slide had been left for about 1 hr.; thus it appears that de-oxygenation of the blood is not the cause of the sickling. If oxygen, nitrogen, or carbon monoxide were bubbled through the blood, the erythrocytes were found not to sickle immediately; but, if left for 1 hr. or more on the slide, sickle cells appeared. Sickling was found to occur at any point over the pH-range studied, 6·4–7·8. Clear solutions of the hæmoglobin prepared from these erythrocytes, when left to stand, were found to develop a precipitate; on examination this was found to be composed of fine granules.

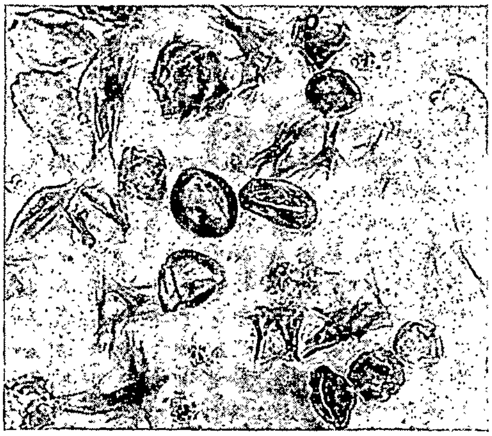

Fig. 1. Sickling of erythrocytes containing hæmoglobin 'Bart's' + H

The easy sickling of these cells seems to be provoked by a peculiarity of the 'Bart's' (= F and P) hæmoglobin. The influence of hæmoglobin H cannot be entirely ruled out, but this hæmoglobin by itself has never been reported to be associated with sickling.

While these investigations were in progress, Atwater *et al.* reported the sickling of erythrocytes containing another fast-moving hæmoglobin (I) in high concentration[7].

Since the completion of this communication, three further cases of severe hydrops fœtalis associated with a large amount of hæmoglobin 'Bart's' have been found. Careful examination of the red blood cells again revealed the sickling phenomenon in all three of them, while control studies were negative.

PATHOLOGY

Energy Pathways of Hepatoma No. 5123

Since the original experiments of Warburg with slices of tumour there has been intense investigation of, and discussion about, a specific tumour energy metabolism[1,2]. This concept, originally characterized by high rates of aerobic and anaerobic glycolysis, has been extended to include certain ancillary features: a moderate respiratory rate with minimal increase in respiration following the addition of succinate and other respiratory substrates[3], a respiratory quotient (*R.Q.*) between 0·75 and 0·90 signifying a mixed protein, fat, carbohydrate respiratory substrate[4], and a protein-synthesizing system which effectively incorporates amino-acid anaerobically if glucose is present[5]. Up to the present time the major exceptions to the concept of a specific tumour metabolism have been certain normal tissues (renal medulla, jejunal mucous membrane, myeloid bone marrow and retina) which share one or more of the characteristics of the tumour slice[2]. Occasional mouse tumours have been observed which display active anaerobic glycolysis without aerobic glycolysis[6], a finding which has been explained by the active respiratory rate and normal Pasteur effect of mouse tissues. The present communication is of particular interest because for the first time a rat tumour is described which displays very low rates of aerobic and anaerobic glycolysis.

Morphological and biological characteristics of the transplantable liver carcinoma No. 5123, induced in a Buffalo-strain rat by the injection of *N*-(2-fluorenyl)-phthalamic acid and carried by subcutaneous and intramuscular transfer, have been described by Morris *et al.*[7]. The levels of certain enzymes of deoxyribonucleic acid metabolism in this hepatoma were found to be similar to those of normal liver by Potter *et al.*[8].

Values of the conventional metabolic quotients (expressed in µl. oxygen or acid per mgm. dry tissue per hr.) for slices (35–40 mgm. dry weight) suspended in Krebs–Ringer bicarbonate or Ringer phosphate medium (total volume 4 ml.) and a gas phase of 95 per cent nitrogen/5 per cent carbon dioxide or of oxygen. An hour incubation at 37° was used with chemical determination of lactate by the method of Barker and Summerson[9].

Table 1. GLYCOLYSIS AND RESPIRATION OF SLICES OF HEPATOMA No. 5123*C* GENERATION 21_1

Quotients		Average duplicate values		
$Q_A^{N_2}$	(manometric)	1·3	1·4	1·7
$Q_{\text{Lactic}}^{N_2}$	(chemical)	1·0	1·0	0·9
$Q_{\text{Lactic}}^{O_2}$	(chemical)	0·6	0·4	0·5
Q_{O_2}		5·1	5·3	4·5
Q_{O_2}	(0·015 *M* glucose)	4·9	5·3	5·0
Q_{O_2}	(0·015 *M* glucose, 0·013 *M* succinate)	18·4	17·7	24·4

Very low rates of aerobic and anaerobic glycolysis were observed in the Morris hepatoma, rates which are lower than those usually reported for normal liver[10]. Hepatoma No. 5123 possesses a modest respiratory rate with a Q_{O_2} of 5·0. Two other features of this tumour which are distinctly unusual for neoplastic tissues are also reported in Table 1. These are the absence of a Crabtree effect and a respiratory rate in the presence of succinate which is more than three times the rate found in its absence. It has also been found that the mitochondrial fraction of the Morris tumour (prepared by centrifugal fractionation in isotonic sucrose[11]) contains 17 per cent of the total nitrogen content of the whole tumour. This value is similar to the 19 per cent value for the mitochondria of normal liver and should be contrasted with values of 2·4–3·9 per cent reported for the mitochondria of other transplantable rat tumours[11].

The data of Table 2 indicate that hepatoma No. 5123 is able to incorporate anaerobically very little amino-acid into protein even in the presence of glucose. This behaviour is similar again to normal liver, but quite different from the glycolysing neoplasms studied in the past which display active amino-acid incorporation in nitrogen if glucose is added[5].

Table 2. INCORPORATION OF ^{14}C-VALINE INTO HEPATOMA No. 5123*C* SLICES

Experimental conditions were similar to those of Table 1 except that 1·4 × 10^5 c.p.m. of valine-1-^{14}C (final concentration of 0·003 *M*) were added to each flask and the radioactivity of the purified proteins determined at the end of the experiment (ref. 5)

Conditions	Incorporation (c.p.m. per mgm. protein)		
Nitrogen (0·015 *M* glucose)	0·8	0·5	0·2
Oxygen	21·6	9·0	
Oxygen (0·015 *M* glucose)	19·4	12·9	10·6

The experiments reported here indicate that the Morris hepatoma possesses a primarily aerobic energy metabolism. This is evidenced by a large mitochondrial content, an excellent response of the respiratory rate to succinate addition, minimal anaerobic and aerobic glycolysis, absence of a Crabtree effect, and little glycolytically supported amino-acid incorporation. Its energy metabolism resembles adult liver, and is remarkable in the absence of the biochemical features which have previously been found to characterize the energy pathways of the tumour slice. The Morris hepatoma, though frequently lethal to the tumour-bearing animal, is a slow-growing and morphologically well-differentiated neoplasm. In the examination of the comparative biochemistry of tumours, this type of neoplasm may prove of more importance than the anaplastic, rapidly growing, glycolysing animal neoplasms which have been investigated in the past. The finding of additional tumours of this type will seriously weaken the hypothesis of a specific tumour energy metabolism.

We wish to thank Dr. Van R. Potter for his valuable suggestions concerning this work. Dean Burk and Mark Woods have also observed very low aerobic and anaerobic glycolysis in hepatoma No. 5123 (personal communication).

Inclusions of Mucopolysaccharide in the Lymphocytes of Patients with Gargoylism

GARGOYLISM is a syndrome which comprises a large number of abnormalities. The skeleton, in particular, is severely affected, with dwarfism, a large and deformed skull, a shortened neck and characteristic abnormalities of the thoracic and lumbar vertebræ. Deafness is often present, and the disease is also associated with enlargement of liver and spleen, with clouding of the cornea and with mental deficiency[1].

The condition is genetically determined and appears to be an inherited disorder of mucopolysaccharide

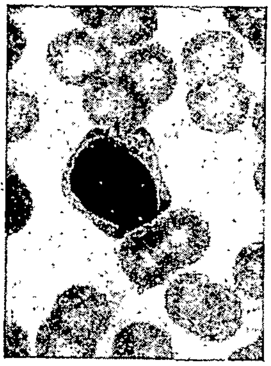

Fig. 1. Lymphocyte with cytoplasmic inclusions. Air-dried film, May–Grunwald–Giemsa

metabolism[2]. Large quantities of chondroitin sulphate have been isolated from the tissues and urine of patients[3], and deposits of acid mucopolysaccharide have been demonstrated histochemically in the liver and other tissues[2,4,5]. An earlier report[6] suggested that abnormal inclusions were present in the lymphocytes. This has now been confirmed in a total of eighteen patients, of whom fourteen were males and four were females.

Blood films were obtained from finger pricks and fixed in absolute methanol. The following stains were used: (1) May–Grunwald–Giemsa; (2) toluidine blue; (3) alcian blue in 2 *N* sulphuric acid (on three patients only).

In all patients some of the lymphocytes contained abnormal inclusions. In air-dried films stained with May–Grunwald–Giemsa they are usually in the form of granules of varying shapes (dots, commas or small rings; Fig. 1), stained purple; often each granule appears to be surrounded by a vacuole. Such inclusions are encountered in lymphocytes of all sizes, even in small ones containing only little cytoplasm. Sometimes one or two larger inclusions may be present instead of a cluster of small ones. The proportion of lymphocytes with inclusions varied between 5 and 50 per cent in different preparations. This may be connected with the fact that the inclusions are fairly soluble in aqueous solutions and dissolve readily in solutions of saline and of phosphate, leaving a vacuolated cytoplasm.

There is usually no difficulty in distinguishing the inclusions found in gargoylism from the azurophilic granules of normal lymphocytes. The inclusions are deeply stained and well defined and tend to occur in clusters, and each granule is typically surrounded by a well-defined vacuole, whereas the azurophilic granules are less well defined and tend to be scattered in the cytoplasm. With toluidine blue the difference is absolute, since the abnormal inclusions stain metachromatically (Fig. 2), while azurophilic granules are not stained at all. In films stained with alcian blue, bluish-green inclusions are present in some of the lymphocytes (Fig. 3).

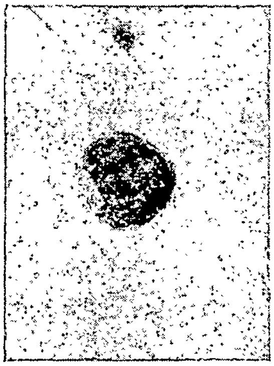

Fig. 2. Lymphocyte with cytoplasmic inclusions. Air-dried film, toluidine blue

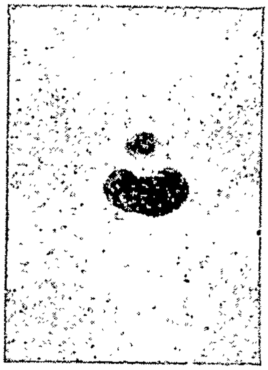

Fig. 3. Lymphocyte with large inclusion. Wet-fixed film, alcian blue and neutral red

The staining reactions of the inclusions with toluidine blue and with alcian blue, as well as their solubility, agree with the assumption that they are composed of acid mucopolysaccharide. There is a close parallel to the staining behaviour of the granules of the basophil polymorphonuclear leucocytes. The latter contain heparin, a sulphated mucopolysaccharide the cytochemical reactions of which are very similar to those of chondroitin sulphate.

The question whether the inclusions are secreted by the lymphocytes or are merely stored there cannot be answered at present, though secretion seems the more likely hypothesis. Lymphocytes containing mucopolysaccharides have so far been described in only one mammalian species, the guinea pig[7,8], and here the evidence suggests that the mucopolysaccharides are secreted.

The fact that, as a result of an inborn error in mucopolysaccharide metabolism, human lymphocytes contain inclusions of acid mucopolysaccharides, provides a simple diagnostic test for gargoylism. It may also throw light on the function of the lymphocyte, which, in spite of much literature devoted to it, is still unknown.

I am grateful to the following clinicians for permission to obtain films of blood from their patients: Dr. R. E. Bonham-Carter, Dr. Margaret Eastwood, Dr. H. R. Ferguson, Dr. O. P. Gray, Dr. B. H. Kirman, Dr. G. S. Mansell, Dr. David Morris, Dr. T. E. Oppé, Dr. B. W. Richards, Dr. Jean Smellie, Dr. D. H. R. Thomas and Dr. J. P. M. Tizard.

CONSTANT LOAD WEIGHING BY SUBSTITUTION

As an alternative to the applied-load system of weighing, Stanton now offers the Unimatic single-pan balances—constructed on the constant-load principle of weighing by substitution. The compact, sturdy aluminium case enclosing the instrument is finished in green and black hammertone. Width 13", depth 16", height 20½", weight 32 lb. With the introduction of the Unimatic series, the Stanton range of precision balances now provides an unrivalled choice to meet every requirement.

UNIMATIC Balances	maintain their accuracy over the whole weighing range being designed on the now well known principle of weighing by substitution.
UNIMATIC Balances	are simple to use—even an inexperienced operator can learn how in a few minutes.
UNIMATIC Balances	are safe in use—their non-magnetic stainless steel weights are adjusted to within the new N.P.L. tolerances for analytical weights (errors less than 1 in 200,000). They are well protected within the balance case and their accuracy cannot vary.
UNIMATIC Balances	are fast—very fast in use. Their controls are conveniently positioned at bench level. Time and Motion study experts have approved this design which results in less fatigue and more weighings in less time—in fact less than 30 seconds for the weighing of an unknown object.

BIOLOGY

Inclusion of Parental Somatic Cells in Sponge Larvæ

THE common boring sponge *Cliona celata* (a marine siliceous type) is oviparous. This characteristic, exceptional among sponges, makes it particularly useful for embryological investigation.

When the fertilized eggs are ejected from a maternal osculum, each carries 20–35 small amœboid cells clinging to its surface. These contain numerous brownish-yellow cytoplasmic granules, and also retain some of the yellow picric acid stain of Bouin's fixative even after prolonged washing. These two points identify them with a type of small amœbocyte widespread in sections of the adult sponge, and conspicuous in the thin edges of reconstitution cultures[1]. They stain deeply if the eggs are immersed in dilute brilliant cresyl blue.

During cleavage, the amœboid cells move into the clefts between the blastomeres, apparently without themselves dividing. In sections of mature larvæ, they are found in the inner mass of amœboid cells and between it and the external flagellated epithelium. Though their cytoplasmic granules have almost disappeared, they are still recognizable by their stubborn retention of picric acid during histological preparation. They can be found in undiminished numbers throughout the 2-day larval life.

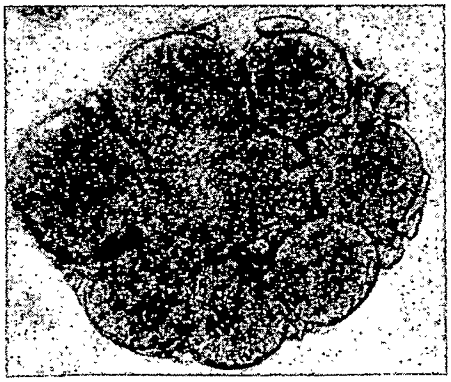

Fig. 1. Embryo of *Cliona celata* showing maternal cells on and among the blastomeres

Unfortunately, I have not been able to learn whether these maternal cells persist through metamorphosis, and become incorporated in the new young sponge, or (as seems more likely) merely serve as a food reserve for the larva. In either case, the larva of *Cliona* is a chimera, composed of parental somatic cells mixed with cells formed by cleavage of the zygote.

In 1920, Gatenby[2] mentioned that maternal cells from the nutrient capsule of the embryo sometimes enter the posterior mass of non-flagellated cells in the embryo of *Grantia compressa*, a calcareous sponge. This suggests that the chimeric structure of the larva may be common throughout the phylum Porifera.

Cyclical Infection of *Glossina morsitans* with Culture Forms of *Trypanosoma rhodesiense*

THE natural rate of salivary gland infection of tsetse flies with trypanosomes of the *brucei* sub-group is very low, being only about 0·25 per cent[1].

One of the main problems associated with the work on trypanosomiases of this sub-group is the difficulty research workers experience in obtaining adequate supplies of metacyclic trypanosomes for experimental purposes. No circumstances are known which will invariably lead to cyclical infection of the natural vector[1].

During 1959–60, one of us (the late R. M. G.) noticed that tsetse flies fed artificially on culture forms of *Trypanosoma rhodesiense* appeared more readily to develop gut infections than flies fed naturally on infected mammalian hosts. In view of the potential importance of this observation, a pilot experiment was planned in which a small number of *Glossina morsitans* were fed on culture forms of *Trypanosoma rhodesiense*, the tsetse flies afterwards being maintained for three weeks on heparinized human blood. One of these flies developed a patent gland infection.

The trypanosome strain used (*S.S.* 354) had been isolated from a human infection in 1959 and sent from Africa in deep freeze. Weinman[2] cultures were set up in January 1960 from the blood of mice previously inoculated with the human material. Since this date regular *in vitro* passages have been made, and in this experiment tsetse flies were fed on the 31st and 32nd sub-cultures.

The tsetse flies had hatched from puparia sent from East Africa, by the courtesy of the Director of the East African Trypanosomiasis Research Organization. They were given three feeds of the cultured trypanosomes. For each feed 0·2 ml. of the water of condensation from the culture containing approximately 2,000,000 trypanosomes was added to 10 ml. of fresh, heparinized human blood. This mixture, heated to 37° C., was offered to the tsetse flies through a specially prepared guinea pig skin membrane. Afterwards the same diluent without culture was fed twice-weekly to maintain the flies.

At time-intervals of 19–27 days after the first infective feed the tsetse flies were induced to probe on to a warmed glass slide[3], and Giemsa-stained drops of saliva were examined for metacyclic trypanosomes. One smear, from a fly first fed 27 days previously, showed typical metacyclic trypanosomes.

The whole group of experimental tsetse flies were then allowed to probe and to feed on an uninfected guinea pig which showed typical blood forms in peripheral wet blood films on the 9th day after the infective bite. Infection is persisting in this animal at a low level at the end of the fifth week after the infective bite. The trypanosomes are polymorphic.

It is hoped to confirm this finding in further experiments by showing that a significantly high proportion of tsetse flies will develop a salivary gland infection after feeding on trypanosome cultures, and that this can be cyclically transmitted by the arthropod vector.

Thyroid Function in Active, Sleeping and Torpid Hummingbirds

HUMMINGBIRDS have been of interest to physiologists for many years due to their small size and high metabolic rate. When it became apparent that these birds could be maintained under laboratory conditions[1] and then studied in regard to various physiological parameters, it appeared of interest to examine the role of the thyroid gland in relation to metabolism. Diurnal torpidity has been demonstrated in two species of hummingbirds[2,3], and recent studies[1] on several other species have quantified the relationship of the active, sleeping and torpid metabolic states to ambient temperature. Although the causes and implications of the torpid state are incompletely understood, it was felt that perhaps the function of the thyroid gland might be related to the metabolic state. Seven hummingbirds that had been maintained under laboratory conditions for nine months were each injected beneath the skin with 1 μc. of carrier-free iodine-131 in a volume of 0·05 c.c. At selected intervals after administration of the isotope, the birds were killed by ether and the thyroid glands removed. The thyroid glands were counted with a probable error not exceeding 1 per cent in a well-type scintillation detector against suitable standards of the original iodine-131 solution. The time of injections was arranged so that the period of accumulation of iodine-131 occurred in birds that were either active, asleep or torpid.

During this period all birds were maintained at 25° C. with access to food and water. Those that were exposed to daylight and artificial light remained active, while those that were kept in the dark were either asleep or torpid. The sex, body-weight, species, and iodine uptake of the birds are given in Table 1.

Table 1

Thyroid uptake of iodine-131 (per cent)	Interval (hr.)	Condition	Genus and species	Sex	Body-weight (gm.)
9·1	2·0	awake	*Calypte costae*	male	3·6
15·7	4·0	awake	*Calypte costae*	male	3·5
25·6	6·0	awake	*Calypte costae*	male	3·6
24·7	6·0	asleep	*Calypte anna*	male	4·6
22·1	12·5	awake	*Selasphorus rufus*	male	3·3
8·6	6·0	torpid	*Calypte costae*	female	3·1
10·4	6·0	torpid	*Archilochus alexandri*	female	3·6

The shape of the iodine-131 thyroid uptake curve based on the four birds that were awake and active resembles the shape of similar curves described for birds and mammals[4]. The maximum uptake of approximately 25 per cent occurring between 6 and 12·5 hr. approximated the findings for other species of birds[5–8]. Although the metabolic studies cited[1] demonstrate a drop in metabolism in sleeping, non-torpid birds, the 6-hr. uptake of the one bird that was asleep, and not active, closely resembled the uptake of the active, awake birds. However, the 6-hr. uptake of the two birds in the torpid state was reduced significantly, when compared with the uptake of non-torpid birds in 6 hr. Perhaps the reduced uptake by torpid birds may be ascribed to the further reduced metabolic activity of the torpid state. A *t*-test comparing the uptake of the two torpid birds to the two non-torpid birds at the 6-hr. interval yields $P > 0{\cdot}91$. It is unlikely that either the sex, or the size, or species differences would influence the thyroid uptake of iodine-131 so drastically[6].

As pointed out by Matthews[9], the factors controlling torpidity are still unknown, but the abruptness of the decline in temperature and metabolic rate suggests that the central nervous system probably controls its initiation and hence the reduced thyroid uptake of iodine-131 observed in the torpid state is, in all probability, a reflexion of the lowered metabolism rather than a cause for the reduced metabolism of torpidity.

Flimmer-flagellum of the Sponge

THERE is a considerable variation in the morphology of the flagella in the lower plant groups and in the flagellates. The flagellar structures have been used as systematic characters since the pioneering work of Petersen[1] and Vlk[2]. The following five types of flagella are recognized:

(1) One-sided flimmer flagella which have one row of hair-like appendages (called flimmer hairs or mastigonemata or, somewhat misleadingly, cilia). The flimmer hairs are about 3μ long, and the row extends along the entire length of the flagellum on its one side.

(2) Two-sided flimmer flagella which have two rows of flimmer hairs along the entire length of the flagellum.

(3) Whip flimmer flagella which have a demarcated thin end region devoid of flimmer hairs and a main region which possesses two rows of flimmer hairs. The flimmer hairs stand perpendicular to the flagellar axis.

(4) Whip flagella which are devoid of flimmer hairs but have a demarcated thin end region. These flagella are also called lash flagella.

(5) Flagella which lack flimmer hairs and also lack a demarcated end region visible in the light microscope.

These characterizations have been made from fixed specimens at high-magnification light microscopy after certain staining procedures. In some cases it has been possible to confirm the findings by dark-field microscopy on living flagella[2]. Manton[3] and Pitelka *et al.*[4] have been able to confirm and extend these observations by electron microscopy, mainly on whole mounts. Flimmer flagella have also become known under the names ciliated flagella and flagella of a tinsel-type structure.

The above classification is of interest mainly because the various groups of protozoans and plants are characterized by specific types of flagella. The flagellar ornaments can thus be used as systematic and phylogenetic characters. The euglenid flagellates have a one-sided flimmer flagellum; the flagellated cells of *Chrysomonadina*, Heterocontae, Phaeophyceae and Saprolegniaceae have one whip flagellum and one two-sided flimmer flagellum.

The whip flimmer flagellum has only been described from choano-flagellates (*Craspedomonadina*). It seems that sponges (Porifera) have never been examined in this respect. This is the more remarkable as prevalent hypotheses indicate that the ancestors of the sponges are to be sought in the choanoflagellate group[5,6].

When I examined several types of animal cilia and flagella in an attempt to find morphological differences that might be correlated to the different types of exhibited movement[7], it was found that the sponge choanocyte possessed a flimmer flagellum. An electron micrograph is published in that paper. The flimmer hairs of these flagella have a diameter of only 20 Å. and a length of 0·2–0·3μ. In a cross-section (∼ 400 Å.) of the flagellum there might be found a dozen flimmer hairs on each side of the flagellar axis. They extend laterally from the membrane limiting the flagellum, and are in the same plane as that which joins the two central filaments of the flagellum. All hairs do not arise at the same spot at the flagellar membrane, as seen in cross-section, and also in their further extension they are not fully parallel. They might therefore be difficult to discern. Although other electron microscopists have examined the sponges, both by means of sectioning techniques[8–10] and of whole-mount techniques[11], the flimmer flagellum of the choanocyte has not been described. It cannot be decided from the sections whether the flimmer flagellum of the sponge choanocyte is of type 2 or 3 in the above classification, that is, whether there is a smooth end region or not. The cross-sectioned choanocyte flagellum may or may not have flimmer hairs in a certain section, depending probably both on the level at which the flagellum has been cut, and on technical difficulties; it seems that the flimmer hairs are easily washed off the flagellum during the preparation technique. Flimmer hairs have not been observed on that part of the flagellum which is outside the collar.

The flagellar membrane might be thrown in folds or show two or more ridges. These protrusions are found without any relationship to the axial filaments or to the flimmer hairs, and are therefore believed to represent a preparation artefact.

The sponges that have been examined in this way are *Microciona* sp. (Demospongiae) and *Grantia compressa* (Calcarea), both from Marine Biological Laboratory, Woods Hole, Mass. They represent two classes of the Porifera.

This is the first demonstration of a flimmer flagellum in a multicellular animal. It is not likely that flimmer flagella will be found in higher metazoans, as flagella and cilia from a great many animals have been examined by electron microscopy without any evidence of the presence of flimmer hairs. The fact that the sponges do have flimmer flagella, possibly of the type called whip flimmer flagella, gives support to the hypothesis that the sponges are descendants of the choanoflagellates. It also supports the idea that the multicellular animals have a diphyletic origin.

Effect of Ethylene Oxide on the Tapping of *Hevea brasiliensis*

IN recent years the importance of bacteria in limiting the effective yield of polyisoprene from *Hevea brasiliensis* has been described[1]. Further, the highly desirable stability and very low content of volatile fatty acids of sterile latex have been fully established[2]. Up to 1960, the apparatus for the extraction of sterile latex was costly, but recently I have used simple polythene 'hoods' to enclose the tapping panel, so that antibacterial atmospheres could be maintained during tapping.

The first gaseous sterilizer chosen was ethylene oxide (1,2-epoxyethane), which in preliminary trials proved an extremely effective bactericide for contaminated *Hevea* latex systems. Liquid ethylene oxide, direct from the cylinder, was placed in a small open cup beneath a polythene hood sealed to the tree immediately above the tapping panel. The lower edge of the polythene was then tied tightly to the tree below the tapping panel by a polythene strip. The lower seal was not entirely airtight, but merely limited the escape of gas from the hood—this proved sufficient. Ethylene oxide is a gas at Malayan ambient shade temperatures (about 28° C.) and thus liquid ethylene oxide, once exposed to atmospheric pressure, boils rapidly; 20 ml. evaporated in 16 min. under these experimental conditions. Preliminary sterilization of the enclosed space was carried out at 3.30 p.m. using 20 ml. of liquid ethylene oxide for the first two trees and 10 ml. for the third and fourth trees. The trees were tapped at 6.30 a.m. on the following morning, and 5 ml. of liquid ethylene oxide was introduced under the polythene hood at the time of tapping. During subsequent tappings of all trees, 5 ml. was used for preliminary sterilization and no ethylene oxide was introduced at the time of tapping. Latex was collected in a clean conical flask exposed to the atmosphere of ethylene oxide within the hood. A nearby control tree of similar girth, age and yield was observed throughout the experiments.

The effect on yield and flow was considerable. The increases in yield are shown in Fig. 1. Time of flow increased to some 27 hr. from 2½–4 hr. Latex from such treatments has remained liquid for up to 34 days at 15° C., provided it was not infected afterwards, and has been proved sterile (less than 1 viable bacterium/ml.) on three separate occasions throughout

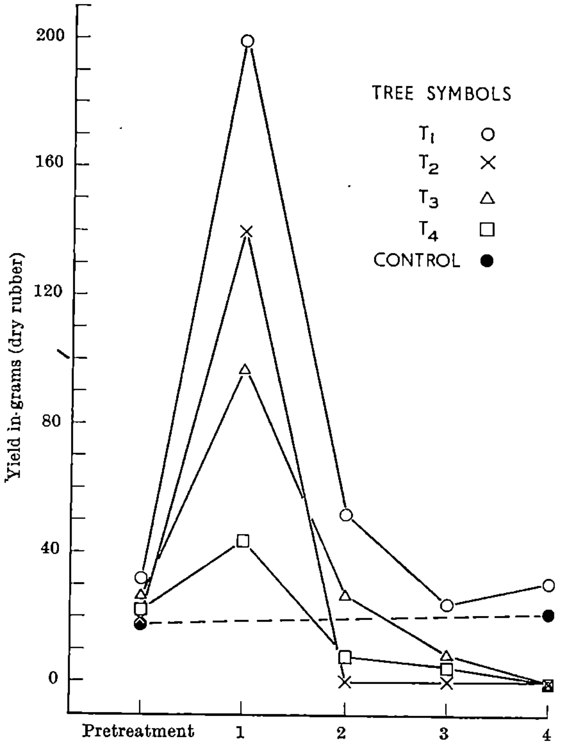

Fig. 1. Effect of ethylene oxide on yield

storage for 34 days. In contrast, normal (contaminated) latex from this area is fully coagulated after 20 hr. at 15° C. The effect of ethylene oxide was to drain latex almost completely from the entire area surrounding the tapping cut. Following this, successive tappings give decreasing yields of rubber until complete drying of the latex-bearing tissue is observed. One treatment with ethylene oxide may achieve this complete drainage, but on other trees up to four tappings may be observed. Complete drainage is followed by rapid necrosis of latex vessels and outer bark accompanied by fungal attack as a first stage.

Another interesting effect has been the bleeding of latex from old healed wounds following treatment of the tapping panel with ethylene oxide. Wounds healed and dry for at least three months and up to 2 ft. above the enclosed tapping cut (in some cases well outside the hood) have begun to bleed, the bleeding proceeding for several hours and in one case for two days. The simplest explanation of this bleeding seems to be a rapid translocation of ethylene oxide coupled with an interaction of ethylene oxide and wound tissue.

As flow following the first tapping with ethylene oxide exceeded 24 hr., it was possible to confirm the resurge of flow about 23–24 hr. after tapping. This had been observed for the sterile cabinet (ref. 1) using a combination of antibiotics and ultra-violet irradiation to achieve sterility and is similar to the resurge of bleeding sap of grape vines[3]. A further point of interest is that the pattern obtained on ultra-centrifuging shows no gross differences, after 24 hr. storage, from the normal pattern shown by fresh latex.

Whatever the fundamental mechanisms underlying this striking series of events, four major points emerge: ethylene oxide enables large volumes of sterile latex to be obtained in a simple way; latex sterilized with ethylene oxide remains stable; ethylene oxide effectively drains all latex from the immediate vicinity of the tapping panel; ethylene oxide induces bleeding from old wounds not deliberately treated with the gas.

Uue of Glacial Acetic Acid for killing Parasitic Nematodes for Collection Purposes

MANY parasitic nematodes have a tendency to coil considerably when placed in water or cold-fixing fluids such as alcohol or formalin. Ideally, in order to facilitate the subsequent microscopic examination, nematodes should die in an extended position. This is best achieved by the use of 70 per cent alcohol or Looss' fluid (9 parts 70 per cent alcohol and 1 part glycerol), near boiling temperature, in which nematodes uncoil and become fixed rapidly. However, hot alcohol is rarely available during field work, and a simple alternative method for killing and fixing nematodes in an extended position is likely to be desired by other workers.

In the summer of 1960, parasitic nematodes from the proventricle of the fulmar (*Fulmarus glacialis*) were fixed in glacial acetic acid by mistake instead of cold 70 per cent alcohol, to which they were transferred a few minutes later. The fixed specimens were found to be remarkably straight, and the idea of using glacial acetic acid on purpose presented itself. More specimens from the fulmar were collected; some were fixed in cold 70 per cent alcohol, and others in glacial acetic acid. Those fixed in alcohol were found to be rather wavy and bent, while those treated with glacial acetic acid straightened almost immediately. After a few minutes, the majority of the latter were transferred to cold 70 per cent alcohol, while a few were allowed to remain in the glacial acetic acid. It has not been possible to make a specific determination of the specimens from the fulmar, but they belong to the superfamily Spiruroidea, sub-family Acuariinae, and appear to be generically related to *Seuratia* Skrjabin, 1916.

Several specimens of *Contracaecum aduncum* (Rudolphi, 1802), a common parasite of the digestive tract of the cod and other marine teleosts, have been treated with glacial acetic acid as described here. The specimens were found first to move vigorously, then they uncoiled and died in a matter of seconds. Small specimens were found to straighten more rapidly than larger ones. Larval ascarids, *Anisakis* sp. larva and *C. aduncum* larva, liberated from their capsules, have been treated with glacial acetic acid with equally good results. The nematodes were kept in the glacial acetic acid for up to 10 min., whereupon they were transferred to and stored in 70 per cent alcohol. Before fixation, the nematodes were washed in water in order to clean them from mucus and debris.

A mixture of three parts 70 per cent alcohol and one part glacial acetic acid did not kill as rapidly as the undiluted acid, nor did the specimens straighten so well in it. When the glacial acetic acid becomes diluted with water after repeated use, the killing effect is retarded and the specimens do not straighten so well in it. The acid should therefore be used undiluted. However, by adding various amounts of absolute alcohol to the glacial acetic acid, specimens of *C. aduncum* were killed even more rapidly, but they did not uncoil as well as in the glacial acetic acid alone. The advantage of adding absolute alcohol is that the freezing-point of the glacial acetic acid is lowered, thus avoiding solidification at low temperatures. A mixture of one part of glacial acetic acid and one part of absolute alcohol was found to remain fluid at $-32°$ C. This mixture may be useful for field work in extreme low temperatures, but at higher temperatures the amount of glacial acetic acid should be increased.

Admittedly, this simple method for killing nematodes seemed promising, but it remained to be seen whether or not the specimens had been damaged by this treatment. Specimens were cleared in the usual media, lactophenol and creosote, in which they cleared very rapidly. On microscopical examination, they were found to be in good condition. When cleared in lactophenol cuticular structures, such as lips, papillæ and striation were found to be very clearly visible. Internal organs were also seen clearly.

After having been kept in the glacial acetic acid for six months, some of the specimens from the fulmar were transferred directly to lactophenol and examined microscopically. The specimens were found to be in good condition.

It thus appears that glacial acetic acid with subsequent transfer to 70 per cent alcohol may be used for killing and fixing nematodes.

Acanthocephalans (*Echinorhynchus gadi*) and trematodes (*Hemiurus communis*) from the cod have also been treated with glacial acetic acid. Before killing in acid, the acanthocephalans had to be left for some time in fresh water in order to extrude their evertible hooked proboscés. No movement of the specimens was observed during fixing. They cleared quickly in lactophenol. The trematodes were washed in 1 per cent saline solution before fixing. Whole trematodes were found to stain fairly well in carmalum.

Manuals on microscope technique[1,2] do not recommend fixing in pure glacial acetic acid for histological work, although it is known to kill with the utmost rapidity. However, as nematodes rarely have to be sectioned, the method described may be useful, at least when it is imperative that they should die and remain extended. However, for histological work it is perhaps better to avoid prolonged stay in glacial acetic acid; the specimens should preferably be transferred to 70 per cent alcohol as soon as possible. It is possible that this method may be regarded as a two-step modification of Carnoy's.

Although nematodes in general are rather difficult to stain, transverse sections of *C. aduncum* killed in glacial acetic acid were stained in hæmalum for 1·5 hr., and overnight in eosin, with quite good results. Even the nuclei stained well. Carmalum or paracarmine alone stained poorly.

In conclusion, it is suggested that the use of glacial acetic acid, followed by transfer to 70 per cent alcohol, is satisfactory for fixing nematodes in an extended position. No adverse effect on cleared specimens was observed after this treatment. In addition, the anatomy may be studied satisfactorily in stained sections. However, it is not known what effect, if any, the glacial acetic acid treatment has on the finer histological or cytological details.

Swarming of the Polychaete *Odontosyllis phosphorea* Moore, var. *Nanaimoensis* Berkeley, near Nanaimo, B.C.

In a communication to *Nature* some years ago[1] I mentioned that the annual concentration of the luminescent swarming forms of *O. phosphorea* in the channel at the entrance to Departure Bay during the summer and early autumn months could be partly attributed to the set of the currents around the islands in the vicinity. This channel has always been regarded as the classical locality from which these forms could be secured, but no effort to collect any had been made for many years until recently. Interest in them revived two years ago in connexion with work on bio-luminescence; diligent search was made for them in the channel throughout the summer of 1959, but not a single individual was seen. If present, they are easily detected at dusk by their brilliant flashes of light when the sexual products are discharged. Moreover, a dredging run through the channel failed to secure an example of the atokous bottom-living form.

The explanation is fairly clear. Since the worms were last collected there, a ferry service between Departure Bay and Vancouver has been established and boats of considerable draught ply many times daily through the channel. This creates sufficient disturbance to nullify entirely effects of currents and, apparently, to disperse the bottom dwellers, but this latter finding requires confirmation.

It is most unfortunate that this should have occurred, and I write regretfully to advise fellow workers interested in bio-luminescence that they can no longer rely with confidence on Departure Bay as an available source of swarming *Odontosyllis phosphorea*.

Light Rainfall and Plant Survival : Measurement of Stem Flow Run-off

Work on the effects of showers on droughted maize necessitated measurement of water run-off down the main stems. The following two collecting devices have proved simple to construct and reliable in use. They are attached directly to the stem 1–3 in. above the ground-surface after the leaf-bases ensheathing the first internode have been removed, and the stem surface dried.

In type 1 a rectangle of heavy-gauge polythene sheet (7 in. × twice the circumference of the stem) is wrapped around the stem in the form of a funnel, the upper circumference being 0·25–0·5 in. away from the stem surface. A small hole is cut in the sheeting near its lower edge and the flared end of a short length of stiff polythene pipe inserted and welded to the funnel wall while the flange is hot. The overlapping edges of the funnel are sealed with suitable plastic cement. The lower edge of the funnel is sealed to the stem in a similar manner and bound in place with wire. A length of flexible plastic tubing connects the exit pipe to a large storage tank sunk in the ground and shielded from the Sun.

In type 2, a large rubber bung with a hole in the centre slightly smaller than the plant stem is cut down one side, and clamped in position around the stem with wire. Any gap between stem and rubber is sealed with melted wax. This supports a rigid funnel made from a polystyrene specimen container of some 3 in. in diameter. The bottom of the container is removed and the remaining cylinder cut down one side with a hot wire. A piece of plastic tubing is sealed into the funnel near the lower edge to form an exit pipe similar to that of type 1. The split edge of the funnel is joined with polystyrene cement and the whole bedded down on to the rubber bung with wax. Melted wax is poured into the funnel to raise the level to the lower edge of the exit pipe which is connected to a sunken storage tank.

In view of the very large quantities of water obtained by the maize leaf catchment area from even very light showers, it is best to have large storage tanks available. These are emptied and the volume measured after each rainfall. Both funnels contain a dead volume of about 5 ml., but this amount is a negligible part of the total catch and represents 0·5–1·5 per cent of that obtained from mature maize plants in rains ranging from 0·3 to 0·1 in. The height of the funnels above ground ensures that they are free from splash effects in most light rains, while the closeness of fitting around the stem reduces the direct entry of rain to a minimum.

ENTOMOLOGY

Double and Single Spermathecæ in Fleas (Siphonaptera)

Two spermathecæ (or receptacula seminis) in female fleas which normally possess only one have been noted on various occasions[1]. In such abnormal specimens or monstrosities one spermatheca is usually smaller than the other. The best published description of this condition in the rat flea, *Xenopsylla cheopis* Roths. (overlooked by M. I. D. Sharma and G. C. Joshi[2]), is that by Smit[3], who figures a specimen in which both spermathecæ and their ducts are fully developed and of almost equal size. A very much rarer abnormality is recorded by Stark[4,5], who discovered a specimen of *Hystrichopsylla linsdalei* Holland (which normally has two spermathecæ) with three spermathecæ.

The spermatheca is single in the majority of insects, although in certain genera, for example, *Blaps* (Coleoptera), *Phlebotomus* and *Dacus* (Diptera), there are two, and in many of the Calyptratae, in *Culex* and the Tabanidae (Diptera) three[6]. In the Siphonaptera there is generally one spermatheca, but two occur in various genera scattered throughout the order. These genera are, on the whole, those in which various but well-marked primitive morphological features have been retained. It would appear likely that paired spermathecæ was the condition in the ancestors of the order. This view is enhanced by the fact that in all the genera in which there is a single spermatheca the blind duct presumed to be that of the missing organ is generally present in varying degrees of reduction. The position of this blind duct indicates that it is the left organ which has been lost. In a few scattered genera two spermathecæ are present, which are normally of unequal size, one being distinctly smaller than the other. Jordan[7] described this condition as a "link between single and double receptacula seminis". In the very scanty, badly preserved material available for study at that time it was not possible to say whether it was the right or left organ which was reduced. In two species recently examined, *Ctenoparia jordani* Smit[8] and *Atyphloceras shogakii* Jameson and Sakaguti[5], it is now clear that the smaller of the two spermathecæ is situated on the left side.

Acaricidal Properties of Di-(*p*-chlorophenyl)-trifluoromethylcarbinol

Di-(*p*-chlorophenyl)-trifluoromethylcarbinol, $(Cl.C_6H_4)_2C(OH).CF_3$ [1,2], has several interesting biological properties: it is a synergist for DDT in the house-fly[1,3–5] and inhibits oviposition, on tarsal contact, in house-flies[6] and mosquitoes[7]. Since it is the fluorine analogue of two acaricides, namely DMC [di-(*p*-chlorophenyl)-methylcarbinol] and 'Kelthane' [di-(*p*-chlorophenyl)-trichloromethylcarbinol], it seemed interesting to assay also its acaricidal properties. The compound was tested against adult females of the red spider mite *Tetranychus telarius* L. on beans, by a method described recently[8], and was compared with the commercial acaricides 'Kelthane' and chlorobenzilate (ethyl *p,p'*-dichlorobenzilate). The activity of the fluorine compound was intermediate between those of 'Kelthane' and chlorobenzilate (Table 1).

It has been demonstrated in field trials on orange trees (A. S. Tahori and E. Swirski, personal communication) that di-(*p*-chlorophenyl)-trifluoromethylcarbinol did not affect the citrus rust mite (*Phyllocoptruta oleivora* Ashm.), but it was noted incidentally

Table 1. Toxicities for *T. telarius* (on Beans)

Compound		Mean 24 hr. mortality*								LC_{50}, p.p.m.
'Kelthane'	p.p.m.	10	15	20	25	30	50	80	100	29
	Mortality (per cent)	8	20	33	43	53	73·5	88·5	96	
Di-(*p*-chlorophenyl)-trifluoromethylcarbinol	p.p.m.	100	150	200	250	350	500	650	1,000	250
	Mortality (per cent)	13	21·5	39	50·5	61	82	89	100	
Chlorobenzilate	p.p.m.	250	300	400	500	700	1,000	1,500	—	450
	Mortality (per cent)	15·5	25	38	62	85·5	88·5	98	—	

* Mean mortalities were calculated from three series of experiments carried out with each compound.

that it caused high mortality among red spider mites on the branches infested with *T. telarius* and *Brevipalpus* sp.

Our thanks are due to Prof. E. D. Bergmann for a liberal sample of di-(*p*-chlorophenyl)-trifluoromethylcarbinol.

MICROBIOLOGY

Auxin Production by Species of *Arthrobacter*

The ability of fungi and bacteria to produce plant growth-promoting substances such as indole-3-acetic acid (IAA) has long been recognized[1–3]. Gruen[3] has recently reviewed the literature on auxin production by fungi. However, reports on bacterial synthesis are widely dispersed, and relatively few known species have been recorded as being able to produce these substances, although many unidentified cultures have been tested[1]. Of the known organisms, *Escherichia coli*, *Pseudomonas fluorescens*, *Agrobacterium tumefaciens*, *Rhizobium* sp. and *Azotobacter* sp. have received most attention[4–6], yet one of the largest groups of soil bacteria, the *Arthrobacter*, has not, to our knowledge, been examined.

Representative species of this genus from the culture collection of the Microbiology Research Institute were grown in a medium of the following composition (per litre): salt solutions *A* and *B* (ref. 7), 5 ml. each; ammonium nitrate, 0·5 gm.; yeast extract, vitamin-free casamino-acids, glucose, 1·0 gm. each; *p*H 6·8. The medium was dispensed in 100-ml. amounts in 300-ml. Erlenmeyer flasks, sterilized and inoculated from 24-hr. agar cultures. After 24 or 48 hr. on a rotary shaker at 26° C. the cells were removed by centrifugation, washed once, dried at 80° C. and weighed. The cell-free culture fluid was brought to *p*H 3·0 and extracted with ether; the extract was concentrated under vacuum at 35° C. and tested for auxin activity by means of a modified *Avena* coleoptile section test.

Table 1. Production of Auxin by Species of *Arthrobacter*

Species	Indole-3-acetic acid equivalents	
	µgm./l.	µgm./gm. cells
Arthrobacter globiformis	10	8
Arthrobacter pascens	8	6
Arthrobacter aurescens	9	7
*Arthrobacter tumescens**	8	11
*Arthrobacter citreus**	15	16
Arthrobacter atrocyaneous	15	15
Nocardia sp.	15	15

* 48-hr. cultures.

As indicated in Table 1, every *Arthrobacter* culture tested as well as a closely related organism of the genus *Nocardia*, which is also common in soil, showed activity. Furthermore, *A. globiformis* and *A. pascens* grown for 48 hr. in a completely synthetic medium (above medium without yeast extract and casamino-acids) produced 3·0 and 2·0 µgm. IAA equiv./l. or 8 and 4 µgm. equiv./gm. cells, respectively. Although its growth was poorer in the synthetic medium, *A. globiformis* produced as much active material per gram cells as it did in the complete medium. In further tests with this organism in the synthetic medium containing tryptophan (added aseptically) it was found that in 48 hr. 120 µgm. IAA equiv./l. or 750 µgm. equiv./gm. cells were produced. This tryptophan effect is well known[2,4].

The active substance produced in the three media (complete, synthetic and synthetic plus tryptophan) co-chromatographed with synthetic IAA in three solvent systems: propanol–ammonia–water, butanol–acetic acid–water and 0·05 *M* potassium dihydrogen phosphate. Segments of the chromatograms were also assayed by the *Avena* method. In every instance activity occurred in sections with an R_F value equivalent to pure IAA.

It is not possible at present to assess the importance of microbial synthesis of auxins in soil or at the root surface. A recent bacteriological study of the composition of the flora of wheat roots showed that *Arthrobacter* species constituted 22 per cent of the isolates (Rouatt, J. W., and Katznelson, H., unpublished results). In absolute numbers this represents 900 million organisms per gram oven-dry roots. To this number may be added approximately 2,000 million bacteria of the genus *Pseudomonas*, one representative of which was found in preliminary tests to produce auxin-like substances. Fungi, living on the surface of the roots[8], may also be expected to produce such compounds. Since it is well established that amino-acids are liberated by roots it is likely that active synthesis of auxins and related substances occurs at the surface of the roots. Kefford *et al.*[9] have reported that the liberation of tryptophan by legume roots permitted auxin synthesis by the legume bacteria when plant and organism were cultured together. Because of the intimate contact between microbial and plant cells at the immediate root surface it may also be expected that these substances would be absorbed directly by the root and would not be susceptible to alteration or destruction as those produced in the soil proper.

Influence of Salts on the Uptake of Streptomycin by *Escherichia coli*

A PREVIOUS report from this laboratory[1] described the kinetics of uptake of streptomycin labelled with carbon-14 by *Escherichia coli W* growing in mineral-citrate-glucose medium *A*[2]. In the procedure used, the cells were separated from the medium on a membrane filter and washed with distilled water before determination of radioactivity. We now find that the uptake had been markedly enhanced by a step not reported previously: dilution of each sample with several volumes of distilled water immediately before filtration. (This predilution in water was considered trivial because the subsequent washing with water removed little of the radioactivity on the filter, although almost all of it could be removed by washing with medium *A*.) When this predilution step was omitted the radioactivity retained on the filter was lower by 50 to 80 per cent (Fig. 1), but there was still, as previously reported, an immediate 'primary' uptake and, after a lag, a gradually increasing 'secondary' uptake. (Szybalski and Mashima[3] have reported kinetics of streptomycin uptake which are difficult to compare with ours since their first sample was not taken until 1 hr. had elapsed and they measured the radioactivity retained after washing with non-radioactive streptomycin.)

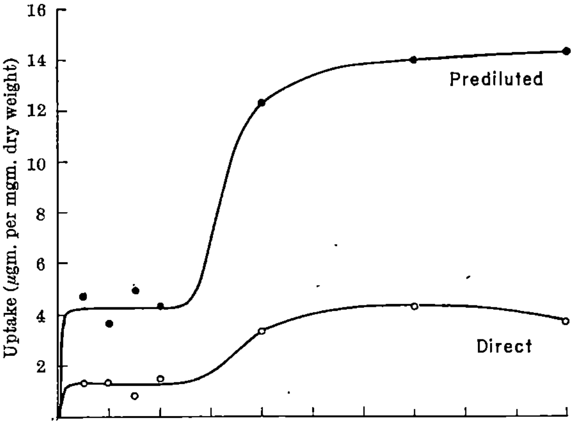

Fig. 1. Uptake of streptomycin by 'prediluted' and 'directly filtered' *E. coli W*

E. coli W was grown in medium *A* (ref. 2) supplemented with 0·5 per cent glucose at 37° C. on a Brunswick rotary shaker. Forty μgm. per ml. of streptomycin-^{14}C (30 c.p.m. per μgm.) was added to the exponentially growing culture when it reached a density of about 0·2 mgm. dry weight of cells per ml. (about 100 Klett units with No. 42 filter, or 4 × 10^8 cells per ml.). 'Directly filtered' samples were pipetted on to a membrane filter ('Millipore *HA*'); 'prediluted' samples were mixed with 4 vol. distilled water immediately before filtration. After washing the filters twice with 5 ml. of water and drying, the radioactivity was determined on a Nuclear-Chicago thin-window gas-flow counter. Sample sizes were chosen to yield 40–200 c.p.m. The data are corrected for cosmic background and for the blank values (about 4 counts per minute) obtained by filtering medium containing streptomycin-^{14}C but no cells

Table 1. TIME-COURSE OF THE PREDILUTION EFFECT

Time in diluting fluid (sec.)	Uptake (μgm. per mgm. dry weight) 5-min. exposure to streptomycin	40-min. exposure to streptomycin
No dilution	1·2	3·6
15	4·4	9·6
45	3·6	9·2
75	4·0	12·0
300	5·2	22·0

Cells were exposed to streptomycin-^{14}C as described for Fig. 1. At 5 and 40 min., 4-ml. samples were transferred rapidly to 16 ml. of distilled water. At the times indicated, 5-ml. portions of the diluted samples were filtered, washed and counted as described.

As Table 1 shows, the effect of predilution is rapid. With cells in either the primary (5 min.) or the secondary (40 min.) phase of streptomycin uptake, the enhancement occurred within 15 sec. of dilution and did not increase significantly during the next 30 sec. Longer periods in diluted medium further enhanced uptake, particularly with cells in the secondary phase, but this effect probably involved further action of the drug (the effectiveness of which is increased by low salt concentration[4]).

It seemed possible that, during the washing, directly filtered cells lost much of the already accumulated drug because of osmotic shock, whereas predilution moderated this effect. However, when cells were filtered directly but not washed, the radioactivity, contributed in part by the retained medium, was much less than that observed with prediluted and washed cells. The predilution step must therefore increase the amount of streptomycin taken up by the cells.

Conversely, it seemed possible that the effect might be due to damage to a permeability barrier by osmotic shock during predilution, increasing the accessibility of binding sites while external streptomycin was still available. However, in sucrose solution isosmotic with the growth medium the predilution effect occurred as readily as in water (Table 2). In contrast, not only did the effect fail to occur on dilution with medium *A*, but after it had occurred in distilled water it was immediately and completely reversed by the addition of 1/10 volume of 10-times concentrated medium *A*. It is therefore clear that one or more of the salts in the medium interferes with streptomycin uptake, and predilution decreases this interference.

Table 2. INFLUENCE OF VARIOUS SOLUTES ON THE PREDILUTION EFFECT

Solute added to diluting fluid	Final concentration (moles/l.)	Uptake (μgm. per mgm. dry weight)
No dilution (direct)		3·6
None (predilution in water)	1/5 medium *A*	9·2
Concentrated medium *A*	medium *A*	2·8
Sucrose	0·22	8·4
**K^+	*0·10	7·2
NH_4^+	*0·015	8·4
**Mg^{++}	*0·0004	4·8
Citrate	*0·0014	4·0
Phosphate	*0·062	2·8
Sulphate	*0·008	6·0

Samples were either diluted with fluid of the appropriate composition or (**) diluted with water and brought to the appropriate composition by the addition of one-tenth volume of concentrated salt solution. Values for the two methods were in close agreement when applied to the same sample. Counter ions were Na^+ and Cl^-, each without effect up to 0·1 *M*. The pH's of the samples after dilution were 6·9 (owing to the phosphate buffer of the medium); when the *p*H of samples diluted with water was varied from 5·6 to 7·7 there was little effect on uptake.

* Same concentration as in medium *A*.

n experiment in which the concen-
dium *A* and streptomycin were inde-
ried over a wide range. The results
the amount of streptomycin taken up
creased markedly as the concentration of
A decreased.

It is evident that the uptake observed with prediluted cells represents a substantial amplification of the uptake that occurs in the growth medium, but this artefact does not affect the earlier conclusion concerning the existence of a primary and a secondary phase (Fig. 1). However, these observations do affect the interpretation of the secondary uptake. It is now clear that with prediluted samples this uptake represents largely molecules taken up rapidly during predilution rather than slowly during prolonged exposure to the drug. The gradual increase during the secondary phase therefore cannot be due solely to binding to sites made slowly accessible by slight damage to the membrane. The uptake curve must rather reflect a gradual increase in the number of freely accessible binding sites. The nature of these sites is under investigation.

This work has been supported by research grant *G*-9078 of the National Science Foundation. We would like to thank Merck, Sharp and Dohme for the gift of streptomycin-^{14}C.

CYTOLOGY

Deoxyribonucleic Acid Structures in the Nucleolus

PHASE-CONTRAST observation and electron microscopy indicate that the nucleolus is structurally heterogeneous consisting of a ground material in which is embedded a more compactly aggregated material generally described as filamentous (Estable and Sotelo[1] proposed for them the names of 'pars amorpha' and 'nucleolonema'). Nucleoli of plant and animal cells are seen at mitosis and meiosis associated with a particular chromosome or chromosomes—the so-called 'nucleolar organizer' chromosomes—at the site of a heterochromatic region. If a chromosomal deletion includes such a region or if a mutation occurs[2], nucleolar material is then produced at other 'loci' (the latent organizers).

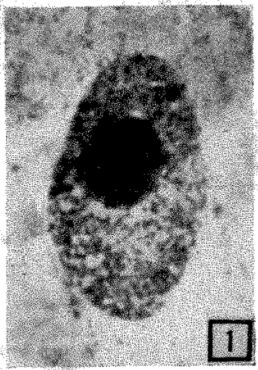

Fig. 1. Early prophase (acetocarmin, × *c*. 800)

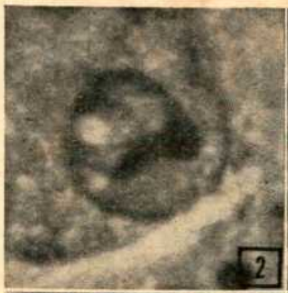
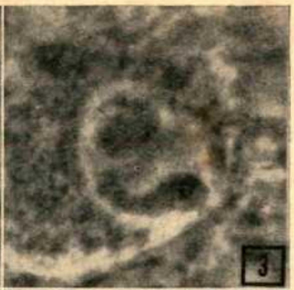
Nucleoli are described as being Feulgen-negative. However, Feulgen-positive granular and filamentous structures have been reported for different types of cell[3-5]. Estable and Sotelo[1,6], on the other hand, described a Feulgen-negative filamentous structure (nucleolonema). Such observations were based primarily on fixed and stained material without discriminatory nuclease digestion. No details are available on how the nucleolar structures were affected in those papers describing a loss of basophilia after treatment with ribonuclease (RNAse). Were RNA the only nucleic acid present in the nucleolus, under ideal experimental conditions only vestiges of RNA would be seen after digestion with RNAse. Granules and filaments of deoxyribonucleic acid (DNA) should be resistant to RNAse and thus become more easily visualized after RNAse digestion.

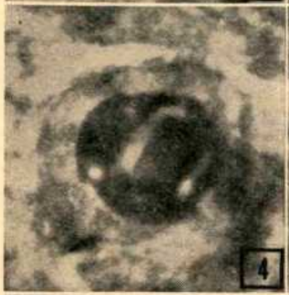
Nucleoli of some species of *Spirogyra* are specially suitable for cytological investigation because of their large size, 10–30μ (Fig. 1). Living cultures of two clonal populations (*Spirogyra* aff. *crassa* and *S.* aff. *lamellata*; identification tentative until fertilized material is obtained), grown under controlled laboratory conditions, were treated with RNAse and DNAse. Contact time with the enzyme was 2, 3, 4 or 5 hr. with RNAse and 2, 3 or 4 hr. with DNAse (the 5 hr. sample was discarded after a microscopic examination disclosed that the plastids were collapsing). To avoid distortions due to sectioning, the material was handled, stained and mounted in bulk. Appropriate controls for the Feulgen reaction, methyl-green-pyronin and acetocarmin techniques were used.

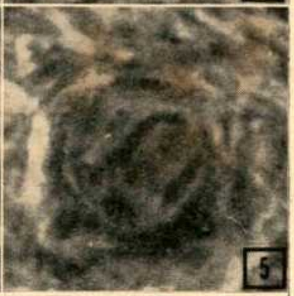
Images observed on stained material resembled those seen under phase-contrast on unstained material prior to any fixation or hydrolysis. Cells at interphase and early prophase treated with either RNAse or DNAse showed a selective enzymatic depolymerization restricted to certain nucleolar areas. If the ground substance and the embedded filamentous structure contain RNA, after RNAse digestion one would expect a homogeneous gradient of enzymatic action from the periphery towards the centre of the nucleolus and with increasing enzyme contact almost total digestion with the exception of nucleolar proteins.

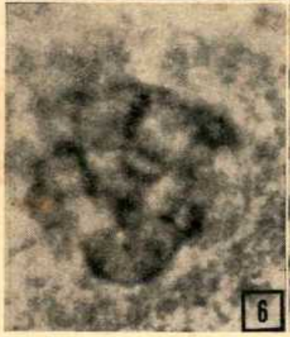
However, as can be clearly seen in Figs. 2 and 3, RNAse digestion was, in fact, restricted to definite nucleolar areas. Enzyme treatment left in the nucleolar material something like a continuous con-

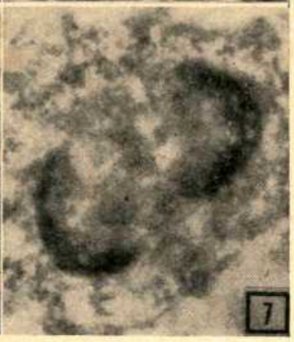












Figs. 2 and 3. RNAse treatment. Feulgen-positive structures. 2, Positive phase; 3, negative phase. (× *c.* 1,550)

Figs. 4 and 5. DNAse treatment. Empty 'tubule' on nucleolar mass. Undigested material Feulgen-negative. 4, Positive phase; 5, negative phase. (× *c.* 1,550)

Fig. 6. RNAse treatment. Early prophase. Chromonemata Feulgen-positive. (× *c.* 800)

Fig. 7. RNAse treatment. Middle prophase. Homologous nucleolar chromosomes. (× *c.* 1,300)

volved 'cave'. The spaces in between those occupied by the now digested material showed a Feulgen-positive and methyl-green positive filamentous structure made up of a double, thin chromonemata with small granules.

DNAse digestion also was incomplete and very selective. The empty spaces left in the nucleolar mass were considerably smaller in diameter; their limits very sharp and neat as if a convolved 'tubule' had been spirited away (Figs. 4 and 5). The ground-material unaffected by DNAse was Feulgen-negative and pyroninophilic. To eliminate the possibility of mistakenly identifying vacuoles for enzymatic digestion, all observations were carried out and recorded by both positive and negative phase-contrast.

An additional experiment was carried out under similar conditions with RNAse and DNAse applied sequentially. After this consecutive digestion for two hours for each nuclease, it was found that a 'ghost' of the nucleolus was left unstainable by either Feulgen or methyl-green-pyronin.

In 1950, Godward[7] described a similar nucleolar structure for *Spirogyra* which she interpreted as the expanded heterochr
region. The double ch
being inside the nucleolu
ments resembling the org
chromosomes in the karyo
my material the nucleolar RN
almost the entire nucleolar
chromosomes are interpreted as
In *Spirogyra* aff. *crassa* it was o
ing that two nucleolar chromosom
length in some cells (Fig. 7) and o
in other cells. In *S.* aff. *lamella*
nucleolar chromosomes were found (F
is therefore believed to occur in the
not in the zygotes.

When two nucleoli were found in teloph
phasic or prophasic cells, a small nucleo
always associated with the shorter chromosome and a larger nucleolus with the longer chromosomes. This would suggest that the material is actually synthesized at these chromosomes and not merely aggregated. The rate of RNA synthesis should thus accelerate at the time when RNA substance is rounding up into a nucleolus, and it should reach the peak some time between telophase and early prophase.

Experiments with RNA anti-metabolites, labelled RNA and DNA precursors, are being completed.

This work was supported by grant *DRG*-535 from the Damon Runyon Memorial Fund for Cancer Research.

I am indebted to Dr. Richard M. Klein for his criticisms.

ANTHROPOLOGY

Inter-Individual Variability in Pigmentation

COLOUR of skin has always been and still is the most frequently used character in definition of races. The essential reason is that skin colour is considered as an inherited trait for which a hypothetical polygenic mechanism of transmission has been suggested (Davenport, Gates and Stern). It was almost the interracial differences that had caught the eye, but the possibility of using a spectrophotometer[1,2] has induced me to explore the inter-individual variability in one population. The essential conclusions of the examination of 143 Belgian male students and 177 female students with an *EEL* spectrophotometer at nine wave-lengths (430 mμ to 700 mμ) during April 1960 are reported here. Measurements were taken at the forehead and inner arm. Table 1 gives means and standard deviations. More detailed results will be published elsewhere[3].

(1) Percentages of reflectance are significantly different for arm and forehead in each of the male and female samples (except for ♀ at $\lambda = 700$ mμ).

Table 1

λ	Inner arm				Forehead			
	♂ $n=143$		♀ $n=177$		♂ $n=143$		♀ $n=177$	
(mμ)	Mean	*S.D.*	Mean	*S.D.*	Mean	*S.D.*	Mean	*S.D.*
430	37·71	4·83	36·50	3·98	27·87	3·63	32·44	3·53
470	44·73	5·01	43·48	3·54	32·53	3·53	37·26	3·66
490	46·74	4·76	45·31	3·53	34·22	3·71	39·05	3·60
520	46·71	4·30	45·65	3·57	33·68	3·90	39·13	4·20
550	44·77	3·96	44·57	3·62	31·56	4·00	37·27	3·74
580	48·87	3·84	48·77	3·34	36·68	4·46	41·86	3·86
600	59·52	3·75	58·50	3·44	51·07	3·92	55·50	3·35
680	65·72	3·15	64·28	2·92	60·67	3·75	63·50	3·95
700	67·27	2·90	65·88	2·47	62·48	3·81	65·66	3·60

(2) Males are darker at the forehead than females but lighter at the inner arm. This latter point does not agree with results collected by Edwards and Duntley[2] (on 3♂ and 3♀) nor with most of the results ollected by Garn *et al.*[4], at $\lambda = 420$ mμ only, on hildren of both sexes, female being lighter than es on the inner arm. However, two of the samples the last authors and just the samples which are the most comparable to mine with regard to age agree with my conclusion:

Garn *et al.*, 1956. Per cent reflectance at $\lambda = 420$ mμ						
	Range of age	n	Inner arm		Forehead	
			Mean	*S.D.*	Mean	*S.D.*
Mature nulliparæ	15–25	23	29·4	3·6	23·7	5·0
Young adult males	20–29	16	30·4	5·2	22·3	4·2

(3) Computation of coefficients of variation (4–13 per cent) demonstrates that their value depends on the wave-length considered and generally greater than similar coefficients for other biological traits (height: 3·60 per cent, weight: 10–12 per cent, pulse: 12·71 to 14·21 per cent).

A comparison with the same coefficient computed from the data published by Barnicot[5] for the forearm of Ibo (12–18·5 per cent) and Yoruba (11·3–21·5 per cent) reveals on the whole a more considerable variability for Negroes and a very different position of the maximum value of this coefficient: for male and female Whites it is a maximum at $\lambda = 430$ mμ, Negroes it is a maximum at $\lambda = 600$–680 mμ.

Table 2 gives correlation coefficients for each -length between percentage reflectance for inner and forehead. All are less than the weakest coefficient height-weight, for example.

Table 2

λ (mμ)	♂	♀
430	0·405 ± 0·070	0·466 ± 0·058
470	0·388 ± 0·071	0·449 ± 0·060
490	0·354 ± 0·073	0·462 ± 0·059
520	0·201 ± 0·080	0·401 ± 0·063
550	0·246 ± 0·078	0·280 ± 0·069
580	0·289 ± 0·076	0·293 ± 0·068
600	0·340 ± 0·074	0·411 ± 0·062
680	0·410 ± 0·069	0·461 ± 0·059
700	0·505 ± 0·062	0·373 ± 0·064

) Preliminary trials (comparison of means per-age reflectance of the skin for the different gories of eyes (scale of Martin–Saller) and hair ur (scale of Fischer–Saller), χ^2 tests applied to distribution of these latest categories charted on atter diagram ([per cent reflectance values at inner arm–per cent reflectance values at forehead] at each wave-length) seem to demonstrate that, in my samples, correlations between eyes or hair colour on one hand and skin pigmentation on the other are nil or extremely weak. This point will receive further consideration in the future: indeed, suggestive association in very different populations (and this is the important point) induced us to think of pleiotropic action of a gene. My results seem to demonstrate that if common genetic factors exist for pigmentation, they are few and minor in action, that lack of association within a geographical group in relation to association within sibships should make linked genes a more probable hypothesis.

This demonstrates once more the fundamental importance of genetics for anthropology and how spurious may be considerations evolved from an exclusively adaptative and geographical point of view[6].

I am indebted to M. Dillaerts, director of the Centre National de Calcul Mécanique, for his co-operation in computing the results.

PSYCHOLOGY

Stimulus-Response Compatibility in the Paired-Associate Learning of Nonsense Syllables

THE concept of stimulus-response (*S-R*) compatibility has been used mainly in the area of sensory-motor skills, where it was developed to explain why certain *S-R* pairs, said to conform to a population stereotype, were more easily learned than others[1,2].

The present experiment tests the hypothesis that language habits, determining *S-R* compatibility, affect the ease with which pairs can be learned. The relative compatibility of pairs of syllables was measured in the following way. A statistical subject is assumed who, given the last letter of the stimulus syllables, attempts to predict the first letter of the response syllable on the basis of the relative frequencies of the digrams in the English language[3]. The number of 'guesses' required is the measure of compatibility. For example, the compatibility score for the pair *QEM POG* is 6 'guesses', because *P* is the sixth most likely letter following *M* in English. If the pair is reversed, that is, *POG QEM*, its compatibility score is 22 'guesses', as there are 21 letters more likely than *Q*, following *G*.

Eight pairs of nonsense syllables were selected from Glaze's list[4], 2 pairs each of 0 per cent, 6·67 per cent, 13·33 per cent and 20 per cent associative value. The pairs were so chosen that in one order they were relatively compatible (mean score 10·8 'guesses'), but when reversed they became relatively incompatible (mean score 19·1 'guesses'). Two lists were made up; in list *A*, pairs 1–4 were in the compatible order and pairs 5–8 were incompatible, and in list *B* the order of each pair was reversed. Each list was learned by one of two groups of 15 naval ratings, using the anticipation method of paired-associate learning[4], with a presentation-rate of 3 sec. per item and an inter-trial interval of 15 sec. The order of occurrence of pairs was random within each trial. The subjects practised to a criterion of 3 successive errorless trials, or if this were not reached, for 20 trials.

Subjects' performances were scored in terms of the total error difference between pairs 1–4 and pairs 5–8.

Thus subjects learning list *A* would be expected to have lower scores than those learning list *B*. The mean score per subject for list *A* was − 0·13 and that for list *B* was + 12·67. A Mann–Whitney test[6] confirmed the predicted difference between the two groups ($P < 0{\cdot}01$, 1 tail). Of the 8 pairs used, 7 were learned more rapidly in the compatible order, indicating that the result was not due simply to the inadvertent selection of one or two atypical syllables.

It was concluded that *S-R* compatibility effects analogous to those shown in sensori-motor skills occur also in verbal learning.

Taste Thresholds and Food Dislikes

ALTHOUGH food likes and aversions are influenced by cultural, social and idiosyncratic variables[1], individual differences in the ability to taste certain classes of compounds may be one determinant of food rejections[2].

In the present work, forty-eight subjects checked food dislikes and aversions on an alphabetical listing of 118 foods previously tested on a college-age Ohio population[3]. Excluding foods unfamiliar or never sampled by each subject, the percentage of familiar foods disliked was used as the individual score. Scores ranged from 0–55 per cent ; the median was 10 per cent, as in the standard population.

Taste thresholds were determined for D-sucrose, sodium chloride and hydrochloric acid in forty-two subjects, and for quinine sulphate and 6-*n*-propylthiouracil[4] in all forty-eight subjects. The compounds were dissolved in double-distilled, copper-free water using twenty concentrations ranging from $3{\cdot}66 \times 10^{-7}$ *M* to $3{\cdot}84 \times 10^{-1}$ *M*, each numbered step representing a doubling of concentration. A preliminary training session, a later test session and a further retest session was used in all forty-eight cases.

Dislikes for foods could not be significantly related to a subject's sensitivity to, or thresholds of taste for, D-sucrose, sodium chloride, or hydrochloric acid. However, taste thresholds for 6-*n*-propylthiouracil and quinine, both bitter substances, show a relation to percentage of food dislikes. Two categories have been set apart, 0–10 per cent foods disliked (low) and 10–55 per cent foods disliked (high). Using the χ^2 test, the value of χ^2 was 3·0 for both quinine and 6-*n*-propylthiouracil, with low taste thresholds (high taste acuity) associated with a higher percentage of food aversions in both cases. On the basis of percentage of food aversions, analysis by the Mann–Whitney *U* test of goodness of fit[5] revealed a difference in taste thresholds, significant at the 1 per cent confidence level for the two categories.

The bimodal distribution of thresholds for 6-*n*-propylthiouracil partially accounts for our finding that the correlation between per cent of food dislikes and thresholds for 6-*n*-propylthiouracil is quite small.

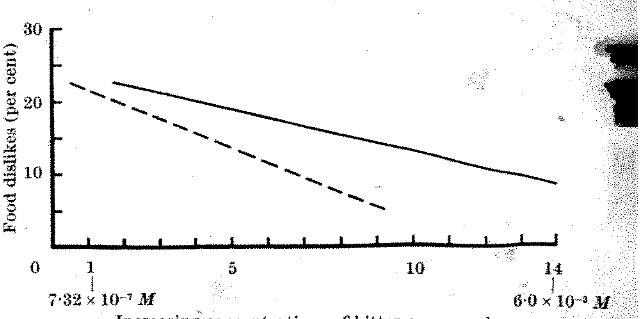

Fig. 1. Linear regression of the distribution of thresholds for 6-*n*-propylthiouracil and quinine related to percentage of foods disliked ($N = 48$). Numbers on the abscissa are concentrations of 6-*n*-propylthiouracil and quinine, each step representing a doubling of the concentration. — —, Quinine; ——, 6-*n*-propylthiouracil

Irrespective of this nearly zero correlation, however, the trend of the linear regression line of the percentage of food dislikes against thresholds of taste is similar to the regression line for quinine (Fig. 1). The equation of regression for 6-*n*-propylthiouracil is $Y = 23{\cdot}8 - 1{\cdot}14X$. The probability is 0·001 per cent that our sample came from a population with a slope of linear regression equal to zero.

The linear regression of percentage of food dislikes versus concentrations of quinine is $Y = 23{\cdot}167 - 2{\cdot}03X$. The probability that our sample came from a population of linear regression of zero is 0·001 using Student's *t* distribution.

The correlation between percentage food dislikes and quinine concentrations is +0·272. Although this accounts for only 7·5 per cent of the variance, it is significant at the 0·001 level of confidence.

While the source of food preferences and aversions is admittedly complex, the evidence indicates that taste-acute individuals have more food dislikes or that the number of foods disliked grows in proportion as the taste threshold for bitter compounds decreases. These findings bear on the adaptive significance [illegible] phenylthiocarbamide taste polymorphism[6], and t[illegible] indicate the need for item-analysis of food aversi[illegible] and attention to the mediating effect of cer[illegible] thyroxine precursors known to alter and to influe[illegible] thresholds of taste[7].

This work has been supported by the State of Ohio, Department of Mental Hygiene, and by grant No. *M*-2731 from the United States Public Health Service, National Institutes of Health. We are indebted to Dr. B. Pasamanick, Columbus, for helpful advice and assistance.

material make it possible by X-ray microscopic procedures to extract information about chemical composition and crystallographic structure of localized areas in a microscopic specimen. It is with these applications in mind that Drs. V. E. Cosslett and W. C. Nixon have composed their monograph *X-Ray Microscopy*, published in the series "Cambridge Monographs on Physics", by Cambridge University Press. In their presentation the authors have had excellent sources of material, such as those which have appeared in the proceedings of two international symposia on X-ray microscopy and X-ray micro-analysis held in Cambridge during 1956 and Stockholm 1959, respectively. A third symposium of this kind is planned at Stanford University, California, 1962. But besides a very careful recording of the literature in the field of X-ray microscopy, the book contains unpublished observations from the authors' own laboratory.

The techniques for the production of X-ray images by contact microradiography, projection X-ray microscopy, reflexion X-ray microscopy and ome other imaging procedures are well covered and ogether with the chapter on the production of X-rays a reader, both the physicist and the biologist, can get an advanced knowledge of the field.

The physics of X-ray microscopy differs from that of common X-ray physics, such as that used in X-ray diagnosis or X-ray therapy in that soft and very soft X-rays have to be used. At present, unfortunately, the numerical values of the X-ray constants, for example, the mass-absorption coefficients, for these soft X-rays, 1–50 Å., are not known with such a high precision as is desired, and in many cases no actual measurements are available at all and therefore only calculated values can be given. It is to be hoped that with the increasing use of X-ray micro-analytical procedures also the X-ray constants in the soft and very soft X-ray regions will be experimentally determined by precision measurements.

The monograph covers the three main forms of analytical applications of X-ray microscopy, namely, absorption micro-analysis, emission micro-analysis and micro-diffraction procedures. The techniques for specimen preparation are given both for inorganic and organic material, and an extensive presentation is devoted to X-ray microscopy of biological material.

It is clear that the possibilities of applying X-ray microscopic procedures to a variety of research problems now are fully established. Among the merits of these non-destructive techniques can be mentioned that it is possible to determine, for example, water and dry weight in a localized volume of a biological specimen less than one cubic micron in size. The quantities determined are in the order of 10^{-12}–10^{-15} gm., and the analytical error is in the order of 5 per cent. In the field of mineralogy and metallurgy the X-ray microscopic procedures, especially the scanning microprobe techniques for elementary analysis by emission, have proved to be most powerful tools. The same can be said about the micro-diffraction procedures; it has been possible to record diffraction patterns of crystals only about 1μ in diameter by such X-ray optical methods.

The field of X-ray microscopy and X-ray micro-analysis is rapidly expanding, and the book produced by Dr. Cosslett and Dr. Nixon is highly recommended all those who have problems in analysing very ll volumes of specimen, whether these workers are in mineralogy, metallurgy or in organic chem- ology or medicine.

ARNE ENGSTRÖM

MANUAL OF BACTERIA AND ACTINOMYCES

Diagnostik der Bakterien und Actinomyceten

Von Prof. N. A. Krassilnikov. Pp. xi + 813. (Jena: Gustav Fischer Verlag, 1959.) 59 D.M.

THE distinguished Soviet author of this manual of bacteria and actinomyces bases his classification on the following four criteria: (1) phylogenesis, and in particular his own view of this inspired guesswork; (2) morphological characteristics; (3) habitat; (4) variability under experimental conditions.

In accordance with his phylogenetic point of view there are four classes of micro-organisms, namely, Actinomycetes, Eubacteriae, Myxobacteriae and Spirochaetae, all of which have been elevated from Orders within Class II Schizomycetes of Bergey's *Classification* (seventh edition). The four criteria for classification have resulted in a far-reaching re-arrangement of orders, families and even species within the families, at the same time excluding conceptions such as sub-orders and tribes. The international principles of taxonomy are largely disregarded.

Keys are provided for the orders, families and species which make it possible to find and identify a particular species within this system if one knows what one is looking for. However, if doubt exists about some characteristic of a certain species this *Diagnostic of Bacteria and Actinomycetes* is of little help and even often misleading.

To quote some examples, the diphtheria bacillus can be found in the class of Actinomycetes, the order of Mycobacteriales, the family of Mycobacteriaceae and the genus *Mycobacterium*, and it figures as a species together with *M. phlei*, *M. tuberculosis* and *M. leprae*. Of the latter it is stated that cultures grow on blood agar plates, broth, serum and substrates containing glycerin. Disregarding the completely erroneous statement on the culture of *M. leprae*, it appears that the reasons for including corynebacteria in the genus *Mycobacterium* are: branching, which, according to the author, occurs rarely and only on certain media and under certain conditions of growth, and marked sensitivity to the antibiotic streptomycin. Organisms hitherto known within the separate genera *Escherichia*, *Salmonella*, *Shigella*, *Haemophilus*, *Pasteurella*, *Brucella*, *Bordetella*, *Klebsiella*, *Aerobacter*, *Proteus* appear merely as species of the genus *Bacterium* within the class of Eubacteria. To quote an instance of inadequacy, the *X* and *V* requirements of hæmophili are not mentioned though it is stated in the case of *Haemophilus influenzae* that growth is only obtained "in the presence of serum or animal tissues, and that additional growth factors are required". "*H. parainfluenzae* cannot be distinguished from *H. influenzae* as regards morphology, culture and physiology". In our present state of reasonably advanced knowledge the task of writing a reliable systematic of microbiology appears to be beyond the capabilities of any single person, which is probably the reason for such glaringly erroneous statements. For future editions Krassilnikov would do well to extend consultation of a few colleagues in a few fields of microbiology to collaboration with many experts in many fields. In mitigation the author's statement in the preface must be quoted that "the work is intended mainly for bacteriologists working in general, agricultural, soil, water and industrial microbiology". Yet, this statement does not make it any easier to diagnose, with the help of this manual, a strain belonging to, say, the hæmophili.

Krassilnikov would be perfectly justified in using his views on phylogenesis, morphology and habitat as a basis for his classification, but most experienced microbiologists in the West would think it quite wrong to make experimental variability and all that that term implies a criterion for classification. Thus the presence of an antibiotic in a culture may lead to bizarre forms which, if taken into account, will distort the criterion of morphology: and how, for example, is a freshly isolated strain of *M. tuberculosis* resistant to streptomycin to be placed in this scheme of things? In the last analysis the author's fourth criterion is the fundamental difficulty for a microbiologist with Western training. It appears that 'Michurinism' is responsible for this divergence of outlook in view of Krassilnikov's statement that external factors are capable of causing changes of the living substance of micro-organisms while denying that any such changes are governed by genes.

The book is well produced and printed, with 285 figures, including photographs of cultures, line drawings and photomicrographs, the latter of inferior standard. The translation from the Russian is competently done on the whole though quite a number of errors have crept in due to the transcription of the names of Western authors from the phonetic spelling in the Russian original text. There are 33 pages of indexes to literature and 53 to organisms.

K. ZINNEMANN

SATELLITE AND SPACE ORBITS

Space Trajectories

A Symposium sponsored by the American Astronautical Society, the Advanced Research Projects Agency, and Radiation Incorporated. Edited by the Technical Staff, Research Division, Radiation Incorporated. Pp. x + 298. (New York : Academic Press, Inc. ; London : Academic Press, Inc. (London), Ltd., 1960.) 12 dollars.

THIS volume is the record of the papers presented at the Symposium on Space Trajectories held in December 1959 and attended by representatives of various companies and institutions in the United States. The items vary widely in their quality and length. R. Hermann contributes a lengthy and excellent paper discussing re-entry trajectories and the problems of hypersonic flow. There is an admirable review of space manœuvres and rendezvous by A. R. Tanguay, and D. C. Hock supplements this with a useful survey of optimization problems, based largely on D. F. Lawden's work. Several papers deal with the detailed computations of satellite orbits, covering both the choice of analytical method and the numerical techniques : the phase of rampant individualism which at present characterizes this complex subject is reflected by the papers, in which, rather bewilderingly, almost every author advocates a different method. It will probably be some years before natural selection weeds out the weaker theories and methods. Perhaps the weakest method (despite its author's commendations) is that described on p. 266, in which the apogee height obtained, approximately 1,400 miles, is apparently in error by about 1,000 miles.

Volumes of individual papers are often marred b errors, inconsistencies and repetitions, and this boo has its share. The corporate wisdom of the edito (who sign themselves at the end of the preface "Radiation Incorporated") has not prevented fr quent mis-spellings of authors' names—Sir Haro Jeffreys enjoys the distinction of having his nam mis-spelt in two different ways—and there are man other irritating peccadilloes. For example, the legen on Fig. 2 on p. 217 is irrelevant and should have bee removed ; but Fig. 2 then becomes the same as Fig. on p. 83 and is superfluous. Also the introductor pep-talk, which has the curious title "Military Space Taking the High Ground", should have been prune of its nationalistic sentiments before being include in a technical book. To sum up, the book contai much to interest the specialist, but cannot be rec mended as a general introduction to the subject.

D. G. KING-HELE

RUMINANT DIGESTION AND NUTRITION

Digestive Physiology and Nutrition of the Ruminan

Proceedings of the University of Nottingham Sevent Easter School in Agricultural Science, 1960. Edite by Dr. D. Lewis. Pp. ix + 297. (London : Butterworth and Co. (Publishers), Ltd., 1961.) 50*s*.

THE importance of ruminants in agricultura economy has provided an effective stimul to the study of their nutrition for more than a centur Perhaps it was natural that the earlier work w concentrated rather on dietetics, with obvious pract cal applications, than on the physiological and bi chemical mechanisms governing the digestion an metabolism of feedstuffs. Nevertheless, it w recognized, long ago, that the most striking differen between ruminants and the familiar monogast animals was the capacity of the former to utilize cellulose as an energy source comparable in value wit starches and sugars. It is one of the most remarkabl features in evolution that only very rarely hav animals acquired the capacity to secrete cellulolyti enzymes—and this capacity does not seem to occ in any vertebrate. Cellulolysis in the digestive trac is essentially a function of microbial activity and, i the ruminant, provision has been made for this activit to take place in the so-called fore-stomach—a complex of three pouches developed from the cardiac region of the more primitive stomach. This development has led to extraordinarily complicated anatomical, physiological, microbiological and nutritional consequences. For more than a century, sporadic—and often brilliant—research contributions have been made in several facets of this field, but it was not until the 1930's that the subject started to receive the attention it merited ; since then interest has steadily accelerated. So rapid has been the development that a student must needs go to the original literature and to a handful of reviews for a survey of the field.

Especially welcome therefore is this recent publication. It is a collection of 23 short papers presented at the University of Nottingham's Seventh Easter School in Agricultural Science, held in 1960. In the space of some 270 pages it was obviously not poss to give a complete account of the present sta this subject, but a great deal of ground is co the 25 authors, all of whom have ma research contributions. Each chapter with a short list of selected references which will give ready access to the appropriate literature.

The work is conveniently divided into three sections. Under "Physiology of the Rumen" consideration is given to the movements and nervous control of the stomach, rumination, eructation, absorption and the flow of digesta. It is interesting to note that the phenomena associated with rumination, in spite of intensive, imaginative and ingenious research, still presents many unsolved problems. So too does the complex sequence involved in eructation—this latter function is especially important as its failure leads swiftly to the fatal consequence of hoven or bloat, a major disease in both dairy and beef cattle.

In the section "Metabolism in the Rumen" a brief outline of rumen microbiology is given, accounts of the fate of carbohydrates, proteins and lipids, and discussions of special techniques applicable to these fields. The microbiota of the rumen must surely be one of the most fascinating collections of organisms in a natural habitat ; the delicately poised system in the rumen, so easy of access for research, is potentially a most fertile source of material for the ecologist who is interested in the dynamics of natural microbial populations.

The third section, on "Ruminant Nutrition", makes no attempt to cover the conventional fields which are adequately treated in many text-books. Attention is focused on a few actively growing points, notably endocrine relations in metabolism and nutrition, and the synthesis of vitamins and microbial proteins in the rumen ; also, the recent advances in ruminant physiology have awakened renewed interest in energy utilization, to which two chapters are devoted.

In spite of the limitations inseparable from any compilation based on a series of conference papers, this book will prove valuable to all students of ruminant nutrition and will provide a good background for readers interested in the metabolic diseases of ruminants.

I. W. McDonald

TUMOUR METABOLISM

The Glycolysis and Respiration of Tumours

By Alan C. Aisenberg. Pp. xiii + 224. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.) 8 dollars.

THE present time seems quite appropriate for a dispassionate survey of our present-day knowledge and theorizing on the respiration and glycolysis of tumours. This subject begins with the original observations of Otto Warburg, made in 1923. The technical basis of these was important in itself: the introduction of the use of the thin slice of fresh tissue as experimental material and the development by Warburg of manometric methods based on those of Haldane and Barcroft; two of the most fruitful contributions to experimental biochemistry.

These are accepted. What is controversial concerns mainly the interpretation of these measurements in relation to the problem of cancer, and on this subject argument has tended to be hasty, intemperate and acrimonious, especially by the 'all-or-noth[illegible]ng' school, who will accept only a single key to [illegible]er, and will discard everything less universal. [illegible] other side of the picture, Warburg himself [illegible] more fervent disciples have sometimes [illegible]ush their case too far against the opposing weight of evidence, or at least to turn a blind eye to inconvenient experimental findings.

The primary beliefs of the Warburg school are briefly as follows: (*a*) in relation to tumour growth, and to the neoplastic process in general, energy-yielding metabolism is all-important; the rest is secondary. (*b*) While growing tissues, both embryonic and neoplastic, when maintained anaerobically have a high rate of glycolysis (that is, lactic acid formation from glucose), aerobically only the tumour tissues show strong glycolysis. (*c*) There is a disturbance in the respiration of tumours which is not only the cause of their aerobic glycolysis but also which is fundamental to the nature of cancer.

As Dr. Aisenberg clearly brings out in his very satisfactory review of the relevant factual information, it is quite easy to assemble data either in support of each of the above dogmas, or contrary to them. Indeed, of the 538 literature references cited, a fair proportion are regarded by their authors as providing decisive evidence one way or the other. The fact that honest and capable workers should find themselves so divided, even sometimes on the experimental findings themselves, is a good reason for the publication of this book, which presents an unbiased and reliable account of the work up to 1960 on the respiration and glycolysis of tumour tissue, and, where the comparison is available, on related normal tissues.

In spite of all the work summarized in this useful book, I am left with an opinion not essentially different from that which I put forward in *The Cancer Review* in 1931: "Perhaps it might even have been assumed to be improbable from the outset that such fine distinctions as exist between various types of malignant and non-malignant growths should be wholly explicable in terms of simple measurement of respiration and glycolysis". Surely the respiration of a tissue should not be assessed for this purpose solely in terms of its rate of oxygen uptake, when it is now very much clearer than when the above words were written that tissue respiration is merely the overall expression of an exceedingly complex chain of enzymic reactions, involving alternative substrates, alternative metabolic pathways, alternative co-enzymes, and alternative routes of energy utilization. Nor can the entity 'aerobic glycolysis' be conveniently divorced from the complex balance of enzymic activities and sub-cellular structure by means of which it is regulated. Finally, the control of synthetic reactions, especially of biosynthesis of protein and of nucleic acids, needs to be considered in relationship to what Krebs has called 'pacemaker' reactions, which, though all-important in regulation of cell metabolism, may constitute only a small part —though a determining one—in the overall crude picture of 'respiration and glycolysis'. The author of this carefully 'neutral' book might not perhaps be willing to go so far, but his well-balanced record of thirty-seven years of experiment, inference and controversy should assist towards a happy issue to this vexed question.

The book is generally excellently produced by the Academic Press, and is a publication of the Cancer Commission of Harvard University. Minor blemishes occur in the spelling of some names (Lipmann, p. 67; Stickland, p. 217); the date of Warburg's book, *Stoffwechsel der Tumoren* (p. 218), was 1926; "anaerobic glycolysis", attributed on p. 14, line 8, only to the very young embryo, should read "aerobic glycolysis".

F. Dickens

A Clinical Prospect of the Cancer Problem

By Prof. D. W. Smithers. (Monographs on Neoplastic Various Sites.) Pp. xv + 232. (Edinburgh and London: E. and S. Livingstone, Ltd., 1960.) 37*s.* 6*d.* net.

MORE than five years ago Prof. D. W. Smithers undertook to act as general editor of a series of monographs on neoplastic diseases at various sites, and four books in this series have already been published, dealing with cancer of the lung, bladder, rectum and œsophagus. Other volumes dealing with the prostate, brain, larynx and pharynx are also in preparation. The justification for this piece-meal way of approach to the cancer problem is derived from the fact that, from the clinical point of view, cancer of each organ of the body has its own particular characteristics, affecting ætiology, pathology and treatment.

Each volume in the series of monographs on neoplastic disease at various sites is edited by someone with special experience in this particular field, and this series of books is proving to be of exceptional value to those doctors who are engaged in the diagnosis and treatment of cancer of the different organs of the body selected for inclusion in the series. But to fill in the gaps another monograph was also obviously needed, one which would survey the cancer problem as a whole yet still preserve the clinical point of view. This necessary introductory volume has now been written by Prof. D. W. Smithers himself.

He has unique qualifications for this task. Not only is he the general editor of the whole series (and incidentally the originator of the idea) but also his work as director of the Radiotherapy Department of the Royal Marsden Hospital and Institute of Cancer Research has brought him into contact with clinicians and research worers concerned with every aspect of human cancer.

Prof. Smithers begins by saying that his book presents "a personal view of the cancer problem". It tends to be "speculative and philosophic" in character. It is certainly original, stimulating and provocative, and provides an admirable introduction to this useful series of monographs.

Cosmology

By Prof. H. Bondi. Second edition. (Cambridge Monographs on Physics.) Pp. viii + 182. (Cambridge: At the University Press, 1960.) 30*s.* net.

THE call for a new edition of this book is a tribute to the excellence of the book itself and also an indication of the vitality of its subject. Ever since the 'modern' work in cosmology was started by Einstein in 1917, or thereabouts, as soon as it has seemed to some workers that a stage had been reached when little more could be done, other workers have revitalized the subject by some major idea or discovery. Thus, for example, Prof. Bondi and his colleagues produced the ideas of continual creation and of steady-state cosmology in 1948, Walter Baade discovered the need for a far-reaching revision of the distance scale in 1952, and this year Prof. M. Ryle and his colleagues have published their new surveys of remote radio sources. To some of us it seems indeed that the subject still awaits the key discovery that may be expected to show the significance of all that has been done hitherto. Anyhow, anyone wanting to make a serious study of the subject at present, and probably for a long time to come, needs to know all that is contained in this book, and he is fortunate indeed in being given the material in such a clear, vigorous and stimulating form.

W. H. McCREA

The Use of Organic Reagents in Inorganic Analysis

By A. I. Busev and N. G. Polianskii. Translated from the Russian by J. T. Greaves. Pp. vi + 76. (London and New York: Pergamon Press, 1960.) 21*s.* net.

THIS translation from the original Russian has been produced, for reasons of celerity and economy, by non-letterpress setting and photolithography. The final result, although lacking the attractiveness of conventional printing, gives a quite legible text.

No booklet of seventy pages could possibly present a detailed practical description of the many applications of organic reagents in the analytical field. The present volume provides extended abstracts of the more important papers on the use of organic reagents, these abstracts being supported by a comprehensive bibliographical and reference section.

The first chapter of the book is devoted to general problems associated with the use of organic reagents for example, specificity, functional groups, masking reagents, effect on redox potentials, and on catalytic reactions, etc.

The determination of cationic elements is dealt with sequentially according to the group system of the Periodic Classification, the presentation being both lucid and informative. No mention is made of anion-reagent complexes.

This is a useful reference book for the practising analyst or researcher in analytical methods, and it also gives an interesting indication of the keen interest taken by Russian chemists in the work on the application of the newer organic reagents to quantitative analytical problems.

D. T. LEWIS

Die Cactaceae

Handbuch der Kakteenkunde. Von Curt Backeberg. Band 5: Cereoideae (Boreocactinae). Pp. xxxix–xliv + 2631–3544 + tafeln 212–255. (Jena: Gustav Fischer Verlag, 1961.) 107 D.M.

HERR BACKEBERG'S fifth volume concludes his vast systematic treatment of the Cactaceae with the remaining groups of the Cereoideae. A final supplementary volume with indexes is announced for next year. The present one is bigger than its predecessors because of the account of the important genus *Mamillaria,* which occupies more than 400 pages. The author recognizes 301 species and then adds descriptions of more than 100 "Wenig bekannte Arten", in alphabetical sequence, in accordance with the similar list in R. T. Craig's Handbook (1945). Herr Backeberg's adoption of the spelling *Mamillaria,* rather than the original *Mammillaria,* to be regarded as an orthographic error, will be hotly contested by many botanists, who will read his discussion in the lengthy footnote on p. 3091. Lewis and Short's Latin Dictionary certainly quotes *mammilla* as an incorrect form of *mamilla,* the diminutive of *mamma.* Th International Code of Botanical Nomencla however, retains the spelling *Mammillaria* list of *Nomina Generica Conservanda.*

N. Y.

SCIENCE AND THE CLASSICS*

By Prof. B. FARRINGTON

Formerly Professor of Classics, University College, Swansea

THE circumstances of our age seem to present us with a very real problem which may fittingly be discussed under the title of "Science and the Classics". In response to an international challenge we are engaged in expanding our educational services. The urgent need is for more scientists, more technologists, more engineers. This means a relative, if not an absolute, decline in the study of the humanities. Is this shift in the character of our education good or bad? Is there anything in the claim that the tudy of the humanities produced a more balanced ype of man? Is there in the scientific mode of training any tendency against which it is desirable to be on our guard?

I think that there is a tendency among scientists to suppose that the physical world alone is real, and that the very successful methods they have devised for dealing with it are applicable to every aspect of life. This, to my way of thinking, is a ngerous illusion. I am one with Schweitzer in lieving that "all progress in discovery and invention olves at last to a fatal result, unless we keep control over it by a corresponding progress in our pirituality"[1]. I am convinced, with him, that in the last resort, the practical can be realised only through the ethical". I fear that a preponderance of scientific elements in our education, and a decline in humanistic studies, may render us incapable of exercising effective control over our science of Nature.

Science, though it has its roots far in the past, is in the present acceptation of the term a recent growth. Four hundred years will cover its history; and the speed of its recent development gives it a still more modern aspect. But four hundred years of science have not put four thousand years of civilization out of date. There is a provincialism in time as well as in space. To think that everything has been changed in the past four hundred years is a mistake. The world did not begin with Galileo and Newton. All culture is not merely scientific culture; but all culture is a mode of thought, and man should try to think with the whole of his past. This is the specific business of the humanistic disciplines.

But I trust that no one will take me for an enemy of science. Twenty-five years ago I concluded a little book on the history of Greek science[2] with some words I should like to recall. "It seems impossible", I then wrote, "that a stable society should ever estab- h itself without the positive knowledge science has offer as a universal subject of education and the rality science imposes as an element in its law." I still stand by that to-day. But I did not believe n, and I do not believe now, that either the aims, the method, or the achievement of science give unds for hope that a stable society could ever be unded on science alone. The sciences are the reation of a specialized use of the mind. They are ot its only valid use. It is not true, as seems now be believed by many, that it is science alone which gs us into contact with 'reality'. The most portant aspects of reality for man are those that rn his own actions and aspirations, and these, for the most part, are not amenable to quantitative analysis; they elude the scrutiny of the exact sciences. Thought about them has not been radically altered by the discovery of the scientific method. Conceptual thought is an older and more necessary tool than the scientific method. Understanding is not always helped by the accumulation of information. Poverty of ideas is a more effectual bar to wise action than the absence of statistics. The intuitive powers of the mind, dependent more on sympathy and imagination than on exact information, open the door to the moral and æsthetic world, that is to say, to that aspect of reality ultimately decisive for our happiness. Neither technological nor sociological knowledge is of any use to us, as Shelley observed long ago, if we lack "the creative faculty to imagine what we know, and the generous impulse to act what we imagine".

Francis Bacon was of the same opinion. He never countenanced the illusion that scientific or technological progress in themselves could benefit mankind. They could only bring an increase of power, which could be used for good or evil according to the disposition of the will. His opinion is particularly worthy of attention since his advocacy played a decisive part in the technological revolution. He convinced his age both of the need for an immensely increased store of factual information, and of the dazzling potentialities of the science that could be raised on this foundation. But we should not pass over his fear lest "from the unlocking of the paths of sense and the enkindling of a greater light in nature any unbelief or darkness should arise in our minds to shut out the knowledge of the divine mysteries". Nor did he leave us in any doubt as to what was, in his eyes, the chief of the divine mysteries. "I would address", he writes, "one general admonition to all, that they consider what are the true ends of knowledge and that they seek it not either for pleasure of the mind, or for contention, or for superiority over others, or for profit, or fame, or power, or for any of these inferior things; but for the benefit and use of life; and that they perfect and govern it in charity." These essentials of which Bacon speaks, namely, "the true ends of knowledge", "the benefit and use of life", and the supreme duty of charity, are no part of a scientific training. The question to consider is whether the apprehension of these aspects of reality has, in fact, gained anything by the scientific revolution and whether it stands to gain anything in the future.

Bronowski, in his recently published *Science and Human Values*—a wise book, well-suited to our present needs—forcefully argues the case for a fundamental identity between the moral, æsthetic, and scientific imagination. The processes, he claims, by which we deepen and advance our understanding of the good, the beautiful, and the true, are essentially one. In each case men seek to find unity in variety, to connect things which previously lay apart. The creative flash in which the unity is perceived is in each case the same. I am sure there is some truth in this contention. Particularly do I appreciate his insistence that science is not the collecting of facts, but the creating of concepts. With an argument conducted at this level I have no quarrel. Nevertheless,

---

bstance of a lecture delivered at Hatfield Technical College ne 2.

I suspect that at the humdrum level of ordinary daily practice there remains an urgent problem which Bronowski's analysis ignores.

Sir Bernard Lovell recently said that, of all the scientists that have ever existed on Earth, 90 per cent are alive at the present moment. Think of the sudden expansion of scientific training that these figures imply. Tens of thousands, hundreds of thousands, of young men and women are now undergoing an initiation into scientific method. I welcome this. All my conscious life I have wished to see it. I believe, and hope, that it is destined to increase. But I am not convinced that such a transformation of human consciousness as this shift in education implies is unattended by the gravest threat. We have the prophetic fear of Bacon, we have the humble testimony of Darwin, that the necessary drudgery of science may dim the more imaginative powers of the mind on which lively apprehension of moral and æsthetic reality depends.

That this is so, I feel. Why it should be so is an obscure question on which I must now try, not very optimistically, to shed a little light. First, I should like to direct attention to the vast difference in time-scale between moral and æsthetic development on one hand and science on the other. No anthropologist that I have ever heard of claims to find among what we call primitive peoples the equivalent of a modern scientist. But anthropologists do profess to recognize in these simple societies philosophers, sages, leaders, law-givers, creators of admirable and viable patterns of social life. Prof. Ashley Montagu, for example, asserts that "in spite of our enormous technological advances we are spiritually, and as human beings, not the equals of the average Australian aboriginal or the average Eskimo—we are very definitely their inferiors"[3]. The reason for this early development of morality seems plain. If any human society at all is to exist, and such have existed for hundreds of thousands of years, its members must evolve or accept some rules of living together, some sense of community, some morality. This is true even of food-gatherers. Morality can be highly developed in technologically primitive societies.

The exploitation of the external environment, however, which is rudimentary science, has always introduced problems of social organization which swamp moral standards. Schweitzer's dictum that "all progress in discovery and invention evolves at last to a fatal result, unless we can manage to keep control over it by a corresponding progress in our spirituality", does not apply only to modern conditions, but also to all history. It was a commonplace with the philosophers of classical antiquity. Neither Platonist, nor Epicurean, nor Stoic would be surprised to find that the period of our greatest triumphs in science and technology coincides with the overwhelming of our humanity and sense of community. The gas chamber, the napalm bomb, the systematic employment of every refinement of torture are characteristics of a high material civilization. The bond of human fellowship is very old and very fragile. Morality has usually come off second best in its encounters with the social problems created by the increase of prosperity. The same appears to be true of man's æsthetic sensibility. It is an early starter and an easy victim. As the cave-paintings of primitive men remind us, hunters could create works of art revealing a power of visual imagination which eludes potters and farmers.

I have said that we should try to think with the whole of our past. One of the thoughts most strongly induced by this practice concerns the unevenness of progress. The most striking gains prove, on examination, to have involved serious loss. An example is alphabetic writing. This surely, one would think, is a wholly beneficent achievement of human ingenuity. It was, in fact, a necessary pre-condition of the emergence of large-scale organization, yet it wrought so decisive a change in human consciousness that it all but obliterated the memory, and certainly destroyed the understanding, of the age-old culture of pre-literate societies. The invention of the alphabet blinded men to the knowledge of some thousands of years of our human story. Much research and a great effort of the historical imagination were needed to restore to the twentieth century an appreciation of the oral cultures which writing destroyed. Yet so accomplished a stylist as Plato was near enough to the world of oral tradition to view the dissemination of the alphabet with a critical eye. He had two main fears. One, that writing would impair the memory. Has it not done so? "Without writing," notes Tom Harrisson, "memory is perfect, tradition exact." Secondly, Plato felt that a book was an inadequate substitute for a living teacher. We may note that the two greatest teachers in the European tradition, Socrates and Jesus, never wrote a book. In our own educational practice at its best, books are treated only as an adjunct to the spoken word.

But this is far from being the end of the matter. There are other penalties literacy exacts: sluggish powers of observation, inability to learn directly from observation, helplessness in the face of Nature. We learn to read and forget how to look and listen. Paul Radin speaks of "the distortion in our whole psychic life, and in our whole apperception of external realities, produced by the alphabet". Schweitzer reminds those charged with the education of simpler peoples that "civilization began with the handicrafts and agriculture, not with reading and writing". Our own Boy Scouts, Girl Guides, and other suc organizations usefully make up the deficiencies of an education too exclusively concentrated on books.

Furthermore, we should note, as particularly relevant to our subject, that the unique vitality a charm of ancient Greek literature arises from th fact that it remained for long much closer to the oral tradition than our modern manner of studying it suggests. Greek boys, like ours, studied grammar but grammar then had a much fuller meaning tha it has now. It meant, not so much learning to read, as to read aloud. A written text was then treated like a musical score. The grammar lesson included elocution. It taught the correct delivery for the various styles: epic, lyric, tragedy, comedy. It concerned itself also with pitch and intonation on which the beauty of composition was thought depend, and on strict observance of phrasin without which the full meaning was obscured. S long as Greek civilization lasted, in every city the founded round the Mediterranean, in the Black Se or the Near East, they preserved their cultur tradition by setting up schools where the boys learne to *recite* Homer, and theatres where adults *hea* great tragedies performed. As for silent readin it can only be said that the Greeks did not have word for it. So when Philip in the *Acts* encounte the Ethiopian eunuch he *heard* him reading prophet Esaias. Some five centuries later whe servants of St. Ambrose *saw* him reading the scrip and *heard* nothing, they took it for a miracle. Silent reading had begun. Literature was on the way to becoming voiceless, a matter of visual symbols which the eye is drilled to take in as quickly as possible. Mercifully, in this case, we manage to some extent to retain the advantages of both worlds. Mere information we take in quickly by the eye alone. Something of the glory of the spoken word as it existed in classical antiquity is preserved in the Church, in the theatre, and in our new medium of mass communication, broadcasting.

These are examples, chosen almost at random, to remind us of the ambivalent nature of social change. Technological advance sets society problems too difficult for its moral resources to handle. The acquisition of powers of abstraction weakens the visual imagination. The art of writing, which in one sense may be said to constitute the memory of mankind, in another sense destroys that memory by externalizing it. Why, then, should we wonder if it should appear that the development of the exact sciences damage the apprehension of all those aspects of reality that are not amenable to its method of analysis.

That this, in fact, is so, the history of ancient Greece strongly suggests. The Greeks were not yet a scientific people when, between the eighth and fourth centuries B.C., they created that literature which still to-day constitutes the most vital part of what we Europeans generally mean by the humanities. Before the end of the fourth century, epic, lyric, drama, history, and philosophy already existed in their most original and perfect examples. Nor is it true, as seems now sometimes to be supposed, that this literature was a sort of superfluous adornment of life, inessential, but adding grace and charm. This is by no means so. On the contrary, it was creative in the fullest sense of the word. It was a new mode of thought, an exploration of reality, and, indeed, the very substance of a new reality arising out of the old. Men then thought about themselves as they had learned how to do from Homer, Pindar, Aeschylus, Thucydides, and Plato. The minds, the characters, the passions of men, the destinies of individuals and of States had been portrayed by thinkers profoundly capable of reflexion on their national traditions and their personal experience, and gifted with the imagination to embody them in new art forms : and the intellectual adventure was carried farther still. Men were equipped with the concepts and the vocabulary to discuss intelligently the facts of society and politics. But not only that. They succeeded also in distinguishing between life itself and its representation in the various arts. They created not only a philosophy of life but also a philosophy of art. Aristotle, for example, freed the criticism of the drama from its entanglement with morals and politics, assigned it a distinct function and analysed its constituent elements in terms which are still the stock-in-trade of all critics. His pupil Aristoxenus did a similar service for music, distinguishing acoustics, which is properly concerned only with the physical antecedents of sound, from music itself in which the sounds are considered in their relation to one another in an integrated composition. Thus was created the humanist consciousness, a new awareness of social life through the instrumentality of literature and art. This, to my way of thinking, is still fundamental, and in no way replaceable by later modes of thought.

Then, after the fourth century, a change in the mental climate set in. Greek geometers set to work on the observational material accumulated by the Mesopotamian star-gazers, and the exact science of astronomy was born. It was discovered how to plot accurately the paths of the Sun, Moon, planets, and stars against a spherical background of which Earth was the centre. Thus was inaugurated a space-probe of a breath-taking kind, even if as yet it was accomplished only in the imagination of the mathematician. The new science had practical advantages for agriculture, navigation, and geodesy. It also adapted the religious consciousness to the new political conditions. Improved communications had begun to unify mankind. It was no longer expedient that different peoples should be divided by their local religious allegiances. The mathematical heavens became the chief object of religious awe. The countless anthropomorphic divinities of sky, sea and land were one by one identified with Sun, Moon, planets, and stars. All peoples were united in a common adoration of universal gods.

So far, so good. But it was not long before this stupendous astronomical conception took on an astrological complexion. When the Sun, who rules the day, and the Moon, who rules the night, had been identified with Apollo and Diana, that is with gods in human shape, when Venus, the goddess of love, and Mars, the god of war, when father Jupiter, strong in wisdom, and Mercury, guide of travellers and friend of thieves and business-men, had been installed as bright luminaries in the sky, was it to be supposed that this lessened their influence over the affairs of men ? Their influence, now that they were enthroned in the heavens, was stronger than ever. What is more, if only the correct technique could be devised, it was calculable. This technique the astronomers bit by bit perfected. It is a mistake to think of astrology as a popular superstition. It was a highly sophisticated way of misinterpreting the universe. Long before astrology was invented the people had their humbler ways of guessing what the future had in store. It was the astronomers, bending their mathematical brains to the task, who established the astrological technique. So vast, so complicated, so daring, so seductive a conception was the work of superior minds. The creators and defenders of this crippling superstition were the Hipparchuses and the Ptolemies. They had, in the language of Bronowski, brought together in one creative flash of insight two aspects of reality that had previously lain apart and fused them into one. It was to take something stronger than science to tear them apart again.[4]

Here, then, is a subject supremely worth pondering. The astrological view of the universe presented, in a degree unapproached by any other ancient system, the aspect of an exact science. Yet despite its scientific aspect and the fascination exercised by the exactness of its procedures, it represented a decline in culture, an impoverishment of personality, an enslavement of the will, a diminishment of man's moral and spiritual nature. Man had previously been understood in terms of what the poets, historians and philosophers had made of him—a being not exempt from weakness and villainy, but yet versatile, adventurous, resourceful, enterprising, adaptable, aspiring, and in great measure his own master. Now he had shrunk to being the puppet of the stars, whose relation to the powers that ruled his destiny could be represented in a mathematical diagram. No longer a wily much-enduring Ulysses, a magnanimous Hector, a Prometheus hurling defiance at the gods, a wise law-giver, a subtle politician, or a martyred philosopher, he had become a helpless lay-figure spread-eagled in a series of concentric circles in which revolved for ever those celestial gods whose influence, streaming down into every limb and organ of his body, determined both his physical and mental constitution and the pattern of his days.

It is often imagined that this harmful superstition was dissipated by the dawn of scientific knowledge and scientific thought. This reading of history is scarcely true. Its great strength was the scientific armature which supported its fantasies, and its opponents were humanists of one sort or another. Epicurus, for example, in antiquity, whose name is, indeed, inseparably associated with the atomism of Democritus, but as the one who asserted in the teeth of that deterministic creed the autonomy of the will. It was in the name of that same freedom of the will that St. Augustine fought astrology, drawing, I believe for the first time, a clear distinction between it and the genuine science of astronomy. At the Renaissance again it was essentially this question of freedom, presenting itself this time in the guise of the dignity of man, that brought a Pico della Mirandola into the ranks of the opponents of astrology. It is in this spirit too that Shakespeare makes his Cassius exclaim :

> "The fault, dear Brutus, is not in our stars
> But in ourselves that we are underlings."

Men had awakened from a sleep of some two thousand years in which they had allowed themselves to be imposed upon by the exaggerated claims of what was, in fact, a genuine advance in knowledge. Their awakening took the form of the resumption of those modes of thought which, though lacking the exactness of the new geometrical astronomy, were yet better adapted to handling those aspects of reality on which man's happiness ultimately depends. Astrology had given man confidence to believe that his understanding could reach out to embrace the stars ; but it was the stars that leaned down to hold him in their embrace. Astrology made man bold enough to declare himself a citizen of the cosmos ; but the tyrannical cosmos retorted that man was no citizen but a slave. It was only when the older humanistic culture had again asserted itself that man could take a more sober view of himself and resume his character of a humble lover of wisdom, neither boasting of his citizenship nor trembling as a slave.

This ancient example of the divergence between humanism and the exact sciences would not be worth dwelling upon were it not that it has something typical about it. Consider, for example, as a parallel from the modern world the history of Cartesianism. The contribution of Descartes to science (I can speak of it only at second-hand) was very great. He welded together Greek geometry and modern algebra, thus making a powerful instrument for the exact analysis of physical phenomena. But he was deficient both in æsthetic sensibility and historical sense, so that no warning voice held him back when it occurred to him to apply his mechanistic philosophy to problems of life and society. The results were disastrous. Regarding as but elegant trifling all that the senses, the imagination, and the memory had to offer, he trusted to the pure intellect alone and regarded the world of the analytic geometer as the sole reality. He arrived by this path at two major conclusions. The first was that the only existence he could be absolutely certain of (except as the result of a tedious argument) was his own. The second was that animals were only machines. He was devoted to vivisection and explained the cries of his tortured dogs as the crash of broken machinery.

From the first of these opinions, namely his solipsism, his friend Gassendi, who as a Christian defender of Epicureanism was doubly steeped in the humanist tradition, tried in vain to wean him. "You will say", he writes in a letter to Descartes, " 'I am mind alone' . . . But let us talk in earnest, and tell me frankly, Do you not derive the very sounds you utter in so saying from the society in which you have lived ? And, since the sounds you utter are derived from intercourse with other men, are not the meanings of these sounds derived from the same source ?" But Descartes could not take the point. Small wonder that Thomas Hobbes, who also knew him, was wont to say that "had Descartes kept himself wholly to geometry he had been the best geometer in the world, but that his head did not lie for philosophy".

As for the second of his pronouncements, that animals are machines, it is as good an example as one could wish of that reductionism which has been called the occupational disease of scientists. Descartes, because he had succeeded in arriving at exact knowledge of certain mechanical principles, was convinced that these principles must be equally valid in a wholly different sphere. For tens of thousands of years man had been in close relationship with the other animals, and his knowledge and understanding of them had not failed to profit thereby. It is certain that without his alliance with the dog man could never have held his own against the larger Carnivora. The dog was the fifth column through which man breached and conquered the animal kingdom. Similarly the ox and the ass, the camel and the elephant, helped him to exploit his physical environment, rendering essential service to agriculture and to trade. Where would the hunter and the shepherd have been without his dog, the trader without his pack-animal, the jungle-clearer without his elephant ?

Through an experience lasting over many thousands of years man had gained an insight into the character and mentality, as well as the physical capacities, of animals both wild and domestic. He appreciated both their resemblances to himself and their essential differences. The knowledge lacked quantitative precision, but it was both true and tested. What was more, it was knowledge of whole animals in their normal habitat. All this accumulation of wisdom was ignored by Descartes' unhistorical definition. Basing himself on his laboratory experience he brushed aside all the animal lore of the past with the curt remark that "the greatest of all the prejudices we have retained from our infancy is that of believing that the beasts think". But, long before Descartes and his experiments in vivisection, men had been capable of distinguishing between the mentality of man and that of animals, without losing the capacity to distinguish between animals and machines. Man had been defined by the Greeks as the rational animal *par excellence*, but to animals the Greek thinkers had allowed sense-perception and memory, and even a limited capacity for organizing experience. Now all this traditional folk-wisdom, together with all these careful philosophical distinctions, is cast aside by a man labouring under the delusion that the only way in which animal behaviour can be understood is to treat it as if it were a branch of mechanics. This is what meant when I gave the caution at the outset of tl article that we should not allow ourselves to be dazzled by our most recent achievements but should try to think with the whole of our past. The tradition of French thought which Descartes was brushing aside can be studied equally in the humanist Montaigne, the Huguenot Palissy, or the Catholic Richeome[5].

These remarks are not intended to belittle either the greatness or the humanity of Descartes. He was, as his biographer William Wallace says, "a type of that self-reliant, harsh, and abstract spirit of science to which erudition and all the heritage of the past seems but elegant and unworthy trifling". But he had also caught from Francis Bacon a warm faith in the humanitarian spirit of science. "I believed", he remarks with regard to his discoveries in natural philosophy, "that I could not keep them concealed without greatly sinning against the law which obliges us to procure, as much as lieth in us, the general good of all men. For they have shown me that it is possible to arrive at knowledge which is very useful to life, and that instead of the speculative philosophy which is taught in the schools, a practical philosophy may be found. By means of this, knowing the power and the action of fire, water, air, stars, heavens, and all the other bodies which environ us, as distinctly as we know the various trades and crafts of our artisans, we might in the same way be able to put them to all the uses to which they are proper, and thus make ourselves, as it were, masters and possessors of nature." No, Descartes did not lack humanity ; but this only makes the more significant that typical kind of scientific blindness which seeks the explanation of the phenomena of consciousness in terms of the physical sciences.

This blindness is not a phenomenon of the seventeenth century but is as alive and vigorous now as ever it was. A recent controversy in *The Observer* shows us Dr. N. S. Sutherland of the Institute of Experimental Psychology, Oxford, insisting that "the behaviour of animals and men can ultimately be explained in terms of the chemistry of the nervous system" ; and that it is arrogant to suggest that "because we have not yet found a full explanation in physical terms for some piece of behaviour, there cannot be one". Now behaviour is a big term. It is not covered by what can be observed in a laboratory under laboratory conditions. To a humanist human behaviour covers the whole field of human history from the appearance of man on Earth to the present day. For Vico, the great eighteenth-century opponent of Cartesianism, reality was not covered by physical reality. It included all man's customs and laws, all his forms of association and his institutions, all his arts and crafts, all literature and the fine arts, all politics and religion. In this field also knowledge is a possibility. But its methods, procedures, and modes of explanation are different from those of the natural sciences, and, perhaps, more difficult. To imagine that chemistry and physics can throw light on them is to make the mistake the old Greeks made before Aristoxenus explained to them that music was not the same as acoustics. It is to suppose that a musical instrument is real and music itself a subsidary and dependent phenomenon which will clear itself up without more ado once the physics of the instrument have been explored. It would be naïve indeed to suppose that with the intensification of scientific training on the scale now reached this sort of blindness will not spread. It is idle to hope that if we give young people the training of Descartes they will automatically be capable of thinking like Vico.

In my view it is impossible to be too deeply concerned about this problem. Within the span of my active life as a university teacher the balance tipped from humanistic to scientific and technological studies. There were sound reasons for the change, and it has been accompanied by solid advantages, by no means only on the material side of life. But the process has gone too far. A university senate used to be a majority of humanists with a sprinkling of scientists, now it is a body of scientists and technologists with a sprinkling of humanists. This change of character in the academic body has meant the emergence in university life of an absolute incomprehension of the older humanistic disciplines. They are felt to be an expendable luxury. I remember a heart-to-heart talk with a Fellow of the Royal Society in a position of great responsibility. He wanted to know why it was not possible to make a definitive translation of all the Greek and Roman classics and thus be done once for all with troublesome business of learning these dead languages. This man could understand the world of Descartes, and his distinction in this kind of knowledge had won high recognition. Of Vico's world he did not even know enough to know that he knew nothing. But we liked one another, and he was kind enough to put his helpful suggestion to me, politely, in the form of a question. However, it left me to chew sadly over a passage in one of Schweitzer's books. "To-day," he writes, "thought gets no help from science . . . The newest scientific knowledge may be allied with an entirely unreflecting view of the universe. . . Our age has discovered how to divorce knowledge from thought, with the result that we have, indeed, a science that is free, but hardly any science left which reflects."

A supreme illustration of the kind of science which divorces knowledge from thought, of a science which is indeed free but has lost the power to reflect, is supplied by the Kinsey Reports. In them an unprecedented effort has been made to bring to the masses a strictly scientific, morally neutral, factual survey of sex. Nor do I deny that these reports exemplify one of the virtues of science, absolute loyalty to the ascertained fact. I believe further that its statistics may in the long run contribute to some good end. But for Kinsey and his team sex is a purely physiological fact taken in its most material aspect because this alone is measurable. Science to be science must be exact. Sex, therefore, in these reports is divested of any specifically human quality. So understood, its analysis will present little difficulty to the experimental psychologists. The chemistry of the nervous system will come into its own and there should be little difficulty in achieving a full explanation in physical terms of this piece of behaviour. All that will be missing is the relevance of this analysis to man. It will set him a high standard of the sexual activity that may be achieved in the course of a life. But it will not answer any questions even about pleasure, still less about happiness, or love, or parenthood, or the family, or any other institution of human society ; for these things do not lend themselves to exact measurement and statistical treatment. To handle such matters as these the Cartesian conception of science must be supplemented by that of Vico[6].

I come back then, to my main point, namely, the insufficiency of the natural sciences as a key to the understanding of society. It is not difficult to see why this should be so. True, there is a sense in which man is an animal like any other, a product of biological evolution : and this fact inclines us to suppose that his behaviour should therefore be intelligible in purely biological terms. But this is not so. When man developed speech and conceptual thinking he cut the umbilical cord which bound him to mother Nature. He then ceased to inherit his specifically human behaviour genetically and began to hand on the tradition of culture by education. In this sense man is not simply a child of Nature. He is a kind of super-Nature. His animal inheritance is only a part of him. The other part of him is his cultural inheritance, which is the means whereby he decides what use to make of his animal nature. In this sense, a limited but very real sense, man is both free and creative. If we seek to explain him purely biologically we rob him of his freedom and his creativity. If we wish to rouse and instruct in him his capacity for free creativity we can only do this by increasing his understanding of what, in fact, man has accomplished in the brief span of human history. There is no key to this knowledge in its full force and significance other than the humanistic disciplines. For the humanist the pageant of history is as much part of reality as the non-human reality investigated by the natural sciences. For the future prospects of mankind it has the tremendous value that it gives him the sense of what man has done and therefore the courage to try to do better. Man in the biological sense is the end-product of a chain of accidents, the passive outcome of a process which he may come to understand but did not in fact control. But his human history is his own creation. In it he can study his mistakes and achievements. It is an infinitely difficult but infinitely rewarding pursuit, and anything that can be done to encourage it is not wasting time and money on frills but getting fully to grips with reality. Nor is there any other means by which man can learn to take his destiny into his hands.

The pitfalls, however, are endless. and there is no lack of false prophets to deceive the elect. Who, for example, would suspect that a biologist so cultivated in the widest sense as Bergson was should nevertheless lead us up the garden path ? But that is just what he did when he took his philosophy of the *élan vital* out of the biological field, in which it had originated, and used it in an attempt to explain some of the most fundamental problems of cultural history. In his *Creative Evolution* the philosophy of the *élan vital*, whether we accept it or not, was a useful hypothesis in the sense that it held together, without violently distorting their true nature, a great chain of biological observations. But Bergson did not stop there. Seduced by the success of his biological theory, he sought to unlock the problems of religion and morals with the same key. He imagined, absolutely gratuitously and without a particle of supporting evidence, that the conception of the *élan vital* was identical with the vision of the great mystics, and that this vision was the true source of progress in morals and religion. The identification is completely without historical foundation. But Bergson, though he could adopt a hare-brained notion, could not write other than brilliantly. The result is that his *Two Sources of Religion and Morality*, having already misled one generation of readers, has now, after a quarter of a century, emerged as a paper-back to mislead a still wider circle. It has, of course, the usual disabling effect of all attempts to explain the human in biological terms. For the *élan vital* is not under human control, and there is absolutely nothing for any follower of Bergson to do in the way of deepening the spirituality of the race except to wait for the unpredictable moment when the *élan vital* will inspire some mystic to utter a new oracle. But if we are ever to build Jerusalem we need some handier weapon which the average man can employ in what must be a co-operative enterprise[7].

By way of summing up let me add only this. I have not forgotten the general title of the series to which I have been privileged to contribute. We were. to discuss the "Common Ground shared by Technology, Science, and Art". Neither do I forget that it is a Technical College that has inaugurated the discussion and invited me to take part in it. This emboldens me to hope that in what I have attempted to do I shall not be misunderstood. I am very much of the opinion, expounded by Sir Eric Ashby in one of his books[8], that it is a function of technology to humanize science. For it is in its technological applications that science is forced to come out of the laboratory and consider the impact of its discoveries on the everyday lives of ordinary men and women. In such a liberal atmosphere I have ventured to interpret the words 'common ground' in my own way. I have hoped to show that it ought to be common ground between us that, in spite of the overwhelming need for science and technology in the world to-day, the humanities have a distinct function. I believe that there is a fundamental aspect of reality, not susceptible of analysis by scientific methods, the understanding of which is the proper business of the humanistic disciplines.

To this sphere of reality, the sphere of human history, the approach is not by way of mathematics and the experimental method. The path is through languages and the study of the masterpieces of art and literature. These disciplines should, in my opinion, even now and in spite of other claims be given vastly increased support. This support should, of course, include facilities for the study of living languages, the knowledge of which is essential in our contracting world. But it must also concern itself with the past, through the study of what are called, perhaps prematurely, the dead languages. For they may be dead, but they will not lie down. For those of us who are heirs of the Western European tradition Hebrew, Greek, and Latin obviously come first. But we must provide also for the languages of the older civilizations of Egypt and Mesopotamia, and for the languages of other continents and civilizations. It has long been recognized as the prerogative of man that he looks before and after. We may, I suggest, be certain that our forward vision will clear when we take the trouble to understand a bit more of our past.

Pulsating Combustion

The Collected Works of F. H. REYNST

Edited by **M. W. THRING,** *Professor of Fuel Technology and Chemical Engineering, University of Sheffield*

The fields of application dealt with in this book are mainly boilers and gas turbines (the latter in particular for aircraft propulsion). In the introduction Reynst's novel contributions to combustion science are enumerated and references to the papers describing the ideas are given. Professor Thring distinguishes eight important new contributions to combustion technology arising from Reynst's work which are developed more or less explicitly in the different papers.

Theory of the Transmission and Processing of Information

A. G. VITUSHKIN *Translation Editor* **A. D. BOOTH,** *Birkbeck College, London*

An important research monograph dealing in a rigorous manner with the estimation of the information content of various problems in tabulation. Translated from the Russian it defines mathematically the concept of the complexity of a tabulation problem (the construction of tables for functions) by using concrete problems as examples.

Theory of the Transmission represents in clear and concise terms the latest Soviet thinking in this field and will be of special importance to all Western workers.

Method of Least Squares and Principles of the Theory of Observation

Yu. V. LINNIK

This important Russian translation work gives an account of the theory of the method of least squares with emphasis on the mathematico-statistical interpretation of the results obtained from the data by this method (which, of course, only has a meaning on the natural assumption that the errors of measurement can be regarded as random quantities). The basic schemes of calculation used in applying the method are also described.

Fundamental Physical Theory and the Concept of Consciousness

JOHAN H. GREIDANUS, *Chief Engineer, Royal Netherlands Aircraft Factory "Fokker"*

This monograph presents an attempt to introduce the concept of consciousness explicitly into fundamental physical theory. The aim is to give this at present extra-physical concept an operationally effective physical status, and to clarify, at least in principle, the relations which exist between displays on the scene of consciousness and processes in its presumed material substrate.

Experimental Correlograms and Fourier Transforms

N. F. BARBER, *Dominion Physical Laboratory, New Zealand*

This authoritative volume reviews the great variety of electrical, mechanical or optical analogue devices that have been invented from time to time for creating further Fourier transforms correlograms and power spectra. The aim is to help the reader in devising a machine to suit his own particular purposes. Fourier theory, including the convolution theorem and the correlogram-power spectrum theory, is also developed. This is done from first principles and from a physical point of view to help the student gain a working knowledge of these ideas.

TRADITION, SCIENCE AND PRACTICE IN DIETETICS

THE third International Congress of Dietetics, organized by the British Dietetic Association and an International Committee of Dietitians, chaired by Miss D. F. Hollingsworth, of the Ministry of Agriculture, Fisheries and Food, was held at Church House, Westminster, London, during July 10–14, under the honorary presidency of Lord Boyd Orr. There were 916 registered members of the Congress from more than forty countries. The purposes of the programme were to place applied nutrition—or dietetics—in a historical setting and to show how dietitians are working throughout the world towards the better nourishment of all people. The programme was designed to allow time for discussion of scientific and of practical problems and for professional visits.

After the formal opening of the Congress by the Mayor of Westminster, Dr. Norman C. Wright, deputy director-general of the Food and Agriculture Organization of the United Nations, spoke on "International Collaboration in the Solution of Problems of Human Diet". He said that primitive man, in common with other animals, learned to procure food from his environment which provided the ingredients needed to ensure survival of the human race, but that with the development of a more complex civilization "this knowledge, acquired by trial and error rather than by scientific experiment, has been increasingly neglected". He traced the growth of international intervention in the problem of inadequate food supplies for the world's rapidly growing population, emphasizing "the vital role of women in ensuring the adequacy of family diets and of the urgent need to improve the status and education of women in . . . [the] less developed countries".

Mr. F. Le Gros Clark (London), in speaking of the "History of Human Diet", underlined the fact that "*Homo sapiens* is the only species whose dietary habits have had any history at all". He postulated that our primitive forebears developed preferences for a thoroughly mixed diet, of foods consumed mainly in their natural state, suited to the primitive mode of life and environment. He emphasized that under primitive conditions there would have been no need to consider the application of nutrition and no place for the dietitian. In his view, "the science of applied nutrition, and with it, the role of the dietitian, are the by-products of a 'civilized' mode of life" and that our task now is "to persuade men and women, whose elementary tastes and food inclinations were built into the species many centuries ago, to match their food habits to a completely changed mode of living".

Speakers from many parts of the world illustrated ways in which traditional food habits have proved to be scientifically sound: the most striking example was, perhaps, that provided by the traditional method in Central America of making tortillas by first soaking maize in lime water and thus making available bound nicotinic acid, a practice which doubtless explains the absence of pellagra in those countries. Many examples were also given of the dangers which follow the introduction of 'civilized' diets to primitive communities: for example, the increase in dental caries among the village children in Fiji and other South Pacific Islands which has followed the introduction to the diet of refined cereals and sugar. More than one speaker with public health experience in developing countries emphasized the prestige value in primitive communities of 'Western' foods and, in many places, the consequent neglect of locally grown foods, which are often of relatively greater nutritional value.

Then followed three and a half days of sessions for discussion and original communications on a variety of topics, including atherosclerosis, diet and ischæmic heart disease, and mother and child, with special reference to protein malnutrition. Other subjects discussed were dietetics and its history, therapeutic diets, feeding older people, survey work, teaching nutrition to nurses, school meals, catering problems and the education and occupations of dietitians.

The two sessions on various aspects of coronary heart disease provided ample opportunity for interchange of opinion and fact. Prof. J. J. Groen and Prof. G. Verdonk and their colleagues in the Netherlands and Belgium presented the results of their work on the influence of nutrition and ways of life on blood cholesterol and the prevalence of atherosclerosis and coronary heart disease among Trappist and Benedictine monks. They showed that the average blood cholesterol was higher among 168 Benedictine monks who lived on a 'Western' diet than among 180 Trappists who were vegetarian. There was more obesity among the Trappists than among the Benedictines, but no difference in prevalence of hypertension, myocardial infarcts, angina pectoris or electrocardiographic signs of ischæmic heart disease. Myocardial infarction appeared to be rarer among both Orders, but the other conditions mentioned occurred to much the same extent as in the general population of the Netherlands and Belgium. The conclusion reached was that the acute occlusion of a major coronary artery, leading to a macroscopic myocardial infarction, seemed to be related not to nutrition and low blood cholesterol, but to psychological factors in the Western ways of life against which monks were protected and that the nature of these factors required further investigation. Hypertension and diffuse ischæmic heart diseases were apparently not prevented by a frugal diet or by a monastic life.

Dr. J. Trémolières (Paris) discussed the many factors concerned in the study of diet and atherosclerosis. He emphasized the importance of obtaining more precise information on the diet, way of life and the cardiovascular condition of individuals. Prof. J. N. Morris and his colleagues from the Medical Research Council Social Medicine Research Unit presented the results of their attempts to devise a method of large-scale individual dietary surveys on middle-aged men, and Prof. G. Verdonk (Ghent) stressed the complexities of lipid metabolism and suggested that 15–20 different biochemical estimations are necessary to study the course of atherosclerosis. He also advanced the clinical opinion that to lower a patient's blood cholesterol-level is to increase his feeling of well-being. Dr. Trémolières concluded that myocardial infarction is more serious among the obese, the anxious, the smokers and those who appear to over-eat for their height and weight, and that a preventive regimen appears to be "une bonne hygiène de vie", without excessive anxiety, and a moderate diet maintaining the individual at slightly reduced weight. He suggested that not more than 35 per cent of the dietary calories should be derived from fats and that the diet should be "sans carence en acid gras essentiels, sans huiles de mais peroxydées et . . . sans trop de fritures". Dr. V. Socolovsky (Moscow) concluded his contribution on the same subject with the advice that one should "eat less and so live longer to eat more in the end". Prof. J. Yudkin (London), in opening the session on diet and cardiac ischæmia, emphasized the uncertainty of present knowledge. The only conclusions to be reached at the end were that more careful observation and painstaking research are required to solve this most complex problem and that, in the meantime, the only possible prescription is moderation of both life and diet.

The present state of our ignorance was also emphasized by Prof. B. S. Platt (London) when he introduced the session on the nutrition of the mother and her child. He then described recent progress in the experimental production of protein malnutrition in animals and new concepts on protein–calorie deficiency diseases, including marasmic kwashiorkor. Miss Margaret Cameron (New Zealand) described recent team work in Prof. Platt's unit to determine the protein values of foods, meals and mixtures as they are eaten by man. The protein value of a diet is affected by the quality of the protein, its concentration, the presence of certain other nutrients in the diet, for example, vitamin B_{12} or magnesium, and the energy value of the diet in relation to the energy needs of the person eating it. It is also affected by the physiological and pathological states of the individual; for example, it changes during growth or lactation and in some illnesses. She described the method of allowing for these factors in the calculation of the protein requirements of a growing child or a pregnant or lactating woman and illustrated ways in which the protein value of the customary diets may be calculated, and where necessary increased, by supplementing or substitution or by reduction of the amount of oil or sugar consumed. She emphasized the care needed to devise acceptable meals, in keeping with the tastes, religious beliefs and cultural patterns of the children and lactating mothers for whom they are intended.

At the final plenary session of the Congress, Mademoiselle Yvonne Serville (Paris) spoke of the means, indirect and direct, of conveying the findings of research on the science of nutrition to the consumer, emphasizing particularly the complexity of the science of nutrition and the need for some training in nutrition for all those concerned with food from production to consumption, and for teachers, particularly of home management and natural sciences.

This was a notable Congress with an admirable combination of discussions on science and practice, which itself was an illustration of the part dietitians can play in the interpretation of scientific findings in the interests of the consumer.

The Proceedings of the third International Congress of Dietetics, under the title *Tradition, Science and Practice in Dietetics*, have been published by Newman Books, Ltd. Copies may be obtained from the British Dietetic Association, 251 Brompton Road, London, S.W.3, or from Newman Books, Ltd., 68 Welbeck Street, London, W.1 (price £3 3*s*., postage paid).

D. F. HOLLINGSWORTH

BARIUM-140 IN NEW ZEALAND RAINWATER

By G. S. McNAUGHTON and R. N. WOODWARD

Department of Scientific and Industrial Research, Lower Hutt, New Zealand

SINCE the testing of nuclear weapons began, attempts have been made to use the resultant fission products as meteorological tracers. A major difficulty has been to know from which series of nuclear tests the radioactivity of any sample has come. One method which has been used to age fission products, and thus to determine in which series of tests they were formed, has been to measure the rate of decay of the gross beta or gamma activity of the sample, and to compare it with observed rates of decay of fission-product samples of known age. In recent years more precise information about sample ages has come from measuring ratios of specific isotopes such as barium-140/strontium-90 and cerium-144/strontium-90, and comparing these ratios with fission ratios for these isotopes formed in different types of fission reactions. An increase in the ratio of shorter- to longer-lived isotopes is indicative of fission products of more recent origin.

In 1958 we decided to try to obtain information relevant to the problem of global air circulation, particularly with respect to the exchange of Northern and Southern Hemisphere stratospheric air, by measuring isotope ratios in rain collected at Lower Hutt, New Zealand (41° S.). In November 1958 we began measuring 28-year strontium-90 and 12·8-day barium-140 in fortnightly accumulated rain samples, and by June 1959 we were determining these isotopes in each rainfall.

Some of the results in this programme have been recorded[1]. In Table 1 are shown the only positive barium-140 depositions obtained up to June 1961. The methods used are being reported elsewhere[2]. The strontium-90 and barium-140 depositions were calculated from the measured activities of their daughter products, 64-hr. yttrium-90 and 40-hr. lanthanum-140. The measured counts, using a low background beta counter with initially type GM-4 counters and later flow-counters, were never greater than 1 c.p.m. and although repeat lanthanum-140 determinations and barium-140 plus lanthanum-140 determinations were carried out, the activities were too small to identify accurately the presence of barium-140 by half-life determinations. It is considered that the samples quoted in Table 1 did contain barium-140. The errors quoted are due to the 90 per cent confidence-level of statistics of counting only.

Reference to measurements reported in ref. 1 will show, in addition to the positive barium-140 values recorded in Table 1, nine samples out of fifty-eight measured in 1959 which showed activities slightly greater than the statistical counting error of measurement. We now believe that these are not real barium-140 results. The first five during January–July were obtained at an early stage of the programme before the routine measurement techniques were completed, and it now appears this apparent activity was

Table 1. Positive Measurements of Barium-140 in New Zealand Rainwater, Lower Hutt, 41° S.: November 1958–June 1961

Sample No.	Dates when collected from to	Rain (in.)	Strontium-90 μc./square mile	Barium-140 μc./square mile at mid-collection	Barium-140 / Strontium-90	Probable source of barium-140	Per cent strontium-90 due to French test
	1958 (2 samples) November 7–December 4						
	1959 (58 samples) January 15–December 1						
	1960 (24 samples) February 13–May 31					1960	
B 044	February 13–February 19	0·2	28 ± 1	2·5 ± 1·2	0·1 ± 0·05	February 13	0·005
B 069	March 9–March 12	1·53	57 ± 1	5 ± 3	0·1 ± 0·06	February 13	0·02
B 072	March 12–March 16	0·23	17 ± 1	5 ± 1·5	0·3 ± 0·1	February 13	0·07
B 085	March 25–March 26	0·25	20 ± 1	3 ± 1·5	0·15 ± 0·1	February 13	0·06
B 122	May 1–May 3	0·13	19 ± 2	11 ± 4	0·6 ± 0·2	April 1	0·12
	1961 (13 samples) January 7–June 1						
C 024	January 24–January 31	0·08	21 ± 1	2·4 ± 1·3	0·12 ± 0·06	December 23	0·03

probably yttrium-90 not lanthanum-140. The other four apparent activities in September/October 1959 were due to the use of an incorrect reagent blank.

During early 1959 the accuracy of our barium-140 determinations was about ± 100 μc./square mile, but this was reduced to about 1–2 μc./square mile by 1961. From the limits of detection of barium-140, the measured values of strontium-90 deposited, and a value of 1480/1 for the barium-140/strontium-90 ratio[3] for the fast neutron fission of uranium-238, the maximum percentage deposition of strontium-90 due to the October 1958 test programme of the Soviet Union can be calculated. These values are compared in Table 2 with the maximum percentage strontium-90 deposited due to this series calculated from measurements of total beta activity which will be published shortly. The percentage contributions quoted here are maximum values; it has not been demonstrated that any strontium-90 is in fact due to this series. Table 2 shows that the percentage contribution of strontium-90 from the October 1958 series of the Soviet Union detectable by our methods increases as the barium-140 decays until after about March 1959 it was no longer possible to detect an influx of debris from this source. The limits of detection for this debris based on total beta activity measurements assumed all the activity came from the series of tests in the Soviet Union. However, age estimates based on rates of decay of the total beta activity of monthly rain samples suggest an influx of fresh debris from about March 1959 at least until our measurements ceased in June 1959. Although this fresher debris could originate in the Soviet Union, it is not possible to rule out entirely the last tests in the Pacific area. Results for total beta activity suggest that the October series of tests in the Soviet Union did not contribute more than 4 per cent of the total strontium-90 deposited at Lower Hutt from November 1958 until June 1959, assuming fast neutron fission of uranium-238.

Table 2. Maximum Percentage Contribution to Fall-out in New Zealand of the October 1958 Series of Tests in the Soviet Union

Sample collection	Calculated from	
	Barium-140/strontium-90	Total β/strontium-90
1958		
November	0·2	0·3
December	3	13
1959		
January	8	3
February	32	8
March	80	1·6
April		10
May		3
June		12

During 1960–61 six positive barium-140 results were found which we believe to be reliable. These results were obtained in the six-week period after the French test on February 13, 1960, and also approximately four weeks after each of the French tests on April 1 and December 23, 1960. If we assume that the fission/yield activity ratio of barium-140/strontium-90 for the fast fission of plutonium-239 is 1820/1 (calculated from ref. 3) then the French contribution to the measured strontium-90 deposited can be found. This is shown in Table 1 for individual rains and has never been found greater than 0·12 per cent. It seems reasonable that this amount of strontium-90 could have arrived at Lower Hutt through the troposphere from the Sahara tests.

OBITUARY

Prof. E. H. Neville

Eric Harold Neville, who died on August 21 aged seventy-two, was educated at William Ellis School where he came under the influence of Percy Nunn, who clearly stimulated in him an innate feeling for mathematics. In 1907 he went up as a senior scholar to Trinity College, Cambridge. It had then been announced that publication of the Mathematical Tripos lists in order of merit would cease with the lists for 1909; this challenged Neville to sit the examination a year earlier than normal, and he was placed second wrangler in 1909. Two years later he won the Smith's Prize and was elected into a fellowship at Trinity, which he held until 1917.

In 1919 he was appointed to the chair of mathematics in University College (now the University) of Reading, which he occupied until his retirement in 1954. He married Alice Farnfield in 1913, who predeceased him in 1956; they had one son who died in infancy.

At the beginning of 1914, while giving a course of lectures in India, he was charged by G. H. Hardy with the task of persuading the Indian mathematician Ramanujan to come to Cambridge. The account of this mission which he gave nearly thirty years later (*Nature*, 149, 292; 1942) is witness to the satisfaction he derived from the successful completion of this task.

His earliest work was in geometry. In *Prolegomena to Analytical Geometry* and *Multilinear Functions of Direction* he was clearing the ground for a treatment of the whole field of differential geometry based on secure logical foundations. Unfortunately, the breadth of his interests led him to undertake other tasks and the work was never completed.

The need to organize the teaching of undergraduates drew his attention to the unsatisfactory foundations of much basic mathematical instruction and he threw himself enthusiastically into the work of the Mathematical Association. With Percy Nunn he was largely responsible for the Association's first *Report on the Teaching of Geometry*. He became librarian of the Association in 1923 and in the course of thirty years he transformed the library from a small collection which could be accommodated in his own house to the valuable reference library for teachers now housed with the University of Leicester. He was president of the Mathematical Association in 1934. He was interested in the work of the British Association, principally in connexion with the Tables Committee, of which he was chairman during 1931–47. He compiled the *Table of the Farey Series of Order 1025* and the *Rectangular to Polar Conversion Tables*. His prefaces to these works contain much that is of interest to anyone contemplating the compilation or printing of mathematical tables. He was a member of the Council of the British Association and, in 1950, president of Section A. He also served on the Council and as vice-president of the London Mathematical Society.

Out of his concern for the improvement of the teaching of pure mathematics arose a number of notes on a wide variety of topics, characterized by freshness of point of view, elegance and economy of presentation. A more ambitious work directed towards the same end was his book on *Jacobian Elliptic Functions*, designed to restore the original beauty and symmetry to a field that had tended to become somewhat unwieldy.

Neville was a man of considerable moral and physical courage—he once rescued a child from the flooded Cam in midwinter. He was essentially a liberal humanist. His love and knowledge of literature matched his interest in the history of mathematics. He was a devoted bibliophile, and it is characteristic that his private library contained not only early editions of all the works of Lewis Carroll and H. G. Wells, but also what is believed to be the most complete set of works on elliptic functions.

R. RADO

NEWS and VIEWS

Textile Engineering at Leeds: Prof. P. Grosberg

ALTHOUGH the wool-textile industry is so highly mechanized, graduates in engineering have so far taken little interest in the construction and use of textile machinery, and have largely neglected the opportunities that all sections of the industry provide. There is here a serious threat to the future of the wool-textile industry of the United Kingdom, and the machinery-users showed commendable foresight in endowing a research chair of textile engineering at Leeds some twelve years ago. The first occupant of the chair, Prof. A. H. Nissan, left to take up an appointment in the United States, and he is now to be succeeded by Dr. P. Grosberg, who brings to the post qualifications in pure science, engineering and textile technology. Dr. Grosberg was born in Cape Town in 1925. After graduation in physics and mathematics, and in chemical engineering at the University of the Witwatersrand, he carried out research on thin film lubrication for the degrees of M.Sc.(Mech.Eng.) and Ph.D.(Eng.). On being appointed to the staff of the newly formed South African Wool Textile Research Institute in 1950, he was seconded to the Department of Textile Industries of the University of Leeds for a two-year course of advanced training in textile technology. After a period of some four years research on worsted drawing and spinning processes in South Africa, Dr. Grosberg returned to Leeds as an Imperial Chemical Industries Fellow in textile engineering, and he was appointed lecturer in textile engineering in 1956. His subsequent investigations, in which he has had the assistance of a number of Wool Textile Research Council Fellows, have already secured for him a reputation in such widely different fields as worsted drawing and spinning, warp-knitting, and drying processes. He is now to have the stimulating task of placing the subject of textile engineering on a sound foundation in the University, and of providing the textile industry with the engineers of which it stands in such great need.

The National Bureau of Standards: Dr. H. C. Allen

DR. HARRY C. ALLEN, jun., has been appointed chief of the Analytical and Inorganic Chemistry Division at the National Bureau of Standards, U.S. Department of Commerce, Washington, D.C. He will direct a broad programme aimed at developing methods for measuring the chemical properties, composition, and behaviour of substances; preparing standard reference materials; and making accurate measurements and data collections on chemical systems. Since 1954, Dr. Allen has been working at the Bureau on the analysis of high-resolution infrared spectra of gases, and the theory of molecular spectra. He spent the year 1959–60 in the Department of Theoretical Chemistry, University of Cambridge. Before becoming a staff member of the Bureau, Dr. Allen was an assistant professor of physics in Michigan State College. He has also been a consultant to the Bureau.

World Population Trends

THE 1960 edition of the *Demographic Yearbook* of the United Nations Organization has as its special feature an analysis of the evolution of the population of various countries, and includes a table showing the populations of each political area in every year since 1920 (Pp. xi+621. New York: United Nations; London: H.M.S.O., 1961). The first chapter entitled "How Well Do We Know the Present Size and Trend of the World's Population?" gives a valuable account of the methods used in preparing population statistics by the United Nations Organization. It is perhaps not always realized that approximately one-half of the world's population is now concentrated in four countries: China, India, the U.S.S.R. and the United States. The Organization assesses the accuracy of the 1953 census for China and suggests that the number of inhabitants of mainland China in that year was between 553 and 612 millions, and in mid-1959 between 605 and 697 millions. This is the population about which there is the maximum degree of uncertainty, India's population is known within 11 millions, and that of the two others within 3 millions. As regards the other areas of the world, it is believed that in most estimates there is a tendency to underestimate rather than overestimate populations, though some errors will no doubt be self-compensating between different territories. Their population is estimated as being between 1,431 and 1,476 millions; the four large areas have populations between 1,416 and 1,508 millions. The world's population in 1959 is believed to be between 2,853 and 2,964 millions, so it is evident that the uncertainty about China is the major factor in the range. The demographers of the United Nations Organization estimate that the annual rate of growth may lie between 1·5 and 2 per cent per annum, resulting in a total annual increase of 44–55 million persons. Tables in the *Yearbook* include data about the economically active and the illiterate population of different countries, as well as vital statistics dealing with births, marriages and deaths. The rudimentary data on expectation of life in African countries indicate the tremendous scope for mortality reduction that still exists in that continent.

Population Statistics in the United Kingdom

THE Registrar General's Statistical Return for the first quarter of 1961 records nearly 204,000 live births, the highest figure for the first (or any) quarter for more than ten years (No. 449. Pp. 28. London: H.M.S.O., 1961. 2*s*. 6*d*. net). Marriages, on the other hand, are fewer at 84,000, compared with 89,000 a year ago. There were 177,000 deaths, giving a relatively high crude death-rate of 15·7, but infant mortality continues to decline, and at 22·9 per thousand births is an all-time low for a first quarter. It will be interesting to see whether the declining trend in the number of marriages will continue, and be followed by a decline in births. The return contains, as is usual in the first quarter, estimates of the home population of administrative counties, boroughs and urban districts at June 30, 1960, together with vital statistics for these areas. In 1960 there were only 22 deaths from poliomyelitis: the lowest number since records began to be kept.

Technical Reports of the U.S. Armed Forces

SINCE the Second World War, the Office of Technical Services had been the agent in the Federal Government for the collection, reproduction and sale of reports of Government-sponsored research to firms and organizations not performing contract work for the Department of Defense. The Armed Services Technical Information Agency is the central agency of the Department of Defense, the mission of which is to provide for the efficient interchange of military research and development reports among Department of Defense agencies and their contractors. The number of technical reports of research and development sponsored by the Army, Navy, and Air Force which are made available to the scientific and industrial public is expected to double next year through an extension of the co-operative activities of the Office and the Agency. With the growing volume of Government-sponsored research, the extension of the co-operative work between the Office and the Agency will enable the Office to offer to the public in the next fiscal year 15,000–20,000 technical reports, prepared under military auspices. The Armed Services Technical Information Agency acquires and catalogues almost 30,000 military technical reports each year—about two-thirds of them unclassified. Under the new co-operative programme, the Agency will provide copies of the unclassified reports to the Office, together with catalogue information. A further use of work already carried out by the Agency will be made in the production of the Office's periodical *U.S. Government Research Reports*, which is used as an announcement medium to inform civilian scientists, engineers, and business men of new reports which are available. The unclassified portion of the Agency's *Technical Abstract Bulletin* which, so far, has been produced only for activities directly concerned with military research and development, will become a section of the *U.S. Government Research Reports*, which, from July 1961, will be published twice a month instead of once a month as in the past. Details of the new programme are outlined in the June–July issue of *Scientific Information Notes* (3, No. 3; June–July, 1961).

The National Lending Library

A RECENT issue of *N.L.L. News*, a news-sheet of the National Lending Library for Science and Technology, indicates broadly the types of literature now available from Boston Spa (No. 1; August 1961. Pp. 4. Boston Spa: National Lending Library for Science and Technology, Department of Scientific and Industrial Research, 1961). These include translations of Russian literature, including 'cover-to-cover' translations; Russian books; the 'PB' reports issued by the Office of Technical Services of the U.S. Department of Commerce; the published reports on German industry produced by the British Intelligence Objectives Sub-Committee, the Combined Intelligence Objectives Sub-Committee and the Field Information Agency Technical (U.S.A.); and certain frequently used periodicals in English which were on a list issued from Stanmore. Loan requests for English language serials and books in languages other than Russian should continue to be sent to the Science Museum Library. With the exceptions indicated above, the National Lending Library is not yet providing a general loan service for publications in the English language, but it is expected that in about twelve months time the man-power problems will have been solved and the transfer from the Science Museum Library completed. It is then proposed to make a full-scale survey of the National Lending Library's use, non-use, and of its failures to meet requests with the view of improving its services and promoting the greater use of scientific literature.

The Use of Scientific Literature

THE *Library Association Record* for August 1961 contains an article on "The Use of Scientific Literature", by B. C. Vickery, which is of some scientific interest. Mr. Vickery summarizes, with a useful bibliography and some account of the methods of study which have been used, the kinds of information sought by scientists, the extent and nature of their reading and the forms of document used. The survey shows that the quantitative contribution to the reading and learning of scientists made by formal bibliographical tools is equalled by the contributions of present-day scanning, cited references, and of oral recommendations. Mr. Vickery recognizes, too, the importance of oral communication, but he indicates rather than discusses the implications of such conclusions as are reached, and emphasizes the need for further research on ways of improving the present position. A second article in the same issue, by W. L. Emerson, discusses an approach to book selection in the sciences for public libraries.

The Geological Society of India

IN January 1959 the Geological Society of India was founded to promote the advancement of geological study and research throughout all India and to co-operate with similar institutions in other lands. One of the aims of the new Society is the publication of a journal, and of monographs and memoirs, dealing with special problems of Indian geology; and the first two volumes from this source have now appeared (*Journal of the Geological Society of India*, Vol. 1, 1959. Pp. 166+6 plates. Bangalore: Geological Society of India, 1959. Rs. 15). This periodical embraces the whole field of geological science, the first two issues comprising 25 short papers mostly of a high standard with many of world-wide interest. In the first presidential address, Dr. D. N. Wadia deals with "The Evolution of the Desert Belt of Asia", delineating briefly, but brilliantly, the overall geological problems of the vast arid tracts which stretch from the Red Sea to Mongolia. Within the past decade the number of geologists in India has increased greatly, and the potential importance of the geological contribution to national development there is becoming widely recognized. The Geological Society of India is likely to play a major part in maintaining the long-established tradition of sound work, and its publications will be warmly welcomed in geological libraries throughout the world.

Atomic Energy-levels in Crystals

Atomic Energy Levels in Crystals, by J. L. Prather, National Bureau of Standards Monograph No. 19, which was issued on February 24, presents a theoretical study of the sharp-line absorption spectra of crystals (National Bureau of Standards. Monograph No. 19. Pp. iv+84. Washington, D.C.: Government Printing Office, 1961. 60 cents). It is largely an exhaustive collection of the results of group theory that apply to the theory of atomic energy-levels in crystals, together with a detailed development of the general theory to permit application of the results to experimental problems. The discrete energy-levels observed within certain crystals are treated as being due to perturbations of the energy-levels of the free ion by an electrostatic field arising from the crystal lattice. The analytic procedures for determining the field from the charge configuration are given, and the resulting fields are classified according to their symmetry. After a general survey of group-theoretical ideas, the applicable groups are analysed in detail, and characters appropriate for both integral and half-integral angular momenta of the free ion are tabulated. The monograph contains eighteen tables and an extensive bibliography. The review on the general subject entitled "Group Theory and Crystal Field Theory", written by Dr. C. M. Herzfeld in collaboration with Prof. P. H. Meijer, which is to be published shortly by the National Bureau of Standards, Washington, treats the subject from the more abstract point of view of modern algebra and concentrates on the fundamental aspects of the theory, and will be a complementary work to that of the monograph.

Travelling-wave Tubes

THE travelling-wave tube is rapidly becoming established as an essential component in microwave links used for civil communications. It is a microwave amplifier that operates on the principle of a continuous interaction between the input signal and an electron beam as they travel together through the tube, and is particularly suitable for operation at frequencies greater than 1,000 Mc./s. It has a broad band-width and high gain. An outline of the construction, characteristics, operation and typical applications of the travelling-wave tube is given in the illustrated booklet, *Travelling Wave Tubes : Their Characteristics and Operation*, issued by the English Electric Valve Co., Ltd. (Pp. 40. Chelmsford: English Electric Valve Co., Ltd., 1961). Following a general description of the tube and its associated circuitry, explained by means of a simplified schematic diagram, the booklet discusses the various types of travelling-wave tubes now commercially available. They can be classified according to their functions into three major groups—power tubes, medium power or intermediate tubes, and low-noise tubes—and these can be subdivided, according to the type of *rf* connexion used, into either wave-guide or coaxial mounting types. All the travelling-wave tubes produced by the English Electric Valve Co., Ltd., require a longitudinal magnetic focusing field for maintaining the electron stream in a concentrated beam over the length of the tube. One section of the booklet deals with focus systems for the tubes, and another with the procedure to be followed in the installation of a tube into a circuit. In addition to the use of travelling-wave tubes as microwave amplifiers in both terminal and repeater stations in communication links, the low-noise tube is being increasingly used in the input stage of radar receivers as a pre-amplifier to the crystal mixer, and travelling-wave tubes may also be used as amplitude or phase modulators, frequency changers, stable oscillators or reflex amplifiers. The booklet is intended as an introduction only to the subject of travelling-wave amplification, and for those who want a more detailed treatment a bibliography of sixteen references is provided. The abridged data listed refer to the English Electric tubes and solenoids.

Lalor Grants and Awards for 1961

THE Lalor Foundation has announced the programme of awards for 1962, which it is offering for support of research on the fundamental biochemical and physiological mechanisms concerned with fertility and the early stages of reproduction in various forms of life. The objectives are to further the knowledge and understanding of the basic phenomena involved and to extend and develop the possibilities for effective regulation and control. The awards are open to all nationalities. The awards may range up to 8,000 dollars a year, depending on the scope and duration of the projects approved. Preference will be given to younger members of university and college faculties and staff with an upper age limit of forty-one years. The work may be carried on at the applicant's own institution or elsewhere. The Foundation will also grant post-doctorate summer or short-term research awards at the Marine Biological Laboratory at Woods Hole, Mass., or elsewhere, for appropriate projects in the fields specified. For these awards, the stipends will normally not exceed 1,000 dollars for a single man or a woman, 1,200 dollars for a married man working at his home institution, and 1,350 dollars for a married man with principal programme at another institution. Applications and inquiries should be sent to the Lalor Foundation, 4400 Lancaster Pike, Wilmington 5, Delaware, and applications must be received by January 15, 1962.

The Bowles Memorial Travel Scholarship

During 1962–63, £500 will be made available to enable a scholar to travel abroad to collect plants for introduction to British gardens, and/or to study practical horticulture in other countries. Applicants must be male, not more than twenty-eight years of age on January 1, 1962, and be holders of the National Diploma of Horticulture, or students or graduates in horticulture or botany at a British university, or past or present student gardeners at the University Botanic Garden, Cambridge, the Royal Botanic Garden, Edinburgh, the Royal Botanic Gardens, Kew, the Royal Horticultural Society's Gardens, Wisley, or other horticultural educational establishments. Applications should reach the Secretary, Royal Horticultural Society, Vincent Square, London, S.W.1, not later than November 20.

The Royal College of Science and Technology, Glasgow

An endowment of £800 has recently been made to the Royal College of Science and Technology, Glasgow, by Mrs. Hilda M. Beilby, of Darlington, Co. Durham, daughter-in-law of Sir George Beilby (who for sixteen years was chairman of the governing body) and grand-niece of Lord Kelvin. The endowment will be known as the Kelvin Prizes, and it will be used to provide awards in the subjects of natural philosophy and applied mathematics. Thus, in conjunction with the endowment made recently by Lord Fleck to commemorate the work of Sir George Beilby, the College is now able to offer awards in mathematics, natural philosophy, metallurgy and chemical technology.

University News: London

The following appointments have been announced: J. P. Quilliam, reader in pharmacology at St. Bartholomew's Hospital Medical College, to the chair of pharmacology tenable at that College; Dr. S. J. Taylor, lecturer in the Department of Pure Mathematics, University of Birmingham, to the University readership in mathematics tenable at Westfield College.

The title of professor of electrical engineering in the University of London has been conferred on Dr. J. H. Westcott, in respect of his post at the Imperial College of Science and Technology.

The following readerships, tenable at the Imperial College of Science and Technology, have been announced: Dr. J. R. Butler (pure geochemistry); Dr. C. B. Alcock (chemical metallurgy); Dr. J. N. Hunt (physical oceanography); Dr. J. A. Kitchener (mineral processing). Mr. J. C. G. Coleridge, lecturer in the University of Leeds, has been appointed as reader in physiology tenable at the Royal Free Hospital School of Medicine. Prof. J. N. Phillips Davies, professor of pathology at Makerere College, has been appointed as reader in morbid anatomy at the Postgraduate Medical School.

Sussex

The following appointments have recently been made: Dr. C. Eaborn, reader in physical-organic chemistry in the University of Leicester, to be professor of chemistry; Dr. R. J. Blin-Stoyle, Fellow and lecturer in physics at Wadham College, Oxford, and senior research officer in theoretical physics in the University of Oxford, to be professor of theoretical physics; Dr. K. F. Smith, Fellow of Sidney Sussex College, Cambridge, and lecturer in physics in the University of Cambridge, to be professor of experimental physics.

Announcements

The Department of Chemical Technology, Bradford Institute of Technology, is organizing a special short course on "Recent Developments in the Chemistry and Technology of Polymers" at the Institute during November 17–18. The fee for the course is £2 5*s*., and further information can be obtained from the Registrar, Institute of Technology, Bradford 7.

The Institute of Physics and the Physical Society announces a symposium on "High Energy Nuclear Physics", to be held in the Physics Department of the Imperial College of Science and Technology, during March 26–27, 1962. Further details can be obtained from the Administration Assistant of the Institute and Society, 47 Belgrave Square, London, S.W.1, during December 1961.

A symposium on "Redundancy Techniques for Computing Systems" will be held during February 6–7, 1962, in the Department of the Interior Auditorium, *C* Street, between 18th and 19th Street, N.W., Washington, D.C. The symposium is being sponsored by the Information Systems Branch, Office of Naval Research. Further information can be obtained from Miss Josephine Leno, Code 430*A*, Office of Naval Research, Washington 25, D.C.

An international symposium on "Enzymic Activity of the Central Nervous System" will take place in Gothenburg, Sweden, during June 18–21, 1962, under the auspices of the Neurochemical Commission of the World Federation of Neurology. Further information can be obtained from the secretaries: Dr. G. B. Ansell, Department of Experimental Psychiatry, Medical School, Birmingham 15, and Dr. A. Lowenthal, Institut Bunge, 59 Rue Philippe Williot, Berchem-Antwerp, Belgium.

Erratum. In the issue of *Nature* for September 16, p. 1142, it is announced that Dr. J. E. Stanworth is to succeed Mr. L. J. Davies. It was not made clear that Dr. Stanworth succeeds Mr. Davies as director of research of Associated Electrical Industries (Rugby), Ltd., Laboratories.

THE INTERNATIONAL MEASUREMENT CONFERENCE

THE second International Measurement Conference was held in the Engineering Societies Building, Budapest, during June 26–July 1. The host organization was again the Hungarian Scientific Society for Measurement and Automation, with Prof. György Striker as executive secretary.

The Conference was attended by some 550 delegates from twenty-two countries and 128 papers were presented in four, or sometimes five, simultaneous sessions. The four working languages of the Conference were English, French, German and Russian; but in fact no translation into French was available and for the first three days translation into English was practically non-existent. This breakdown in the translation service, coupled with the failure to provide reprints of the papers until the final day of the sessions, seriously reduced the value of the Conference.

The 128 papers were divided into eleven sections covering metrology and terminology; technology and organization in instrument manufacture, electronic measuring instruments, border questions related to measurement and automation, instruments and methods for measuring geometrical and mechanical quantities including geodetic measurements, instruments and methods for measuring thermal quantities, instruments and methods for physico-chemical measurements, instruments and methods for measuring electrical and magnetic quantities, instruments and measuring methods in radio engineering and instruments and methods for measuring radioactive radiation. Since papers from four different sections were presented concurrently, it was impossible for any one person with more than the most narrow field of research to attend all the papers in which he was interested.

The standard of the papers varied considerably from the specific to the most general survey and from new basic research to the re-statement of well-known principles: a reduction in number would have benefited all concerned.

Among the papers of general interest, that by T. Kemény (Hungary) described an automatic electronic potentiometer in which the conventional slide-wire had been replaced by a strain-gauge bridge. The four, all active, gauges of the bridge are attached in the standard configuration to a singly supported cantilever beam of low-energy-consuming elastic material. The free end of the beam is deflected by a cam driven through a gear train by the servo motor driving the pen carriage, until the out-of-balance voltage generated by the bridge is equal to the voltage being measured. Advantages claimed are no slide-wire maintenance or wear, high linearity and infinite resolution, and ease of generation of logarithmic and other non-linear scales merely by changing the cam. Other transducers, such as electromagnetic, capacitative and inductive, were suggested, but only the strain gauge bridge has been tried experimentally.

A method for measuring small capacities of about 100 pF., with an accuracy of 1 per cent, was presented by K. Tarnay (Hungary). The method is said to combine the advantages of both heterodyne and resonance methods. Essentially, the unknown capacity and a standard are switched, at mains frequency, alternately into an oscillatory circuit, the output being fed to a phase-sensitive rectifier and thence to a phase-sensitive voltmeter.

A paper by three Soviet authors dealt with a new instrument for the accurate measurement of power, current and voltage at frequencies up to 20 kc./s. A null method is employed in which the unknown alternating current or voltage is used to heat a resistance element, the temperature of which is monitored by a detector element consisting of a bank of some 35–40 thermocouples in series. The thermal e.m.f. is measured by means of a potentiometer and a direct-current voltage is then switched in in place of the unknown alternating current and is adjusted to give the same heating effect as measured by the potentiometer. The equivalent direct-current voltage is then measured by means of a second potentiometer of high accuracy. Good accuracy is obtained with power factors as low as 0·1 by using two heaters. The main source of error is said to be the reactance of the heater elements and shunts in the circuit, and this limits the frequency range. The overall error in comparison of alternating and direct current is less than 0·05–0·2 per cent, depending on range.

Prof. Gy. Striker (Hungary) discussed the possibilities of a long-range planning of instrumentation in a planned economy and suggested that the basic data required were the expected trend in capital investment in the respective industries and the index of instrumentation, that is, the ratio of instrument investment to capital investment and the expected changes in this index. Examples were given of how these factors may be fitted to equations to predict instrument requirements for a longer period.

An electronic statistical quality control apparatus which indicates average and variance directly was discussed by A. Ambrózi (Hungary). The method requires that the parameter to be controlled may be presented by means of a suitable transducer as a proportional alternating current. A batch of components is fed into the unit and the corresponding alternating-current signals are fed to a simple computer which then indicates the mean and the variance on meters, the chief advantage being the speed with which the required data can be obtained.

Two papers on measuring systems for flight testing of aircraft by J. K. Stotz and V. R. Boulton (United States) both stressed that main expenditure was the cost of data reduction which could take up to ¾ man-hr. per point. Strain gauge transducers are used wherever possible because of their inherent accuracy—0·1 per cent—and because they enable standardization of supply voltages and amplifiers as well as being easily calibrated by electrical simulation before and after a test. Recording is by magnetic tape either airborne or ground station, and overall system accuracies of 1–3 per cent may be obtained. Typical recorders have a band-width up to 90 kc./s. at a tape speed of 60 in./sec. Frequency multiplexing is used, up to 10 channels per tape track being common, while for low-frequency data, time division multiplexing at a rate of 900 samples/sec. is used. Such attention to the design of instrumentation and data handling equipment has reduced the data reduction cost by a factor of 4, produced 100 times as much data, which are four times more accurate, and are available for analysis in 1/15 of the time.

S. G. Rabinovitch, B. A. Seliber and V. I. Tchervyakova (U.S.S.R.) presented details of electrical measuring-instruments based on the photo-compensating amplifier. These included multi-range measuring units with a sensitivity up to 5×10^7 divisions per volt, panel amplifiers with 0·1 per cent accuracy and semi-automatic potentiometers, with an accuracy of 0·03 per cent, for instrument checking, etc.

B. Sternlicht (United States) described an indirect but extremely accurate method for measuring film thickness on bearings. He pointed out that there is a direct correlation between film thickness and temperature and he has used temperature-sensing elements for the measurement of the film thickness as well as the film temperature.

A novel technique for re-using resistance strain gauges was put forward by A. Bray (Italy). He pointed out that gauge factors cannot be given to an accuracy better than about ± 1·5 per cent, yet in many applications it is not possible to calibrate the gauge after it has been attached to the surface under test. The method entails using a second carrier of mica between the gauge and the test surface. The author used Eastman 910 cement, but it should be remembered that this is water-soluble. After the gauge has been used it may be recovered by splitting the mica. Experience has shown that the thickness of the mica must not be greater than 0·03 mm., and it must be about 6 mm. larger than the paper or foil base of the gauge. The mica will support 4,000 microstrain, and gauges have maintained a constant gauge-factor while being used and recovered four or five times.

T. M. Dauphinee presented the paper by Dauphinee, Kirby and Preston-Thomas (Canada) on the accurate measurement of temperature and depth in the ocean. Temperature was measured by means of a bifilar-wound copper-resistance thermometer cemented on to a thin-walled copper tube to give close thermal contact with the sea-water; accuracies of ± 0·01 per cent to depths of several kilometres have been achieved, as have accuracies of 0·2 per cent in depth measurement. Two methods were used for measuring depth, the sensing element of one being the bulb of a commercial mercury-in-glass regulator, change in depth being measured by the lowering of the control temperature that results from reduction in volume of the bulb due to the increase in pressure. The second method uses a water boiling-point apparatus with a thermocouple to measure the boiling temperature. An interesting planetary type of slip-ring was used to enable the cable to be wound on a drum winch. This consists of a copper stator and rotor, electrical connexion between the two being maintained by four hollow cylinders of thin spring bronze acting as planet wheels. The system was said to have thermal e.m.f.'s of less than 0·1 μV. and resistance variations of less than 0·01 ohm.

T. A. Perls (United States) described the use of pyroelectric transducers for heat-transfer measurements. A typical transducer of lead zirconate titanate 0·25 cm. in diameter and 0·05 cm. thick has a heat sensitivity of approximately 10 mV./W./cm.^{2} with a 1 M.ohm load. At present it is necessary to calibrate the transducers if accuracies to better than ± 20 per cent are required: a quartz lamp in a gold-plated reflector has proved satisfactory for this purpose, over the range 100–0·1 W./cm.^{2}. Advantages of pyro-electric transducers suggested include small size, low cost, good frequency response, high output, good linearity and ageing, and little sensitivity to temperature.

Dr. Cz. Graczyk (Poland) presented an account of a new method of measuring rate of flow of coal dust. The method is based on the application of a Venturi tube; two pressure drops are measured and it was shown that the dust concentration may be represented as a function of the ratio of the two pressure drops.

The measurement of dynamic flow by means of hot-wire anemometers of the constant-current and constant-temperature type were discussed by I. Kidron (Denmark), who pointed out the superiority of the constant-temperature type which will operate at frequencies several hundred times higher than a constant-current unit because of the reduced effect of the heat capacitance of the wire. The upper frequency limit increases with flow speed and is higher than 50 kc./s. at 100 m./sec. air speed. Kidron then discussed a newly developed hot-film transducer consisting of a thin platinum film fused to a glass support to give greater mechanical strength. The dynamic response is slowed by the heat capacitance of the glass support, but is still only 5 db. down at 50 kc./s. for 100 m./sec. air speed.

A novel bi-parametric displacement transducer with good frequency response and high sensitivity was described by Prof. N. Racoveanu (Rumania). The transducer consists of a magnetic core coil with a variable air-gap and also a condenser with variable plate-spacing. In use both coil air-gap and plate-spacing are varied together, modulating the frequency of a resonant circuit in a more linear manner than may be obtained by varying inductance or capacity alone. Designs with a plate condenser and a cylindrical condenser have been examined and a design with multiple concentric cylinders offers greatest linearity. Over the linear range of 2,000μ a sensitivity of 0·25 kc./μ is obtained in the frequency-range 370–870 kc./s.

A. Haas (Hungary), in his paper on the calibration of contact type surface thermometers, stressed the need for intimate contact between the detector and the surface under investigation and complete thermal-equilibrium between the detector, the surface and the surrounding atmosphere. The ultimate aim was 100 per cent thermal coupling, as was achieved by the immersion technique with the ordinary mercury-in-glass thermometer. He then discussed a detector consisting of a thermocouple junction set in a copper block which had been developed at his Research Institute, and which is capable of accurate results with only 60 per cent thermal coupling, and in spite of varying ambient temperature. Another surface pyrometer with an accuracy of 1 per cent was described; this consisted of two iron constantan couples separated by a layer of mica and connected in opposition across a sensitive galvanometer. A heating element above the second couple enables conduction and convection losses to be compensated. The instrument is calibrated against a third couple set into the calibrating surface. It was emphasized that during calibration it was necessary to ensure that thermal coupling should be the same as would be met in use, and thus for calibrating a surface pyrometer for use on rotating drying cylinders, a special calibrating surface was designed. This cylinder was oil heated and thermostatted, and its circumferential speed was set so that approximate thermal similarity with practical conditions may be achieved for a small area of the surface and the atmosphere surrounding the pyrometer. The cylinder has a Ward Leonard speed control and built-in thermocouples brought out via slip-rings so that the true calibration surface temperature is obtained.

Some ninety-five scientific institutions and manufacturing companies exhibited at the second International Instruments and Measurement Exhibition, which was held concurrently with the conference. The usefulness of the exhibition was reduced considerably by the lack of stand attendants and absence of literature on some stands. It was generally agreed by competent observers that nothing was shown by Eastern European countries which was in advance of equipment available in the West, and in many cases development in the former appeared to be 5–10 years behind the West. No Russian equipment was shown. Among Western exhibitors, emphasis was mainly on process instrumentation and control, particularly for the chemical industry, and on radiation counters of all types, while the Eastern countries exhibited more laboratory measuring equipment and in particular microwave equipment in the 8–10 cm. band for telephone and television uses.

Equipment exhibited by the Hungarian Measuring Instrument Research Institute included a six-channel transistorized amplifier for pressure pick-ups, strain gauges, thermistors, etc., with an input impedance of 10^{12} ohms and an output impedance of 1 ohm, with a frequency-range of direct current to 5 kc./s., and better than 5 per cent linearity. A transistorized servo amplifier measuring 6 × 6 × 20 cm. contained a two-stage pre-amplifier and a class *B* push–pull power amplifier stage, with an output capacity of 12 W. and working temperature range of -40–$+50°$ C. Other transistorized modular blocks of the same dimensions included current and voltage amplifiers, 400 c./s. RC oscillators, a direct-current amplifier with a gain of 100 and a non-contacting relay which was basically an inductive pick-off from a moving pointer unit, with a sensitivity of ± 0·5 mm. pointer movement and a switching capacity of 500 m.amp. at 50 V. supply.

A self-compensating ionization vacuum gauge on show was a transistorized miniaturized version of the Modion gauge and covered the range 10^{-8}–10^{-3} mm. in a single span. A differential β-ray thickness meter suitable for measuring coating weights of paper or impregnation weights of fabric had an accuracy of 1 per cent for an impregnant weight-range of 0·5 to 2 × the fabric basis weight. The time constant of the measuring unit was variable between 5 and 20 sec. Several other examples of β- and γ-radiation measuring equipment were on display.

The Czechoslovak Export Agency (KOVO of Prague) showed a long range of electronic equipment and accessories, including a high sensitivity direct-current oscilloscope with a band-width to 7 Mc./s. 3 db. down; alternating-current sensitivity 9 mV./cm., direct-current 25 mV./cm., input impedance 1 M.ohm at 30 pF. or 70 ohms direct current, time-base 5–500 kc./s., with provision for external input to *X* plates. A two-channel oscilloscope had a sensitivity of 10 mV./cm. and band-width to 1 Mc./s. with beam switching at 120 kc./s., and a two-gun oscilloscope with similar sensitivity had a frequency-range to 2 Mc./s. 3 db. down. The O.P.D. oscilloscope for slow-speed phenomena had a 25-cm. diameter, high-resolution tube. Maximum sensitivity was 100 mV./cm., a band-width of 0–6 kc./s., and a slowest time base sweep of 1·5 min. The 'Meopta' oscilloscope camera shown had an *f*/1·8 lens of 35-mm. focal length and held 6 m. of 35-mm. film. It is a continuous recording camera with a maximum film speed of 1,000 m./sec.

A semi-automatic valve tester with punched card setting up was shown also, and an electronic null point indicator with CRO indication for indicating alternating-current bridge balance.

The Polish Exterior Trading Co. for Electrical Technology, Warsaw, showed a limited range of equipment, somewhat out of date by Western standards. Also exhibited were chemical balances and thermographs, a phase-contrast microscope and a projection microscope, refractometers and *p*H meters, a disappearing-filament-type optical pyrometer and a twin-beam oscilloscope with a band-width of 10 c.p.s. to 5 Mc./s. A valve test meter looked about 1945 vintage. The sole electromagnetic flow meter exhibited was on the stand of Eckandt of Stuttgart, together with a proportional pneumatic controller, diaphragm operators, a twin-channel recorder and various Bourdon tube and diaphragm pressure units, and a smart-looking range of edge-on panel meters.

Precision slide-wire potentiometers were exhibited by Carl Zeiss of Jena. These were to *DIN R*5 standard with linearity of 1 per cent and a torque movement of 35 gm. cm. for the smaller sizes. Armoured and sealed versions were also available for use in basic heavy industries and in corrosive atmospheres. A precision instrument potentiometer requiring a torque of less than 2 gm. cm., and a small, low-inertia, magnetic clutch were also shown. A photomultiplier with a cathode diameter of 140 mm. and maximum gain of 10^7 was on display together with selenium cells with a spectral response said to be nearer the human eye than any other available, making it eminently suitable for colour matching, etc.

M. A. W., Messergate and Armaturenwerk, showed a self-balancing potentiometric recorder with a 250-mm. scale-length. Sensitivity was 0·1 per cent, reproducibility 0·5 per cent, response time better than 1·5 sec., minimum range 2 mV. f.s.d. suppressed zero available, models with 1, 3, 6 and 12 channels, chart speeds 0·2–3,600 mm./hr. This appeared to be the standard recorder on Eastern European equipment. A miniature recorder of the chopper-bar type was also shown and a thermocouple temperature-indicator/transmitter/controller of the lamp and pointer-vane type with 0–5 m.amp. transmission.

The most interesting pneumatic control equipment was to be found on the stand of G.S.T. (Automatic Temperature Control C.), Berlin. As well as high- and low-pressure pneumatic differential potential cells and a force-balance electropneumatic converter for thermocouple e.m.f.'s was a well-engineered three-term controller with push-button selection of hand or automatic control and balance, with a proportional band setting between 2 and 1,000 per cent, integral and derivative action times of 0·36 sec. to 200 min. and a sensitivity of better than 0·01 per cent. Also on display was a flow-metering unit which monitored the flow-rate of the main stream fluid and at any desired time interval would meter into it by means of a solenoid valve any desired proportion of a second liquid component. Fritz Hollige (Freiburg) demonstrated the 'Helcoscriptor' high-speed recorder available with 1–8 channels. All can be used with heated stylus on sensitized paper writing and are flat to 100 c./s. for 30-mm. recording width, or with cold stylus on carbon paper flat to 130 c./s. Sensitivities of 10 mm./V. input and paper speeds up to 200 mm./sec. are available.

Hottinger Measuring Techniques, Ltd., Darmstadt, showed a range of miniature inductive pick-offs suitable for carrier frequencies of 5 and 50 kc./s., the minimum range being 20 × 10^{-4} mm. f.s.d., and a maximum operating temperature of 90–120° C. according to type. Strain gauges with a minimum gauge-length of 3 mm., and which would withstand a maximum strain of 2 per cent up to 200° C., were also exhibited together with a strain gauge bridge torque-meter transmitting a maximum torque of 1,000 metre kiloponds, at 4,000 r.p.m. with a reproducibility of 0·5 per cent and an output of 1·5 mV./V. supply at maximum torque loading; silver/silver graphite slip-rings with up to 12 channels, with brushes that may be replaced during running, were capable of running at 6,000 r.p.m. continuously and 12,000 r.p.m. intermittently.

Krohne of Duisburg displayed their range of rotameter-type flow-meters with magnetic pick-off of float position to provide remote indication, and a float-type density meter with inductive pick-off which fits directly into the process stream line and is independent of fluid velocity; the most sensitive range is 0·99–1·01 gm./c.c. and the accuracy of this range is ± 1½ per cent. Heating or cooling coils and built-in temperature compensation are available. AB Lars Ljungberg, Sweden, demonstrated the 'Agnar' burette, a new and ingenious approach to precision metering, titrating and decanting. The burette has no tap, and is essentially a syringe in which the piston is positioned by means of a screw drive. Various syringe sizes are available, the 2 ml. size delivering 1 ml./rev. of the coarse knob and 12 μl./rev. of the fine knob. The drive is reversible, thus the burette is equally suitable for drawing off any volume from 1 μl. to 20 ml.

The Yokogawa Electric Works, Ltd., Tokyo, exhibited a range of direct-current precision measuring instruments including a good-looking miniature portable Wheatstone bridge. Panel meters were contemporary in style but appeared crudely manufactured and designed without regard to their function of precise indication of a measured quantity. Fully transistorized printed-circuit strip-chart recorders of about 4-in. and 8-in. chart-width had self-folding charts facilitating reading of back records. A three-term electronic controller was on view but no information about it was available.

A new instrument under development by DISA Electronik measures departures from constancy of the angular velocity of rotating equipment at speeds up to 100,000 r.p.m.

J. A. Place

ASSESSMENT OF PAIN IN MAN AND ANIMALS

A THREE-DAY symposium on the assessment of pain was organized by the Universities Federation for Animal Welfare (UFAW) in collaboration with Prof. C. A. Keele, presided over by Sir Russell Brain, and held in the Department of Pharmacology at the Middlesex Hospital Medical School during July 26–28. UFAW had been asked to arrange such a symposium by Dr. C. Radouco-Thomas, secretary of the Collegium Internationale Neuro-Psycho-Pharmacologicum in Geneva, who made many useful suggestions. In his presidential address, Sir Russell Brain referred to the usefulness of bringing together the peripheral and central aspects of the neurology of pain and the need for reconsidering views which at present are widely held on the subject; he said that UFAW's interest in the latter arose from the fact that pain sensations in many species appear to differ little from those experienced by man.

After Dr. K. D. Keele (London) had reviewed the history of theories of pain from primitive times, Prof. C. A. Keele (London) outlined a technique used by himself and his colleagues in which a blister is formed on the arm and the blister base is then stimulated in various ways, the resulting sensations being reported by the subject. The receptors appeared to be stratified in depth. The sensation at low levels of stimulation was not painful, and he proposed the term 'metæsthesia' for it under those conditions. Dr. Robert Smith (London) dealt with the quantitative relation between stimulus and sensation and described metæsthesia produced with potassium and polypeptide stimulations.

Prof. J. A. B. Gray (London) took the chair at a discussion of peripheral pain mechanisms. Dr. A. G. M. Weddell (Oxford), dealt with the structure of the nerve terminals in the skin as they appeared in electron and optical microscopy. Prof. Y. Zotterman (Stockholm) dealt with the specificity of cutaneous nerve fibres and the search at sub-microscopical level for the cause of this specificity. Dr. A. Iggo (Edinburgh) discussed the conduction in single *C* fibres of impulses initiated by noxious stimuli in the viscera, muscles and skin. Prof. H. Hensel (Marburg) showed a film record of afferent impulses in human single cutaneous nerve fibres. Dr. W. Koll (Göttingen) described the effects of morphine and other drugs on nociceptive spinal reflexes. An open discussion of the specificity of peripheral mechanisms followed.

Prof. D. Hill (London) presided over a session on central mechanisms of pain. Dr. D. R. Bowsher (Liverpool) and Prof. D. Albe-Fessard presented a joint paper showing that somatic sensations fall into two classes: discriminative sensations travelling by lemniscal pathways to the cortex via the thalamus and entailing a perception of location, and non-discriminative sensations travelling by extra-lemniscal pathways. Dr. G. Gordon (Oxford) described the electrophysiological approach to central mechanisms of somatic sensation. Dr. P. W. Nathan (London) dealt with traces of pain remaining in the nervous system, as in the case of phantom limbs. Dr. J. Hankinson (Newcastle upon Tyne) described the relief of pain by destruction of intracerebral structures under the guidance of stereoscopic radiography. In the ensuing discussion, Prof. J. Scherrer (Paris) and Dr. G. L. Kidd (Liverpool) suggested possible mechanisms of phantom pain, and Dr. M. R. A. Chance (Birmingham) directed attention to audiogenic seizures which do not arise in rodents unless these are deprived of escape routes.

Prof. O. L. Zangwill (Cambridge) took the chair for a session on the assessment of pain in man. Dr. H. K. Beecher (Boston, U.S.A.) discussed some working hypotheses and described his work on the effect of drugs on high-level intellectual performance.

He considered that data from experimental pain are often difficult to relate to clinical experience. Dr. J. D. Hardy (New Haven, Connecticut) described work on the pain threshold in relation to measurement of the intensity of human pain and the effects of analgesics. Dr. R. W. Houde (New York) said that an analysis of quantitative data on pathological and experimental pain in terms of the 'ridit' unit could establish a relation between these two different types of data. Dr. C. Wilson (Liverpool) discussed the factors affecting the placebo response, which may give rise to bias even in blind experiments. A general discussion of psychophysical correlation problems followed.

In a session devoted to the assessment of pain in animals, with Prof. C. A. Keele (London) in the chair, Dr. D. D. Bonnycastle (Jersey City), Dr. R. L. Kitchell (Minnesota), Dr. H. O. J. Collier (London), Dr. C. Radouco-Thomas (Geneva), Dr. K. Soehring (Hamburg), and Dr. J. Jacob (Paris) discussed the testing of analgesic drugs on animals. The final session, in which Prof. C. A. Keele again took the chair, was devoted to practical applications to animals used in research. In the unavoidable absence of Prof. A. Haddow, Dr. E. J. Delorme described several arrangements devised at the Chester Beatty Research Institute for the comfort of the animals used. Major C. W. Hume (UFAW, London) directed attention to the desirability of ensuring that experimentation on animals be restricted to scientifically qualified persons who recognize their responsibility towards the rodents and other animals used, the training of technicians and of beginners in research being particularly important in this respect. A discussion on legislation for the protection of laboratory animals followed.

A report comprising the full text of the papers with summaries of the ensuing discussions is to be published by UFAW and will, it is hoped, be available early in 1962.

SOCIAL STUDIES IN BRITAIN

IN the debate on science in the House of Commons on July 10, Mrs. Judith Hart urged the need for a social sciences research council, referring particularly to the contribution which social science could make in dealing with the special problems of the new towns, in urban research and development generally, in the National Health Service, and in the economic and social problems arising out of automation and industrial change in general. Mr. D. Freeth, Parliamentary Secretary for Science, did not deal with this subject in his reply in that debate, but it was raised afterwards by Mr. A. Albu in a debate on August 4. In the meantime, on July 18, Mr. Freeth had stated in answer to a specific question from Mrs. Hart that the Council for Scientific and Industrial Research is reviewing the support given by the Department in this field, and considering whether there is need to alter the present organization for encouraging and supporting these studies. Mr. Freeth said that the Minister for Science expects to receive the Council's views in the autumn, and on August 4 he added that the House would expect the Minister to await the Council's advice, though he was authorized to emphasize the Minister's great interest in the social sciences. The Minister would note very carefully the views expressed in the debate; Lord Hailsham believed that more work should be done in the universities and elsewhere in this field, and his continuing study would be directed to strengthening the social sciences in future.

The debate on August 4 was notable for the very full review of the whole position of the research effort in Britain in this field at present, and warm appreciation of Mr. Freeth's statement was expressed by Mr. F. Peart. Mr. Freeth began by referring to the report of the Clapham Committee in 1946, as a result of which the University Grants Committee made earmarked grants from 1947 until 1952 for the social sciences at a steadily increasing rate. A change in policy led to the discontinuance of earmarked grants after 1957, but at the present time the Department of Scientific and Industrial Research is making grants and awards totalling £140,000, the £40,000 mentioned by Mr. Albu covering grants to universities and colleges of advanced technology only. For this purpose, the Department has a special committee, and in addition the Industrial Grants Committee of the Department has made a 5-year grant to the National Institute of Industrial Psychology, depending on the amount of money raised for the purpose by the Institute. A list of investigations supported by the Human Sciences Committee of the Department is available, and although all these awards are related to industry they cover a wide field. Mr. Freeth cited as examples research at the Birmingham College of Advanced Technology into social factors affecting relations and individual performance in factories; at the University of Durham into worker–management relations in four industries in the north-east of England of differing techniques; at Brunel College, into the subjective nature of judgments made in the inspection and quality control of manufactured goods; at the University of Leicester into problems of the employment of married women in hosiery factories; and at the University of Oxford into plant-operating skills in relation to automation.

In this context Mr. Freeth referred to the dissemination of the results of such research; for example, the Ergonomics Conference held in September 1960 and the series of meetings organized to introduce the topics discussed to the research associations.

About £60,000 a year is being expended on research in this field at the Department's own laboratories, including, for example, the work at the Warren Springs Laboratory on ergonomics, such as the design and study of key-boards and a study in conjunction with the University of Manchester of secondary modern school-leavers. At the Building Research Station investigations are being made of the design and provision of flats for old people and the design of offices and hospitals. The Road Research Laboratory is continually examining the personal characteristics of road-users in relation to their behaviour on the road, and the National Physical Laboratory is investigating motor-vehicle noise, the effects of the light in a room on colour rendering, and readers for blind people, and the British Iron and Steel Research Association and the British Boot and Shoe and Allied Trades Research Association have human science and ergonomic sections.

The Medical Research Council is spending some £250,000 in this field, at its own research units and through grants for research undertaken in the universities. At Graylingwell Hospital, Chichester, the Council has a unit with a programme including the evaluation of a community mental health service to determine the social and clinical factors which favour admission of patients to hospital and those which favour treatment at home. The unit was also studying the effects on the family of caring for a member who is mentally ill. Work in the social sciences at the universities, however, must depend largely on the importance attached to it by the universities, and the extent of their resources, but it is also influenced by the scarcity of first-degree courses in sociology as such and the difficulty in attracting postgraduate students.

Mr. Freeth referred to considerable expenditure on research into such subjects as criminology and penology by the Home Office, though he did not indicate the amount. Lists of such researches were given in a written answer by the Minister of State at the Home Office on April 13, 1961. Other Departments finance work on such subjects as perception and reaction to extreme environmental conditions, and grants are also made by certain local education authorities. How far this should be done by central bodies and how much within the Departments is a difficult problem. Mr. Freeth made no specific reference to the Ministry of Education, although in opening the debate Mr. Albu had commented on the absence of such research by that Ministry, and had referred to a memorandum recently submitted to the Minister for Science by the Parliamentary and Scientific Committee.

The memorandum pointed out that the total expenditure on empirical research on education in Great Britain was less than £125,000 a year, or about 0·014 per cent of annual expenditure on education; and it pointed out that most university research education is carried out part-time either by staff or students for higher degrees, most of whom are practising teachers with full-time jobs. There are only ten research fellowships devoted to empirical research in education, and most of the research carried out by teachers and local education authorities loses its principal value because it has no skilled advice on such matters as experimental design, test construction and statistical analysis. The memorandum urged the establishment of an educational research council with a substantial budget and an independent chairman under the direction of a committee of the Privy Council and reporting to Parliament through the Lord President of the Council.

Mr. Freeth said that the work of the Social Survey of the Central Office of Information, on which some £129,000 is expended, also covers a wide field, including inquiries on behalf of Government economists and statisticians with a special interest in economic development, inquiries into health and social problems, and inquiries into the development of techniques for supplementing and completing existing official statistics and studying operational problems of public services.

There is also the considerable support to social science research given by the major charitable foundations, but Mr. Freeth thought that this source of support is likely to diminish in future. He believes that much more work in this field is needed in the universities and colleges of technology, and hopes that those interested in strengthening the study of the social sciences there will give evidence to the Robbins Committee.

In welcoming Mr. Freeth's reply, Mr. Peart expressed the opinion that a research council for the social sciences should be created, and hoped that the Government would act after considering the views of the Council for Scientific and Industrial Research and the recommendations of the Robbins Committee. Referring particularly to the need for more educational research to provide the basis of objective advice for decisions, he instanced the value of a proper survey into the way in which comprehensive schools are meeting educational needs and fitting into local environment, and of a proper social survey of university education, embracing the place of students, the nature and length of courses and the wastage of resources. It is as a stimulus to social research in the universities, to undergraduate and postgraduate training in this field and the provision of field observation groups and group behaviour studies in a wide field of human activity in industry as well as detailed socioclinical studies and surveys that Mr. Peart thinks that a social research council would help to supply the detailed information needed as a basis for sound decisions by the Government in matters which are often non-political.

B.B.C. ENGINEERING MONOGRAPHS

IN 1955, the British Broadcasting Corporation began the issue of a series of B.B.C. Engineering Monographs[*], describing technical work carried out by the Engineering Division of the Corporation in the development and operation of their sound and television broadcasting services (*Nature*, 177, 519; 1956). Nineteen of these monographs had been issued up to June 1958 (*Nature*, 182, 1490; 1958); and a further eighteen have been published in the following three years, up to June 1961. The authors of these monographs are usually members of the staff of the various departments of the Engineering Division of the Corporation, and collectively they show the progress of the development of the service of sound and television broadcasting through the Research, Designs and Planning and Installation Departments to the practical operation of the service transmitting stations.

The range of subjects dealt with is indeed wide. On the sound-broadcasting side, the problems of programme switching, control and monitoring have been described, together with details of the methods used to check the quality of very high frequency broadcasting. The various methods which can be used for stereophonic broadcasting have been surveyed and discussed with the view of appreciating the possibilities of this technique for domestic reception. In connexion with television, the subjects dealt with in recent monographs, range from the performance of optical lenses in the cameras, the general testing of cameras, and the processing of films, to the equipment of television studies and a new survey of experimental colour transmissions.

---

[*] B.B.C. Engineering Monograph No. 34: A Mobile Laboratory for U.H.F. and V.H.F. Television Surveys. E. W. Taylor and L. C. Munn. Pp. 16. No. 36: Some Aspects of Optical Lens Performance. Part 1: Secondary Flare in Lenses. By K. Hacking. Part 2: The Design of Lens Hoods. By W. N. Sproson. Pp. 19. No. 37: An Instrument for Measuring Television Signal-to-Noise Ratio. S. M. Edwardson. Pp. 23. (London: British Broadcasting Corporation, 1961.) 5*s*. each.

Progress common to both sound and vision broadcasting is reported in such subjects as the design of transmitting aerial systems and the general study of radio wave propagation. This work is essential in assessing the coverage likely to be attained from new transmitting stations, and particularly from those which will be required for extended services in the future. Some of the research work is carried out with mobile laboratories, while the operational engineers use mobile studios and control rooms for their outside sound and television services. The latest types of these mobile units are described in separate monographs.

Altogether these publications show that the B.B.C. is well aware of its responsibility to keep the technical side of its services up to date, and to take full advantage of progress and developments, whether these arise from within its own organization or from elsewhere in the fields of radio research and application.

THE LISTER INSTITUTE OF PREVENTIVE MEDICINE

THE report of the Governing Body of the Lister Institute of Preventive Medicine for 1961* again contains a detailed record of the numerous investigations carried out in the various departments.

In the Department of Microbiology, for example, the Guinness–Lister Unit continued its exploration of bacterial genetics, mainly of the *Salmonella* bacilli. The problems investigated include conjugation and gene-transfer initiated by the colchicine type of fertility factor and by a mutant of the classical fertility factor, *F* of Hayes; the effect of a colchicine factor on the resistance to ultra-violet irradiation; the genetics of resistance of *E. coli* to colchicines; the genic control of flagellation in a number of *Salmonella* mutants and of the production of different varieties of flagellar protein; and the chemistry of flagellar proteins and of the cell-wall polysaccharides.

The rates of bacterial multiplication in the infected mouse were studied with pathogenic *Salmonella* marked either with a non-replicating prophage or with an abortively transduced gene from another strain of *Salmonella*. The other purely microbiological investigation concerns the antigenic analysis of certain free-living protozoa.

In researches concerned with the immunology and pathology of infective diseases, the Institute's work includes infections by viruses, pleuropneumonia-like organisms, bacteria and protozoa.

The Trachoma Research Unit continued its epidemiological field study in The Gambia of trachoma in terms of virus and of bacilli of the *Haemophilus* group. Laboratory work at the Institute includes growth of trachoma and inclusion conjunctivitis virus in tissue culture, serological classification of the viruses, the vaccination of baboons against inclusion conjunctivitis and the serology of Gambian *Haemophilus* strains. In the smallpox-vaccine department, there is continued progress towards making vaccine from virus grown in tissue culture. The properties of measles virus were also studied.

As an indirect means of determining the significance of antibody to pleuropneumonia-like organisms in human subjects with abacterial urethritis and other kinds of genital infection, the study of the relation of pleuropneumonia-like antibody to the infecting agent and stage of infection in rats and mice was continued.

The immunological study of bacterial infections includes an analysis of the action of two types of protective antibody in mice infected with the whooping-cough bacillus; the biological activity of the *C* polysaccharide of *Streptomyces pyogenes*; and the process of refinement of antitoxin by proteolysis.

Further investigation has been made of the immunology of experimental trypanosomiasis in terms of soluble and bound immunizing antigen as well as of methods of bulk growth of the trypanosomes for antigenic analysis.

The refined serological methods devised to identify the animal source of food for blood-sucking insects provides valuable facts about the feeding-habits of tsetse flies in regions where these insects are vectors or possible vectors of disease.

In the Department of Biochemistry, the researches concerned were again with three kinds of substances, namely, the blood group substances, the cellular phospholipids and starches.

The investigations of the substances of the *ABO* blood-group system include analysis by improved methods of partial hydrolysis, determination of the amino-acid moiety of the substances and its relation to serological specificity, transformation of blood-group specificity by the action of selected enzymes and measurement of the molecular properties of the substances.

Work on the structure of phospholipids, their distribution in the tissues, cells and cellular particles, and their possible function in the cell includes analysis of the phospholipids of *Micrococcus lysodeikticus* of the pig kidney, lung and spleen and of mammalian plasmalogens.

The enzymes of plants, animals and bacteria synthesizing and degrading starch and glycogen were studied with regard to their specific effects on natural carbohydrates and on modified carbohydrates produced by chemical methods, including starches and various glucose phosphates. A disaccharide other than isomaltose was obtained from a dextran, and a new trisaccharide. Carbohydrates were synthesized for use as haptens in the immunochemical analysis of dextrans.

With human and animal plasma proteins, the Institute's work is concerned with the isolation, refinement, characterization, assay and, in some cases, clinical trial of the various biologically active proteins of human plasma.

A reliable assay of human antihæmophilic globulins was devised and improvements made in separation of stable preparations of the globulins from plasma.

Work on the isolation and characterization of biologically active proteins include those of plasmin, plasminogen, albumin, caeruloplasmin and Christmas factor.

ISOELECTRONIC PRINCIPLE, THERMOCHEMISTRY, AND REACTIVITY OF RELATED FREE RADICALS

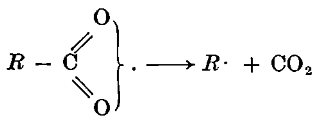
By Dr. PETER GRAY and J. C. J. THYNNE
School of Chemistry, The University, Leeds, 2

THE isoelectronic principle states that molecules containing identical numbers of valence electrons show many similarities in physical properties, molecular symmetry, structure and chemical reactivity. The principle was originally based on the striking physical resemblance between such isoelectronic molecules as nitrogen and carbon monoxide or nitrous oxide and carbon dioxide. It may also be applied to free radicals. Moreover, its range of usefulness is widened by the possibility of substitution of isoelectronic groups (such as —CH_2—, —NH— and —O—) for one another.

Recently, attention has been directed[1] to the usefulness of the isoelectronic principle in correlating the patterns of reactivity of two families of free radicals, namely, the alkyl radicals $R\text{CH}_2\cdot$ and the alkoxy radicals RO: For example, the parallelism between their decomposition reactions $R\text{CH}_2\dot{\text{C}}\text{H}_2 \rightarrow R\cdot + \text{C}_2\text{H}_4$ and $R\text{CH}_2\text{O}\cdot \rightarrow R\cdot + \text{CH}_2\text{O}$ has been discussed. In general it is to be expected, if two free radicals are isoelectronic, that they will exhibit similar patterns of reactivity. An important qualification should be made, however. It is well known that thermochemistry plays an especially important part in determining the behaviour and reactivity of free radicals. If a certain free radical may react by either of two paths, then their relative thermochemical requirements may be at least as important a consideration as a comparison with the behaviour of an isoelectronic analogue. When the isoelectronic principle and thermochemistry reinforce one another's influences, then prediction of the behaviour of the radical is probably safe. When they oppose one another, which will be dominant is not known.

Accordingly, in this article, we are concerned with the thermochemistry and the reactivity of two isoelectronic pairs of radicals: (i) the acyloxyl ($R\text{CO}_2\cdot$) and the azoxyalkyl radicals ($R\dot{\text{N}}_2\text{O}$), and (ii) the alkoxycarbonyl ($R\text{O}\dot{\text{C}}\text{O}$) and the alkoxyazo radicals ($R\text{ON}\dot{\text{N}}$). These radicals, it will be noticed, also form two isomeric pairs (iii) $R\dot{\text{C}}\text{O}_2$ and $R\text{O}\dot{\text{C}}\text{O}$, and (iv) $R\dot{\text{N}}_2\text{O}$ and $R\text{ON}\dot{\text{N}}$; so that comparison may be made not only between the behaviour of isoelectronic radicals but also between the behaviour of isomeric radicals.

(1) Acyloxyl and azoxyalkyl radicals, $R\dot{\text{C}}\text{O}_2$ and $R\dot{\text{N}}_2\text{O}$. Of these families of radicals the acyloxyl radicals are the most well known. They may conveniently be prepared[2] by the thermal decomposition of diacyl peroxides. The acyloxyl radicals readily decompose yielding carbon dioxide together with an alkyl radical (reaction 1), and it is this fact that has resulted in the frequent use[3,4] of diacetyl peroxide as a low-temperature source of methyl radicals:



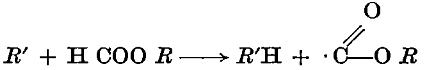
$$R-\text{C}\left.\begin{matrix}\nearrow\!\!\text{O}\\ \searrow\!\!\text{O}\end{matrix}\right\}\cdot \longrightarrow R\cdot + \text{CO}_2 \qquad (1)$$

Isoelectronic with the acyloxyl radicals are the isomeric pair of azoxyalkyl radicals $R\text{—N=}\underset{\substack{\downarrow\\ \text{O}}}{\text{N}}\cdot$ and $R\text{—}\underset{\substack{\downarrow\\ \text{O}}}{\text{N}}\text{=N}\cdot$. (These are related to the azoxyalkanes $R\text{N}_2\text{O}R$ in the same way as the acyloxyl radicals $R\text{CO}_2\cdot$ are related to the esters $R\text{CO}_2R$). Although aliphatic azoxy-compounds[5] have been prepared, their possible use as a source of radicals does not appear to have been much investigated, perhaps because of the hazards involved in their use.

Each of these families appears to have only one obvious mode of decomposition: acyloxyl radicals according to reaction 1, and the azoxyalkyl radicals according to reaction 2:

$$R\dot{\text{N}}_2\text{O} \longrightarrow R\cdot + \text{N}_2\text{O} \qquad (2)$$

(2) Alkoxycarbonyl and alkoxyazo radicals, $R\text{O}\dot{\text{C}}\text{O}$ and $R\text{ON}\dot{\text{N}}$. The alkoxycarbonyl radicals ($R\text{O}\dot{\text{C}}\text{O}$) have, until recently, been less well studied than the acyloxyl radicals although they are of considerable interest kinetically. They can be generated by the alkyl radical-induced decomposition of alkyl formates[6] (reaction 3), and this reaction has been shown[7] to be a good general source of thermalized alkyl radicals:



$$R' + \text{H COO}\,R \longrightarrow R'\text{H} + \cdot\overset{\text{O}\,\,}{\overset{/\!\!/}{\text{C}}}\text{—O}\,R \qquad (3)$$

Isoelectronic with these radicals are the alkoxyazo radicals $R\text{ON}\dot{\text{N}}$. These may be prepared by the thermal decomposition of hyponitrite esters[8,9] (reaction 4).

$$R\text{ON} = \text{NO}R \longrightarrow R\text{ON}\dot{\text{N}} + R\text{O}\cdot \qquad (4)$$

Comparison of the two isoelectronic families $R\text{O}\dot{\text{C}}\text{O}$ and $R\text{ON}\dot{\text{N}}$ is more subtle than that of the radicals $R\dot{\text{C}}\text{O}_2$ and $R\dot{\text{N}}_2\text{O}$, because, in principle, each may undergo either of two decompositions:

$$R\text{O}\dot{\text{C}}\text{O} \rightarrow R\text{O}\cdot + \text{CO} \qquad (5a)$$
$$\rightarrow R\cdot + \text{CO}_2 \qquad (5b)$$
$$R\text{ON}\dot{\text{N}} \rightarrow R\text{O}\cdot + \text{N}_2 \qquad (6a)$$
$$\rightarrow R\cdot + \text{N}_2\text{O} \qquad (6b)$$

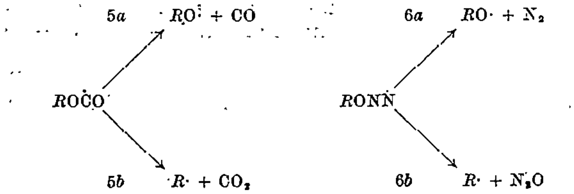
In fact, the observed decomposition behaviour is clear-cut and different in the two families. Alkoxycarbonyl radicals yield only alkyl radicals and carbon dioxide, for in none of the experiments[6,7,15] on the radicals $R\text{O}\dot{\text{C}}\text{O}$ ($R = \text{CH}_3$ to $R = \text{C}_4\text{H}_9$) is any product characteristic of alkoxy radicals found. Alkoxyazo radicals produce only alkoxy radicals and nitrogen. Neither in the decomposition of the lower alkyl hyponitrites[8] in the gas phase nor of benzyl hyponitrite[9] in solution is nitrous oxide or any product compatible with the formation of alkyl radicals found.

This striking difference is a departure from the behaviour expected on the basis of the isoelectronic

Table 1. ENERGY REQUIREMENTS OF ALTERNATIVE DECOMPOSITION PATHS FOR RELATED RADICALS $RO\dot{C}O$ AND $RO\dot{N}_2$

R	$\Delta H_{5b} - \Delta H_{5a}$ (kcal. mole^{-1})	$\Delta H_{6a} - \Delta H_{6b}$ (kcal. mole^{-1})
CH_3	35·7	51·5
C_2H_5	34·7	52·5
$n.C_3H_7$	32·7	54·5
$i.C_3H_7$	35·7	51·5
$n.C_4H_9$	31·6	56·5

$\Delta H_{5b} - \Delta H_{5a}$, enthalpy difference between reaction paths 5b and 5a; $\Delta H_{6a} - \Delta H_{6b}$, enthalpy difference between reaction paths 6a and 6b.



principle. Since it is essentially a kinetic difference it is helpful to consider the contribution of the Arrhenius factor A and the activation energy E to the velocity constant of decomposition. It is difficult to see any real basis for predicting different A factors for unimolecular decomposition of the radicals $RO\dot{C}O$ and $RON\dot{N}$, and it may be considered that the difference is attributable to difference in activation energies. In turn, the origin of the differences in activation energy may be sought in the thermochemistry of the radicals. Table 1 summarizes the differences in the energy requirements between the two decomposition paths for some members of each family of radicals. Thus in each family the energetically favoured path is followed. While carbon dioxide formation from the alkoxycarbonyl radicals needs some 35 kcal. less than carbon monoxide formation, nitrous oxide formation from the alkoxyazo radicals requires some 50 kcal. more for the production of nitrogen.

It is worthy of comment that the differences in energy requirements of the individual reaction paths of each radical can be evaluated without knowledge of the heats of formation of the individual radicals; thermochemical data for the reaction products are sufficient.

(3) Thermochemistry and reactivity of the acyloxyl and alkoxycarbonyl radicals. Although, for the purpose of comparison above, values of the heats of formation of the radicals $RO\dot{C}O$ are not needed, they are needed to make a comparison of the isomers $RO\dot{C}O$ and $R\dot{C}O_2$. Enthalpies of formation for some of the lower acyloxyl radicals are known[10] and these are tabulated (col. 2, Table 2). Values of enthalpies of formation may also be obtained for free radicals by group-energy terms[11], using a value of −39 kcal. for $H(CO_2.)$. These values also appear in col. 2. They have been used to calculate the enthalpy change of the decarboxylation of acyloxyl radicals, and these results appear in col. 3, Table 2.

No experimentally obtained thermochemical data exist for the alkoxycarbonyl radicals. Values for $\Delta H_f(RO\dot{C}O)$ which are unlikely to be seriously in error can be inferred from kinetic work on hydrogen abstraction by alkyl radicals for a series of aldehydes[13] ($RCH\dot{O}$) on one hand, and from various formate esters[14] ($RO.CHO$) on the other. In general, the values of the activation energies of hydrogen abstraction for both aldehydes and formates differ by little more than 1–2 kcal. mole^{-1} for members of both series, suggesting that the groups R and RO (which are not immediately adjacent to the point of radical attack) have little effect on the strength of the C—H bond being broken. If these bonds have similar strengths in the two families, then:

$$D(H - \overset{\overset{O}{\|}}{C}.CH_3) \simeq D(H) - \overset{\overset{O}{\|}}{C}OCH_3) \simeq 82 \text{ kcal.}$$

Since:

$$D(H - \overset{\overset{O}{\|}}{C}OCH_3) = \Delta H_f(H) + \Delta H_f(COOCH_3) - \Delta H_f(HCOOCH_3)$$

then a value of − 53·6 kcal. mole^{-1} may be calculated for the heat of formation of the methoxycarbonyl radical. Thermochemical data exist for few formates; however, it is still possible to obtain values for the heats for formation of the radicals from thermochemical data[15] for the acetate esters. In this case a similar assumption of equivalence of bond dissociation energies is made, this time comparing the appropriate bond-strengths of acetone and the acetates, using a 'medium' value for $CH_3 - COCH_3$, that is:

$$D(CH_3) - \overset{\overset{O}{\|}}{C}.CH_3) \simeq D(CH_3 - \overset{\overset{O}{\|}}{C}.OCH_3) \simeq 79 \text{ kcal.}$$

Using this bond energy, a value of − 51·7 kcal. mole^{-1} is obtained for $\Delta H_f(CH_3O\dot{C}O)$ which is in reasonable agreement with the value of − 53·6 kcal. obtained using methyl formate as the radical source. Values of ΔH_f for other alkoxycarbonyl radicals obtained in this manner appear in col. 4, Table 2, and using these values we may now make a direct comparison of the acyloxyl and alkoxycarbonyl radicals.

Assigning a value of − 18·5 kcal. to $H(\dot{C}O)$, then by using the usual group-energy terms, values of $\Delta H_f(RO\dot{C}O)$ may be calculated. These values are tabulated in col. 5, Table 2, and are in quite good agreement with the values obtained using the heats of formation of the acetate esters (col. 4).

Table 2. ENTHALPIES OF FORMATION AND BOND DISSOCIATION ENERGIES OF ACYLOXYL AND ALKOXYCARBONYL RADICALS
All values in kcal. mole^{-1}

R	$\Delta Hf\, RCO_2$	$D(R—CO_2)$	$\Delta Hf\, RO\dot{C}O$	$\Delta Hf\, RO\dot{C}O$	$D(RO—CO)$	$D(R—O\dot{C}O)$
CH_3	-45^a	−17·5	−51·7 (−53·6 from $HCOOCH_3$)	−55·8	24·8	−10·9
C_2H_5	-54^a	−15·5	−59·6	−60·8	24·7	−10·0
nC_3H_7	-60^a	−13	−65·8	−65·8	26·4	− 6·3
iC_3H_7	-60^b	−16·7	−68·9	−67·0	27·5	− 8·2
nC_4H_9	-64^b	−12·2	−71·9	−70·8	28·5	− 3·2
			c	d	e	e

a, Values reported by Jaffé, Prosen and Szwarc (ref. 10); b, calculated from group energy terms ($H(CO_2.)$ = −39 kcal.; c, obtained using $D[R—COOR]$ = 79 kcal., and using heats of formation of acetates (ref. 15); d, calculated from group energy terms $H(CO)$ = −18·5 kcal.; e, values of $\Delta Hf\,(RO\dot{C}O)$ taken from col. 4.

(4) Energetics of decarboxylation of $RO\dot{C}O$ and RCO_2. Since:

$$D(CH_3O - CO) = \Delta H_f(CH_3O) + \Delta H_f(CO) - \Delta H_f(CH_3O\dot{C}O)$$

and

$$D(CH_3 - OCO) = \Delta H_f(CH_3) + \Delta H_f(CO_2) - \Delta H_f(CH_3O\dot{C}O)$$

then, using a value of $-$ 51·7 kcal. for $\Delta H_f(CH_3O\dot{C}O)$, we obtain:

$$D(CH_3 - OCO) = -\ 10{\cdot}9 \text{ kcal. mole}^{-1}$$

and

$$D(CH_3O - CO) = 24{\cdot}8 \text{ kcal. mole}^{-1}.$$

Similar values for other alkoxycarbonyl radicals appear in columns 6 and 7 of Table 2. Decarboxylation of the $RO\dot{C}O$ radicals, although involving bond fission, is always exothermic (ΔH is negative): thus the alkoxycarbonyl radicals are thermodynamically unstable with respect to decarboxylation. This is the same rare behaviour that is observed in the acyloxyl radical where, for instance, $D(CH_3 - CO_2) = -\ 17{\cdot}5$ kcal. Throughout the two series, the alkoxycarbonyl radicals are thermodynamically less unstable than their isomers.

(5) Stability and reactivity of the $RO\dot{C}O$ and $RCO_2^{\cdot}$ radicals. There has been some controversy[16,17] about the kinetic stability of the acetyloxyl radical. The discussion has centred on whether the acetyloxyl radical survives long enough to react with a substrate and simultaneously decarboxylates, or whether the radicals are decarboxylated so that the substrate is attacked only by the methyl radicals produced. Recently, Herk and Szwarc[17] have concluded that, even in the liquid state, the reactions observed with the acetyl peroxide system are due to methyl radicals not to acetate radicals. No methyl acetate has been found in the gas-phase thermal decomposition of the peroxide, suggesting that there the acetyloxyl radical is not stable enough to associate with methyl radicals by:

$$CH_3CO_2\cdot + CH_3 \longrightarrow CH_3\ COO\ CH_3$$

Szwarc and Herk[12] consider that the decarboxylation of the acetyloxyl radical requires some small activation energy, about 1–2 kcal. mole^{-1}.

Less is known about the stability and reactivity of the alkoxycarbonyl radical. It appears from a consideration of the energetics of decarboxylation and from experimental observations[6,14,18] that the radical is unstable. Kebarle and Lossing[19], however, found traces of methyl acetate in a mass-spectrometric study of the mercury-photosensitized decomposition of methyl formate, presumably produced by the association of methyl with methoxycarbonyl radicals, that is:

$$CH_3^{\cdot} + CH_3OCO \longrightarrow CH_3\ COO\ CH_3$$

This apparent stability would suggest that the activation energy for decomposition of the methoxycarbonyl radical is perhaps somewhat greater than the value of 1–2 kcal. suggested for the acetyloxyl radical, a conclusion which would also concur with the relative bond strengths we have calculated for $CH_3CO_2\cdot$ and $CH_3O\dot{C}O$ ($-$ 17·5 kcal. and $-$ 10·9 kcal. respectively).

One of us (J. C. J. T.) would like to thank the Department of Scientific and Industrial Research for a research fellowship.

PATHS OF INTER-MOLECULAR ENERGY TRANSFER IN PHOTO-SENSITIZED OXIDATION-REDUCTION

By N. TAKEYAMA

Institute of Biophysics, Faculty of Agriculture, Kyushu University, Fukuoka, Japan

IT has been recognized that there are two types of energy transfer of the electronic excitation from sensitizer to energy acceptor; one corresponds to the case of weak resonance coupling owing to the transitional dipole–dipole interaction between photo-excited sensitizer and unexcited acceptor, the other is the case of strong resonance coupling for which the effect of the first order of the same interaction as above is responsible.

The problem in this article is confined to the solution system of organic dyes. When S and A refer to the sensitizer and the energy acceptor, respectively, the types of energy transfer mentioned here are written in the manner of a chemical reaction as follows:

$$h\nu_s + \underbrace{S + A \rightarrow S^* + A \rightarrow S}_{+\text{reductant (or oxidant)}} + A^* \rightarrow A' \qquad \xrightarrow{\hspace{4em}} \text{redox process} \quad (a)$$

$$h\nu_s + \underbrace{S + A \rightarrow S^* + A \rightarrow [S \ldots A]^* \rightarrow S}_{+\text{reductant (or oxidant)}} + A' \qquad \xrightarrow{\hspace{4em}} \text{redox process} \quad (b)$$

where $h\nu_s$ denotes the energy of a photon absorbed by S, the molecular species accompanied with asterisk mean the photo-excited molecules in the singlet state, and A' stands for the metastable A in the triplet state. Here we have written the resonance state as $[S \ldots A]^*$. In other words, this state can be described as the resonance between the states (S^*, A) and (S, A^*). The case of (a) is called the weak resonance coupling, and the case of (b) is called the strong resonance coupling.

The following criteria, which were appointed by Simpson and Peterson[1] in the problem of the electronic spectra of molecular crystals, serve as an answer for

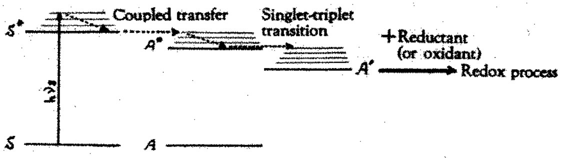

Fig. 1. Simplified diagram of sensitization in the case of weak resonance coupling

why either type (*a*) or (*b*) can be found in the mechanism of sensitization:

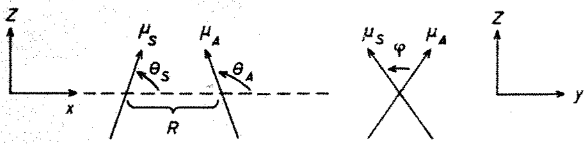
$2V/\Delta \ll 1$ for the case of weak coupling (*a'*)
$2V/\Delta \gg 1$ for the case of strong coupling (*b'*)

where V represents the so-called resonance coupling parameter, which is defined by the matrix element of the electronic dipole–dipole interaction, and Δ is the width of the band related to the electronic transition under consideration.

In the former case, it can be said that the energy transfer is achieved with the transition from the initial state $\psi(S^*)\psi(A)$ to the final state $\psi(S)\psi(A^*)$ owing to the dipole–dipole interaction, and the transfer probability has the dependence R^{-6} on the intermolecular distance R, where $\psi(S),\psi(S^*)$, and $\psi(A)$, $\psi(A^*)$ are the electronic wave functions of the unexcited and excited S and A, respectively. In the present problem, the resonance coupling parameter becomes:

$$V = -\frac{1}{\varkappa R^3}\int \psi(S^*)\psi(A)\mu_S\mu_A\psi(S)\psi(A^*)\mathrm{d}\tau_S\mathrm{d}\tau_A \times$$
$$(2\cos\theta_S\cos\theta_A - \sin\theta_S\sin\theta_A\cos\varphi) \qquad (c)$$

where $\varkappa$ is the dielectric constant of the medium, μ_S and μ_A are the dipole moments referring to S and A, and the angles of relative orientation of the dipoles are defined as:



If S and A are parallel in the resonance state, $\theta_S = \theta_A = \frac{\pi}{2}$ and $\varphi = 0$. Hence, V can be written as:

$$V = \mu_S'\mu_A'/\varkappa R^3 \qquad (d)$$

where μ_S' and μ_A' are the transitional dipole moments given by $\mu_S' = \int\psi(S^*)\mu_S\psi(S)\mathrm{d}\tau_S$ and $\mu_A' = \int\psi(A)\mu_A\psi(A^*)\mathrm{d}\tau_A$, respectively. It goes without saying that the transition probability of the energy transfer in weak resonance coupling is proportional directly to the square of equation (*c*) (ref. 2). The energy transfer from S to A is succeeded by the non-radiative transition from the excited singlet state to the triplet state due to the spin-orbit coupling in the acceptor molecule. The metastable molecular species of the produced triplet state take part in redox processes with a reductant or oxidant. This is the mechanism of photo-sensitized redox reaction in the case of sensitization due to the weak coupling. A simplified energy diagram of this mechanism is shown in Fig. 1.

The example can be found in the following system: in the ethanol solution of S = uranin, A = methylene blue and reductant = ascorbic acid or phenylhydrazine, the bleaching reaction of A photo-sensitized by S occurs with photo-excitation of S (ref. 3).

A characteristic property of the sensitization in the case of weak resonance coupling can be seen in the fact that the vibrational motion in the excited electronic state continues during an interval of time of $10^{-9} \sim 10^{-8}$ sec. (that is the life-time of fluorescence) according to the inequality (*a'*).

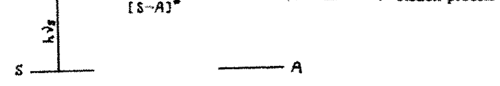
On the other hand, in the case of strong resonance coupling the resonance effect of the first order of interaction must be taken into account by taking the following linear combinations of both states $\psi(S^*)\psi(A)$ and $\psi(S)\psi(A^*)$ at a fixed molecular configuration:

$$\psi_+ = 2^{-1/2}\{\psi(S^*)\psi(A) + \psi(S)\psi(A^*)\} \qquad (e, \mathrm{i})$$
$$\psi_- = 2^{-1/2}\{\psi(S^*)\psi(A) - \psi(S)\psi(A^*)\} \qquad (e, \mathrm{ii})$$

because the electronic coupling occurs before the vibrational motion in the degenerate excited state at a reasonance configuration; this is the meaning of the inequality (*b'*). The resonance split of energy is given by the difference between the energy-levels of ψ_+ and ψ_-, or by $2|\mu_s'||\mu_A'|/\varkappa R^3$. Provided that $\vec{\mu}_s' = -\vec{\mu}_A'$, the lower energy state is ψ_+ and the higher one is ψ_-. Moreover, it is important that the dipole transition from ψ_+ to $\psi(S)\psi(A)$, in which $\psi(S)\psi(A)$ is the ground state free from interaction, is forbidden owing to vanishing the total transitional dipole moment.

Because the energy-level of the state ψ_+ is lower by $|\mu_s'|^2/\varkappa R^3$ than the level of the excited state of S without A, we can interpret the state ψ_+ as the excited state stabilized by the transitional dipole–dipole coupling with A. It can be expected that the transition probability from the stabilized singlet state ψ_+ to the lowest triplet state of A in the resonance complex is much greater than the transition probability from the excited singlet state of A only to the same triplet state, because the stabilizing energy, or $|\mu_s'|^2/\varkappa R^3$, is comparable with the energy of separation between the first excited singlet state and the lowest triplet state of A itself; in many cases of organic dyes the energy is a few thousand cm.$^{-1}$ (refs. 4 and 5). After the transition of A to the triplet state, the resonance complex $[S \ldots A]^*$ dissociates repulsively, owing to the vanishing of the transitional dipole moment. The metastable molecule A' in the triplet state proceeds to redox process with a reductant or oxidant. These processes are shown diagrammatically as Fig. 2.

Although it is not the example of sensitization in a narrow sense, an interesting example of the latter case can be found in the photo-reduction of some organic dyes in an aqueous solution of high polymer; in this reaction it is important to produce the metastable species of the dye due to the interaction between the photo-excited and unexcited dyes in the bound state with high polymer[6]. Another example is the reduction of crystal violet photo-sensitized by trypaflavine in the aqueous solution. As is well known, the triphenylmethane dyes cannot be photoreduced by ascorbic acid or some other reductant in



⟶, radiative transition; - - ⟶, radiationless transition

Fig. 2. Simplified diagram of sensitization in the case of strong resonance coupling

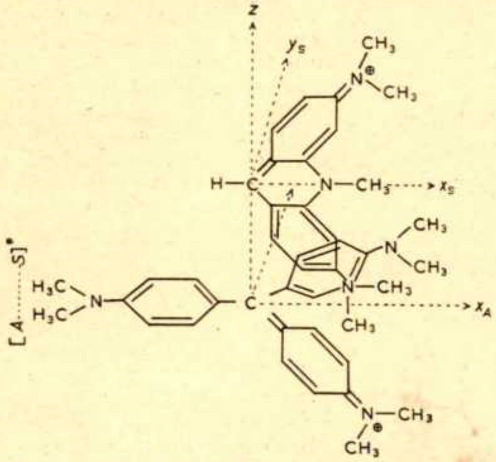


Fig. 3. A possible configuration in the resonance state of trypaflavine (*S*) and crystal violet (*A*)

free solution except in the presence of high polymer which contains the carboxyl groups. However, the photo-reduction of the dye with ascorbic acid occurs when trypaflavine is used as sensitizer[7]. The mechanism can be explained by sensitization of the latter case. In the resonance state in which the excited trypaflavine interacts with the unexcited crystal violet, the molecular plane surface of crystal violet will be conserved as a result of resonance stabilization. A possible molecular configuration in the resonance state is shown in Fig. 3. The excitation energy absorbed by crystal violet in the free system from trypaflavine, or even in the presence of trypaflavine, does not activate the redox reactivity, because the dissipative processes predominate over the intramolecular transition to the triplet state due to the deficiency of the stability of the excited singlet state of crystal violet.

The experimental facts show that the metastable crystal violet produced after the resonance stabilization in the sensitization takes part in the redox process with ascorbic acid, and the stabilization of the excited crystal violet results also from the resonance interaction with the unexcited crystal violet in the presence of high polymer.

ELECTRON MICROSCOPIC OBSERVATIONS OF STRUCTURE IN ULTRA-THIN SECTIONS OF VITRINITE IN COAL

By J. T. McCARTNEY, SABRI ERGUN and R. E. WALLINE

Pittsburgh Coal Research Center, Bureau of Mines, U.S. Department of the Interior, Pittsburgh, Pa.

MOST electron microscopic examinations of coal have been made on replicas of polished, etched, or natural fracture surfaces[1-4]. Faithful reproduction of structures in such replicas may be questioned, and resolution of detail is inferior to that which may be expected in direct observation of coal specimens. Consequently, the preparation of coal sections thin enough to transmit electrons has been an important objective. Recently, workers at the Centre d'Etudes et Recherches des Charbonnages de France[5] have succeeded in cutting ultra-thin sections of soft coals, using a microtome and a diamond knife. We have adopted their procedure and succeeded in cutting sections, 500–2000 Å. thick, of coals of various ranks and hardness. Success in preparing such sections has opened up a very promising field of study involving ultra-fine structures in coals such as preserved plant cell components, pores, and possibly structural units or crystallites.

Ultra-thin sections of coal are cut with a diamond knife mounted on a microtome designed for preparing sections for electron microscopy. The sections are cut from an 8–14 mesh particle embedded in a polymerized mixture of equal volumes of methyl and butyl methacrylates. They have an area of approximately 1 mm.^{2}. When cut the sections float out on a liquid surface from which they are picked up on specimen screens. A detailed description of the technique of preparing these sections will be presented elsewhere[6].

The limited number of electron microscopic observations of ultra-thin sections of vitrinites made thus far have revealed interesting structural details. Interpretation of these details has been approached

cautiously because of possibilities of artefacts introduced in section preparation. One type of structure is shown in Fig. 1. This is an electron micrograph of a relatively thick section (≈ 2000 Å.) of a semi-anthracite. It shows outlines of areas resembling cross-sections of cells, with little internal detail visible. These areas have dimensions of about $3 \times 10\mu$. The manner in which such a cell structure might be preserved in coal is illustrated in Fig. 2[7]. Compression of the original plant cell form can result in the type of structure shown, to which the areas in Fig. 1 bear a striking resemblance. Such structures have been seen in electron micrographs of replicas of etched coal surfaces[1], but the dimensions were about $5 \times 50\mu$. Turner[8] has shown cells in anthracite averaging about $16 \times 33\mu$, and Raistrick and Marshall[9] have shown relatively uncompressed cells, in coals of unspecified rank, ranging upwards from 30μ in diameter. Thus, the areas of Fig. 1 seem to be considerably smaller than the normal cell sizes seen in coal. However, these differences in size are possible and the pattern is so well-defined that it probably represents an authentic structure. Structures of this kind appear to become prominent in the thicker ranges of these ultra-thin sections. This may be due to distortion of the structure because of compression in the thinner sections or to greater contrast in the thicker ones.

Another kind of structure similar to that of Fig. 1 is shown in Fig. 3. This was seen in a section of high-volatile *A* bituminous coal from the Pittsburgh bed. Here, too, there are some of the characteristics of a cell structure. These units average about $\frac{1}{2} \times 2\mu$, about a fifth as large as those in Fig. 1. Variations of this pattern also appear in several other coals. The appearance of this structure may have been determined largely by stresses operating during the cutting process. However, even if this were the case, the strains contributing to this pattern must have been conditioned by some repetitive inhomogeneity in the coal substance, for this pattern is not always obtained, it does not always cover the whole section, and it is not restricted to the middle or to the edges of the sections. It may be premature to accept the observed pattern as a definite structure; nevertheless, it could be regarded as an indication of some basic periodicity in the coal make-up.

Another type of structure seen in several vitrinites of different rank is shown in Fig. 4. This appears to be a very fine fibrillar structure with recurring units less than $0\cdot 1\mu$ in width. A fibrillar structure similar to, but coarser than, this has been seen in an ultra-violet light photomicrograph of a delignified cell wall of western hemlock[10]. It has been suggested that the cell walls of wood consist of interpenetrating systems of cellulose and lignin. Although coal is believed to contain little cellulose, it is possible that the fibrillar structure of wood is preserved in coal. However, this apparent structure may be an artefact introduced in the section during the cutting process. Its prevalence throughout the sections of this coal and several other coals favours this suspicion. An authentic interpretation must await further examination.

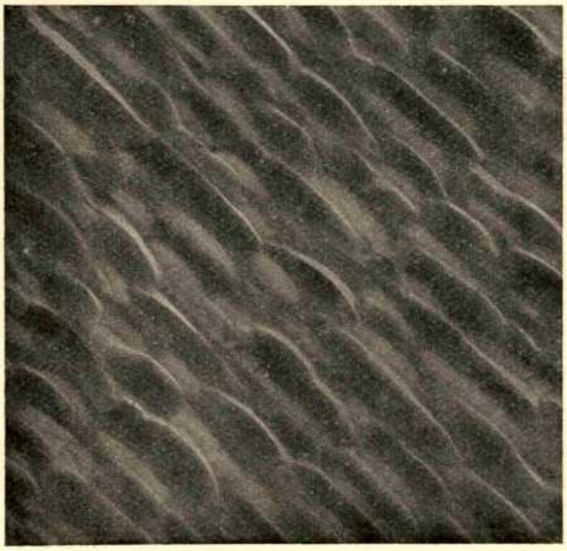

Fig. 3. Electron micrograph of structure in an ultra-thin section of a high-volatile *A* bituminous coal (× *c*. 7,500)

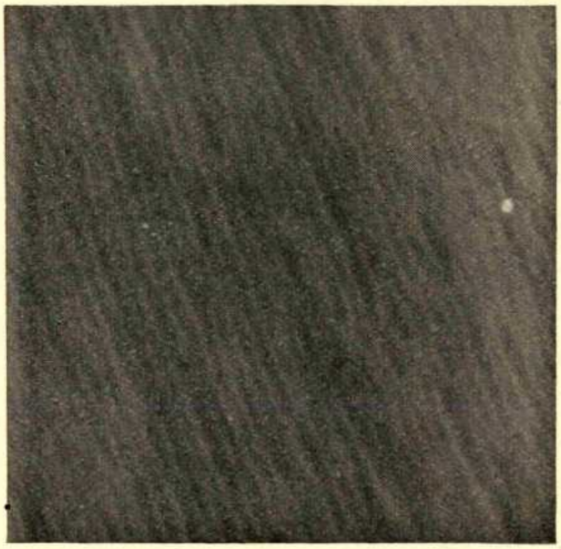

Fig. 4. Electron micrograph of structure in an ultra-thin section of a high-volatile *C* bituminous coal (× *c*. 22,500)

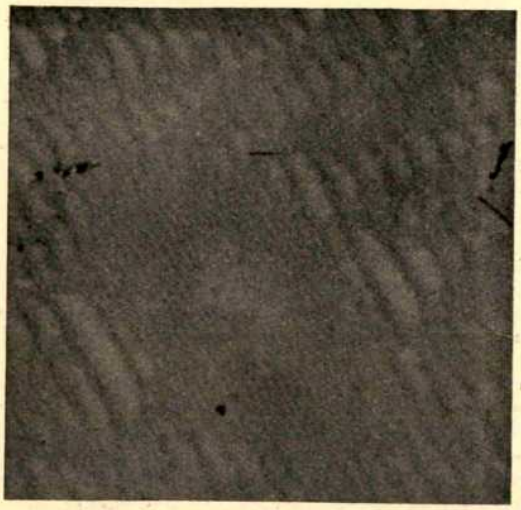

Fig. 5. Electron micrograph of structure in an ultra-thin section of an anthracite (×c. 7,500)

Fig. 5 shows an ultra-thin section of an anthracite. Three features are evident in this electron micrograph: an irregular pattern of thin areas surrounding an oval portion with a central thin area, and an overall background of striæ. The significance of the first two features with regard to coal structure is not readily evident, but it seems highly unlikely that the oval area and others similar to it could be preparation artefacts. They may be remnants of resin globules. The striæ, which persist throughout this section, are no doubt similar to those observed in Fig. 4 and, as discussed there, may or may not have structural significance.

It may be readily inferred from the foregoing discussions that interpretations of electron micrographs of these ultra-thin sections are far from conclusive. However, these preliminary results and comments are presented here as a stimulus to further studies of the physical fine structure of coals.

POISONING AND SIGN REVERSAL OF PERMSELECTIVE MEMBRANES

By Dr. FRANCIS de KŐRÖSY

Negev Institute for Arid Zone Research, Beer-Sheva, Israel

WHENEVER the counterions of a permselective membrane are held firmly to the fixed ions of the membrane, its conductivity decreases[1], and as a part of the fixed charge is neutralized the permselectivity of the membrane decreases also. The higher the electric charge of the counterions, the more firmly are they attached to the fixed sites. George, Rosenberg and Potter[2] even found that the transference number of Th^{+4} ions sank below 0·5—that is, the sign of permselectivity was reversed—when a cation-selective membrane was placed between two Th^{+4} solutions. In this experiment the Th^{+4} functioned both as 'poison' and as an indicator of 'poisoning'; it was the reduced mobility of these ions in the membrane that gave rise to low cationic transference.

I wanted to see whether the membrane could be poisoned to an extent that it became reversed even against ions which in themselves were not poisonous to it. Membranes were immersed between two solutions of potassium chloride of different concentration; here the mobility of K^+ and Cl^- was certainly the same. I then added equal amounts of 'poisoning' ions to both sides, so that there was no concentration gradient of these ions between the two sides. They served only to poison the membrane, while the potassium chloride indicated the degree of poisoning. As soon as the total charge of firmly bound counterions equals the sum total of the charge of fixed membrane-ions, the permselectivity of the membrane becomes zero, and, as the charge of bound counterions increases further, the sign of charge of the membrane changes and its permselectivity is reversed.

I worked with membranes made of parchment impregnated and cured with a phenolsulphonic acid-formaldehyde or with *N*-acetic acid-pyridinium-phenolformaldehyde resin. Permselectivity was generally determined by measuring the e.m.f. across the membrane between two potassium chloride solutions of different concentration which contained the same concentration of poison on both sides. In one experiment where permselectivity had been reversed by Th^{+4} ions I confirmed the sign reversal in a Hittorf transference-number experiment in $N/10$ potassium chloride (containing 0·008 N thorium chloride) and found a Cl^- transference number of 0·6 instead of nearly zero in pure potassium chloride.

Up to now I have found three ions which induce sign-reversal in these systems: Th^{+4}, $Fe(CN)_6^{-3}$ and $Fe(CN)_6^{-4}$. Equilibration of the systems was slow, ranging from about ½ hr. with $Fe(CN)_6^{-3}$ to about ½ day with Th^{+4}, being slower at low poison concentrations. It was reversible with the complex cyanides but not entirely reversible with Th^{+4}: though the sign of permselectivity changed back to normal in pure potassium chloride, the original e.m.f. value never returned.

Fig. 1 shows the poisoning curves of the $N/1 : N/2$, $N/10 : N/20$ and $N/100 : N/200$ potassium chloride systems with increasing amounts of $K_3[Fe(CN)_6]$. The points where the e.m.f. disappears are at $1{\cdot}5 \times 10^{-3}$, $1{\cdot}5 \times 10^{-2}$ and $1{\cdot}5 \times 10^{-1}$ poison normality respectively. This is exactly proportional to the three potassium chloride concentrations. The close agreement may be partly fortuitous, but it demonstrates that there is a competition between Cl^- and $Fe(CN)_6^{-3}$ for the active sites of the membrane according to the law of mass action. The membrane capacity was 0·55 m.equiv./gm. At the three respective concentrations

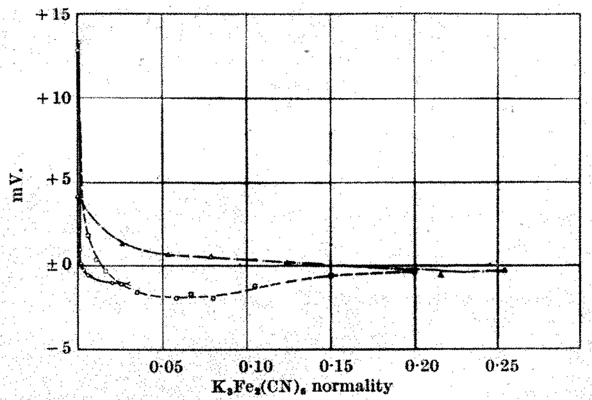

Fig. 1. Changes in e.m.f. due to adjusting the $K_3/Fe(CN)_6$ normality on both sides of an anion-selective membrane to the value given by the abscissa

Membranes between 0·010 *N* and 0·005 *N* (○), 0·10 *N* and 0·05 *N* (□) and 1·0 *N* and 0·5 *N* potassium chloride (△)

where the e.m.f. was zero, the membrane was blotted between filter paper and was found to contain 0·63, 0·57 and 0·47 m.equiv./gm. $Fe(CN)_6^{-3}$ respectively. It was not possible to distinguish between 'site-bound' and 'immigrant' counterions, but their concentration within the membrane was high and nearly the same whenever sign reversal occurred.

Permselectivity at high potassium chloride concentration is smaller than at low because of the Donnan equilibrium. The fact that the *N*/10 : *N*/20 curve shows a minimum of −2mV. at 5×10^{-2} poison normality may be due to the fact that progressive addition of the same amount of $K_3Fe(CN)_6$ to both sides decreases the ratio of ionic concentrations between the two sides and it is this ratio which determines the e.m.f. according to the Nernst equation. At high poison concentration the e.m.f. is swamped.

Increasing the potassium chloride concentration on both sides works competitively against poisoning according to Fig. 1. But a reversed e.m.f. may either grow or decrease if the potassium chloride concentration on the concentrated side is increased. It grows in the reversed direction if the poisoning ion is attached so firmly to the resin that only slight competition of potassium chloride occurs. Then the poisoning remains but the ratio of potassium chloride across the membrane increases, and hence the reversed e.m.f. increases also. Two such curves with Th^{+4} as poisoning ion are shown in Fig. 2. On the steeper curve, where the poison concentration and the potassium chloride ratio were both high, the considerable reversed e.m.f. of −19 mV. was attained.

The opposite effect is observed if the competitive influence of potassium chloride overrides its effect on the concentration ratio, as often with the complex cyanides. In such cases, the poison concentration in the membrane evidently decreases on the side towards the more concentrated potassium chloride as more potassium chloride is added, in spite of the fact that the concentration of the poison ion is the same on both sides. The resulting e.m.f. may hence decrease if it was reversed and even change back and increase in the normal direction.

It could be postulated that sign reversal is due to difference in the activity of poisoning ions on the two sides: though their concentration is the same, their activity is less in the more concentrated potassium chloride solution. This difference in activity could override the potassium chloride activities and be the cause of sign reversal. Calculations using the Debye–Hückel formula showed, however, that this hypothesis can be practically excluded for Th^{+4} poisoning and is very improbable with the complex cyanides. Difference in Th^{+4} activity would, for example, account only for a reversed e.m.f. of 0·4 mV. at a point of Fig. 2 where actually 15 mV. was observed. It is certain that the sign of the charge bound to the membrane has been reversed.

Al^{+3}, Fe^{+3}, Cu^{+2}, Ca^{+2}, Mg^{+2}, hexamethonium^{+2}, *N*,-*N*-tetramethyl-pyrazolidinium^{+2}, 1,2,3-*tris*-triethylammoniumethoxybenzene^{+3} ('Flaxedil'), HPO_4^{-2} and $O_3P.CH_2.PO_3^{-4}$ ions have been examined also on the same membranes in the same set-up. None of them was sufficiently active as poison to reverse the e.m.f. between *N*/10 : *N*/20 potassium chloride, though Al^{+3} seemed to reach this point within the limits of error (0·2 mV.). Fe^{+3} lowered the permselectivity without reaching zero e.m.f. The other three metal ions and the organic cations were scarcely active at all except that they swamped the e.m.f. by decreasing the ionic ratio. In the experiments of George *et al.*[2], however (that is, without potassium chloride), when only the active ions were present, a sign reversal was observed between *N*/1 : *N*/2 calcium chloride and *N*/1 : *N*/2 magnesium chloride solutions.

It is interesting to note that the three isolated single charges of 'Flaxedil' and the two double charges on the methanediphosphonic ion were not effective, though they gave the total charge of 3 and 4 respectively to their ions. This is probably due to the fact that the charge is spread out in space and not concentrated enough to be active in Coulomb attraction.

The physiological implications of this poisoning and the sign reversal effect are obvious. The small amount of 'poison' necessary to change the potential of, say, a

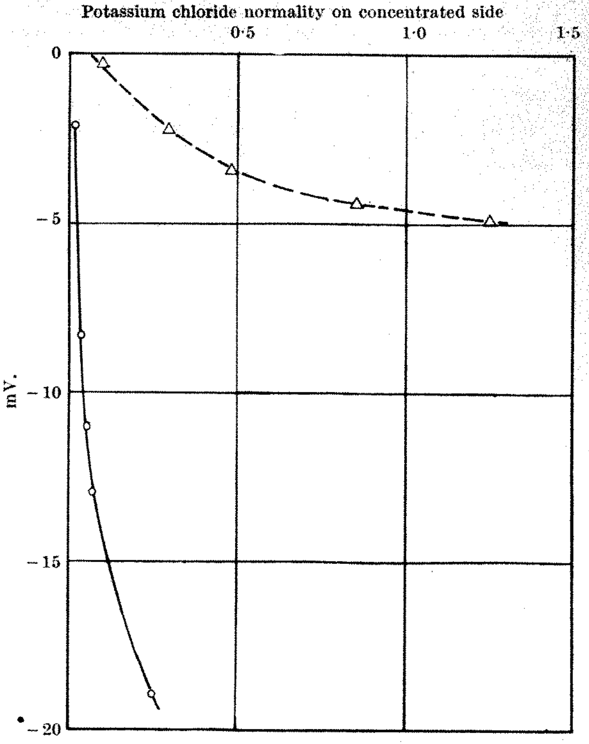

Fig. 2. △, Th^{+4} normality on both sides, 0·038 *N*, potassium chloride normality on dilute side, 0·06 *N*; ○, Th^{+4} normality on both sides, 0·079 *N*, potassium chloride normality on dilute side, 0·006 *N*

nerve ending might be generated by some physiological process and the short circuit could then well travel along the whole fibre. The active volume of such a physiological membrane is very small and the amount of poison necessary very small also, especially bearing in mind that specificity may increase its sensitivity compared with our crude artificial membranes.

I am indebted to Prof. F. Bergmann and to T.E.V.A., Ltd., Jerusalem, for the gift of hexamethonium salts, and to SPECIA S.A., Paris, for the gift of 'Flaxedil'.

CONTROL OF SPECIFICITY IN HÆMOGLOBIN SYNTHESIS

By Dr. J. BISHOP*, Dr. G. FAVELUKES†, Prof. R. SCHWEET and Dr. E. RUSSELL‡

Department of Biochemistry, College of Medicine, University of Kentucky, Lexington

In recent years much attention has been focused on the control of specificity in protein synthesis. In general terms it is clear that the ultimate control of specificity resides in the genetic material of the cell. The mechanism whereby the information of the genetic material is translated into the unique amino-acid sequence of the finished protein molecule is generally believed to involve ribonucleic acid. The present article presents results which demonstrate that a particular cell structure, the ribosome, directly controls the amino-acid sequence of the protein which it synthesizes.

Recent work in this laboratory[1-3] has shown with some clarity that in the reticulocyte the site of synthesis of the hæmoglobin molecule is the ribosome. This, together with the large size of the ribosome[4], might suggest that the amino-acid sequence of the hæmoglobin molecule is determined by the structure of the ribosome. The possibility remains, however, that the amino-acid sequence is not determined by the ribosome alone, but by the ribosome acting in conjunction with other cytoplasmic factors. In this respect it is important to note that soluble cytoplasmic factors are known to be implicated in protein synthesis. A specific activating enzyme[5] and a specific soluble ribonucleic acid[5] are thought to be required for the incorporation into protein of each individual amino-acid. Furthermore, it has been suggested[5] that it is a correspondence between the structure of the soluble ribonucleic acid molecule to which the amino-acid is bound, and a specific structural site on the ribosome, which ensures that the amino-acid is incorporated into protein in the correct position. The question to be raised in the present article is whether or not these soluble factors, and in particular soluble ribonucleic acid, play a more direct part in the determination of the amino-acid sequence of hæmoglobin. This work was made possible by the demonstration[1,2,6] of the synthesis of soluble hæmoglobin in a reticulocyte cell-free system.

A first approach to the question was made using ribosomes and soluble fractions from reticulocytes of two species, rabbits and mice. The *C57BL/6J* inbred mouse strain shows a single hæmoglobin fraction by chromatography on 'Amberlite *CG*-50' type II resin with the sodium phosphate buffer number 2 of Allen *et al.*[7]. Under the same conditions rabbit hæmoglobin is strongly bound to the resin, but can be eluted with a two-fold concentration of the same buffer. Thus almost quantitative separation of these two hæmoglobins is possible.

Reticulocytosis was induced in rabbits as described elsewhere[1,3]. Mice were made reticulocytic by the subcutaneous injection of 0·1 ml. of 0·8 per cent phenylhydrazine daily for six days. Twice-washed ribosomes and supernatants were prepared from reticulocyte lysates as described elsewhere[1,3]. Rabbit ribosomes (40 mgm. dry weight) were incubated with 0·6 μmole of uniformly labelled ^{14}C-L-leucine (7 mc./mmole) in a total volume of 8·4 ml. under conditions described[1,3] except that isolated soluble ribonucleic acid and enzyme were replaced by a mixture of 30 mgm. each of the soluble supernatants of both species. After 40 min. of incubation the ribosomes were removed by centrifugation and a hæmoglobin fraction isolated[2] from the supernatant. On chromatography on *CG*-50, 61 per cent of the radioactivity recovered was seen to be associated with

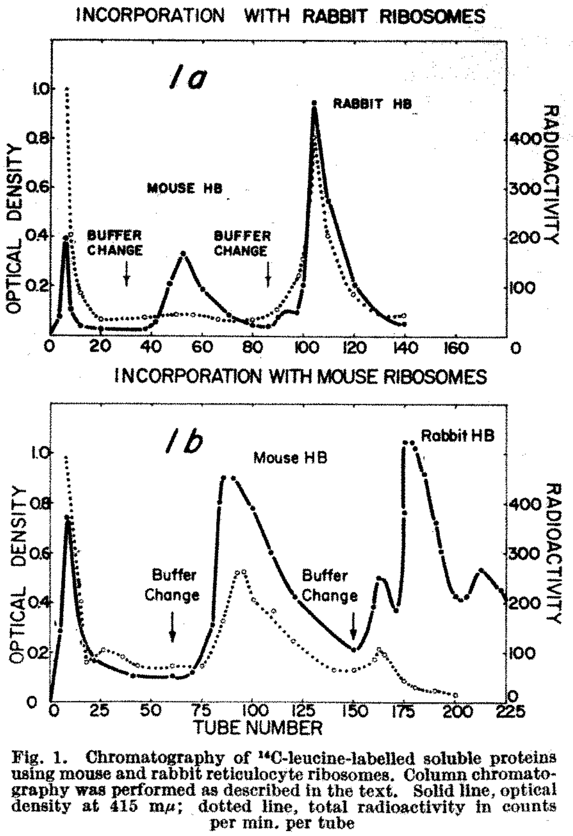

Fig. 1. Chromatography of ^{14}C-leucine-labelled soluble proteins using mouse and rabbit reticulocyte ribosomes. Column chromatography was performed as described in the text. Solid line, optical density at 415 mμ; dotted line, total radioactivity in counts per min. per tube

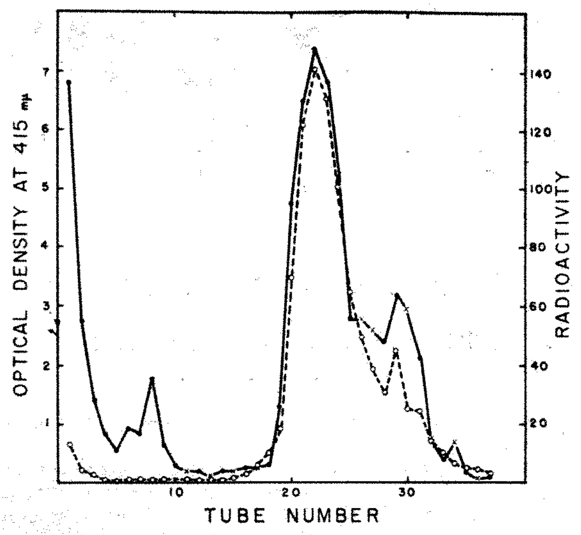

Fig. 2. Chromatography of soluble proteins after incubation of rabbit reticulocyte ribosomes with guinea pig liver ^{3}H-leucyl-ribonucleic acid. Dashed line, optical density at 415 mμ; solid line, total radioactivity in counts per min. per tube. Guinea pig liver soluble ribonucleic acid was labelled by incubation with ^{3}H-DL-leucine (150 mc./mmole) and 17 other unlabelled amino-acids, and isolated as previously described (ref. 8). Isolated ^{3}H-leucyl-ribonucleic acid (3·6 mgm.) was incubated at 37° with 18 mgm. of reticulocyte ribosomes and 42 mgm. of a reticulocyte enzyme fraction (ref. 9) plus $3 \cdot 3 \times 10^{-4}$ *M* guanosine triphosphate, 0·07 *M* potassium chloride, $3 \cdot 3 \times 10^{-3}$ *M* magnesium chloride, 0·02 *M* glutathione, and 0·033 *M tris* buffer, *p*H 7·5, in a volume of 9 ml. To increase the amount of soluble labelled protein, after 10 min. $3 \cdot 3 \times 10^{-4}$ *M* adenosine triphosphate, 0·01 *M* creatine phosphate and 0·34 mgm. of creatine kinase were added and incubation was continued for another 30 min. Ribosomes were removed by centrifugation, and the proteins precipitated with ammonium sulphate and chromatographed as described (ref. 2)

rabbit hæmoglobin, and only 5 per cent with mouse hæmoglobin (Fig. 1*a*). On the other hand, when the reciprocal experiment was performed (mouse ribosomes incubated with the mixed supernatants) 52 per cent of the radioactivity recovered was associated with the mouse hæmoglobin and only 3 per cent with rabbit hæmoglobin (Fig. 1*b*). Thus, in these experiments, the hæmoglobin synthesized was the specific hæmoglobin of the species which contributed the ribosomes. The small amount of labelled protein in the other hæmoglobin is believed to be an artefact, since in a control experiment, when labelled rabbit hæmoglobin was mixed and chromatographed with unlabelled mouse hæmoglobin, 3–4 per cent of the recovered radioactivity was found in the mouse hæmoglobin peak, while 65 per cent was found in the rabbit hæmoglobin fraction. In each experiment radioactive protein was also found in a fraction which did not partition between resin and buffer, but passed directly through the column. It is not possible to conclude from these experiments that soluble components, such as soluble ribonucleic acid, have no function in sequence determination. For example, since soluble ribonucleic acid from both species was always present (and, besides, ribosomes cannot be completely freed from soluble ribonucleic acid[3]), it is possible that soluble factors contain sequence information, but that ribosomes can react only with soluble factors from the same species. However, the experiments do demonstrate that the reticulocyte cell-free system synthesizes a specific protein, and that the ribosome must play an important part in the determination of the amino-acid sequence of this protein.

In order to preclude the participation of endogenous soluble ribonucleic acid, experiments were performed with rabbit reticulocyte ribosomes using labelled amino-acyl-ribonucleic acid rather than free ^{14}C-amino-acid as starting material. Guinea pig liver ^{3}H-leucyl-ribonucleic acid was used since it differed in both organ and species from rabbit reticulocyte soluble ribonucleic acid. A large-scale incubation of the ^{3}H-leucyl-ribonucleic acid and reticulocyte ribosomes was required to provide sufficient labelled soluble protein for chromatography (Fig. 2). The results show that much of the radioactivity was recovered with the hæmoglobin fraction and the labelling of protein fractions using this guinea pig liver amino-acyl-ribonucleic acid was similar to that obtained with rabbit reticulocyte soluble ribonucleic acid. These experiments demonstrate the formation of labelled rabbit hæmoglobin from unrelated amino-acyl-ribonucleic acid, indicating that the determination of amino-acid sequence is controlled by the ribosome. In a similar manner, labelled hæmoglobin has been isolated after incubation of *E. coli* ^{14}C-amino-acyl-ribonucleic acid and reticulocyte ribosomes (von Ehrenstein, G., and Lipmann, F., private communication).

It was previously shown[1] that starting with free amino-acids labelled with carbon-14, the ratios of various amino-acids incorporated corresponded to the composition of crude globin. This was taken as evidence that the incorporation represented hæmoglobin synthesis. The pattern of incorporation of different amino-acids should be a function of the ribosome if amino-acid sequence is determined by the ribosome. Ratios of amino-acids incorporated starting with labelled guinea pig liver amino-acyl-ribonucleic acid were therefore studied. In each experiment, the ribonucleic acid was labelled with two amino-acids. One was ^{3}H-leucine (150 mc./mmole) and the other was either ^{14}C-valine or isoleucine or lysine (uniformly labelled, 6–10 mc./mmole). Rabbit reticulocyte ribosomes treated with deoxycholate were prepared as previously described[9]. Guinea pig liver ribosomes treated with deoxycholate were prepared in the same manner, but with twice the concentration of deoxycholate. The isolated labelled amino-acyl-ribonucleic acid was incubated in the standard way[10] with either 2·5 mgm. of reticulocyte or 3·7 mgm. of liver ribosomes for 3 min. The reaction mixtures were precipitated by the addition of 10 ml. of acid acetone (6 ml. of 4 *N* hydrochloric acid per litre of acetone) and the protein was washed as previously described[1,3]. The dried powders were each dissolved in 1 ml. of hyamine base and counted in the Packard 'Tricarb' liquid scintillation counter using a naphthalene, xylene and dioxane mixture[9]. The amounts of ^{14}C- and ^{3}H-amino-acids incorporated in each tube were calculated by the method of differential equations[11] using known mixtures of the labelled amino-acids as standards. The relative amounts of the amino-acids transferred to protein in the presence of rabbit reticulocyte ribosomes (Table 1) did not resemble the composition of the amino-acyl-ribonucleic acid, but that of rabbit globin. Very similar results were obtained when the incorporation of labelled free amino-acids was examined in the complete[3] reticulocyte cell-free system. The results with leucine and isoleucine were quite different for guinea pig liver and reticulocyte ribosomes, six times more isoleucine being incorporated into protein by the liver ribosomes. Thus, the amounts of different amino-acids incorporated appear to be controlled by the ribosome, as part of the selection needed to build a specific peptide chain.

Table 1. TRANSFER OF AMINO-ACIDS FROM GUINEA PIG LIVER AMINO-ACYL-RIBONUCLEIC ACID (RNA) TO RIBOSOMES

Amino-acid	Composition of amino-acyl-RNA	Transferred from amino-acyl-RNA		Globin composition*	Incorporated from free amino-acids†
		G. pig liver ribosomes	Reticulocyte ribosomes		
Leucine	100	100	100	100	100
Isoleucine	45	45	7	11	9
Valine	29	—	63	77	77
Lysine	63	—	71	67	—

Results are expressed as moles of each amino-acid per 100 moles of leucine.

* Microbiological assay of crude rabbit globin (ref. 12).

† 40 min. incubation in the complete cell-free system (refs. 1 and 3), all components from reticulocytes.

From this it might be thought that rabbit reticulocyte amino-acyl-ribonucleic acid and guinea pig liver amino-acyl-ribonucleic acid are completely equivalent in their action. That this is not so was demonstrated by the following experiment. ^{3}H-leucyl-ribonucleic acid was prepared from guinea pig liver as above. ^{14}C-leucyl ribonucleic acid was prepared from isolated reticulocyte soluble ribonucleic acid. To overcome the interference which might be caused by the different relative amounts of amino-acids carried by the two types of soluble ribonucleic acid, by differences in the extent of labelling, or by other unknown differences between the preparations, the two leucyl-ribonucleic acids were mixed and then incubated with guinea pig liver or rabbit reticulocyte ribosomes. 0·2 mgm. of guinea pig liver amino-acyl-ribonucleic acid (0·41 mμmoles ^{3}H-leucine) and 0·4 mgm. of rabbit reticulocyte amino-acyl-ribonucleic acid (0·42 mμmoles ^{14}C-leucine) were incubated for 3 min. at 37° with either 2·5 mgm. of reticulocyte deoxycholate-ribosomes or 3·7 mgm. of guinea pig liver deoxycholate-ribosomes under conditions previously described[10]. The incubation mixtures were washed up and counted in the liquid scintillation counter as described here. Table 2 presents the results of two experiments, showing that more leucine was transferred to guinea pig liver ribosomes from guinea pig liver amino-acyl-ribonucleic acid (^{3}H-leucine) than from reticulocyte ribonucleic acid (^{14}C-leucine) and vice versa. It appears that while no function was found for amino-acyl-ribonucleic acid compounds in determining the nature of the protein synthesized, some species differences may exist in soluble ribonucleic acid structure which result in a greater rate of transfer with ribosomes of the same species.

All the results given here rest on the conclusion that labelling of hæmoglobin represents a limited synthesis of this protein. The evidence for this point of view has been discussed[2,6]. However, the final test of the synthesis of a specific protein is the demonstration that the amino-acids are incorporated in their correct locations in the polypeptide chain. This has not yet been shown in any cell-free system. The first stages of such an investigation have provided further evidence supporting the conclusions given here. Three types of hæmoglobin, each labelled with radioactive leucine, were prepared and 'fingerprinted' as described below and the distribution of the radioactive leucine in various peptides determined.

Table 2. TRANSFER OF LEUCINE FROM MIXED AMINO-ACYL-RIBONUCLEIC ACID (RNA)

Source of ribosomes	Amount of transfer		Ratio*
	Rabbit reticulocyte ^{14}C-leucyl-RNA mμmoles	G. pig liver ^{3}H-leucyl-RNA mμmoles	
Rabbit reticulocytes	0·047 0·049	0·043 0·041	1·12 1·21
Guinea pig liver	0·026 0·024	0·035 0·034	0·74 0·71

* The ratio is the amount transferred from reticulocyte leucyl-RNA divided by that from liver leucyl-RNA.

^{3}H-leucyl-ribonucleic acid was prepared from guinea pig liver using ^{3}H-leucine at a specific activity of 3,000 mc./mmole and 1·2 mgm. of this isolated amino-acyl-ribonucleic acid was incubated with 7·5 mgm. of reticulocyte ribosomes for a total of 40 min. The hæmoglobin fraction was isolated by ammonium sulphate fractionation as described here. A 'uniformly labelled' hæmoglobin was prepared from 2 ml. of intact rabbit reticulocytes incubated with 2 mgm. of DL-leucine-1-^{14}C (specific activity 10·3 mc./mmole) for 6 hr. under conditions previously described[2]. Equal amounts of the two hæmoglobins were mixed and digested with trypsin[13]. 1·25 mgm. of the digest was applied to a sheet of Whatman No. 3 mm. filter paper and fingerprinted by the technique of Katz *et al.*[14] except that butanol : pyridine : water (4 : 3 : 3) was substituted as the chromatographic solvent. The paper was sprayed lightly with 0·025 per cent ninhydrin in ethanol and developed for 10 min. at 80° in a water-saturated atmosphere. The peptide spots were cut out and eluted[15] and the eluates were dried down in 20 ml. counting vials. The material was counted in the liquid scintillation counter as described here but with the omission of hyamine from the counting mixture. Under these conditions tritium and carbon were counted with efficiencies of 10 and 90 per cent, respectively. A third hæmoglobin fraction was prepared by incubation of reticulocyte ribosomes for 20 min. with free ^{3}H-leucine (3,000 mc./mmole) as described elsewhere[1,3] and treated in an identical manner. The assignment of peptides to alpha and beta chains was based on separation of these chains on '*CG-50*' columns in an acid–urea gradient[16].

Table 3 shows the relative amounts of labelled leucine found in the peptides of the alpha (valyl–leucyl) chain of rabbit hæmoglobin, and in several regions of the fingerprints which did not show ninhydrin staining. Similar results were noted in the beta-chain peptides. It is seen that the pattern of labelling in the three types of labelled material is similar. The peptides which carry labelled leucine after the incubation of intact reticulocytes also carry labelled leucine from the cell-free labelling experiments, while the peptides which were not labelled in the whole cell (presumably due to the absence of leucine) were not labelled in either cell-free system. In addition, a number of blanks which did not show ninhydrin colour were counted and showed a low level of activity. These results offer convincing evidence for the synthesis of hæmoglobin from heterologous amino-acyl-ribonucleic acid when rabbit reticulocyte ribosomes are used, and also for the validity of previous conclusions which assumed the synthesis of hæmoglobin in the cell-free system. For example, the validity of amino-acyl-ribonucleic acid as an intermediate in hæmoglobin synthesis is established. It should be noted that the exact percentages of radioactivity in the ^{14}C-labelled peptides (used as internal controls of recovery) vary between the two fingerprints, probably due to variations in elution from the paper.

The reticulocyte ribosome, rather than the transfer-ribonucleic acid, therefore, is responsible for the correct assembly of the hæmoglobin molecule. Which component of the ribosome carries the information remains to be determined. Treatment of ribosomes with tiny amounts of ribonuclease which did not release any detectable nucleotide material[3,17] resulted

Radioactivity is expressed as the percentage of the total radioactivity in all peptides. 0 denotes less than 0·1 per cent.

† Fingerprint 1 is the mean of two experiments, fingerprint 2 the mean of three.

* 12 blanks taken in close proximity to the 12 ninhydrin-stained regions showed a total of less than 9 per cent of the recovered radioactivity in each case.

in a total loss of incorporating ability. Thus, it is likely that it is the ribonucleic acid of the ribosome which is important, as originally suggested by Crick[18]. Ribosomal ribonucleic acid, however, may consist of many components, some or all of which may have functions in protein synthesis unrelated to sequence determination. At the moment, a considerable amount of interest centres on a particular type of ribonucleic acid having a base composition related to that of deoxyribonucleic acid[19]. The work reported here makes it possible to examine directly the components, and the structural aspects of these components, which control the assembly of amino-acids in the correct sequence of the specific protein.

Note added in proof. Recent work on the 'messenger' ribonucleic acid of *E. coli* suggests that it is destroyed and replaced continuously in bacterial ribosomes during protein synthesis[20]. The species of hæmoglobin synthesized by rabbit reticulocyte ribosomes has been changed by incubation with soluble components from other species[21], under different experimental conditions from those used here. Thus, while specificity information may be added from soluble components, this was not essential for hæmoglobin synthesis in the experiments reported here. It is suggested that specificity information is therefore more stable in reticulocyte than in bacterial ribosomes, and that rapid 'turnover' of this information may not be an obligatory feature of protein synthesis.

This investigation was aided by grants to Prof. R. Schweet from the National Science Foundation and the National Institutes of Health, and to Dr. E. Russell from the National Institutes of Health.

ANABOLIC AGENTS AND HISTAMINE METABOLISM

By DR. K. S. KIM

Department of Physiology, University of Malaya in Singapore

TESTOSTERONE propionate has been shown to reduce urinary histamine output in rats[1,2,3]. Using new anabolic steroids with low androgenic activity, an attempt has been made to determine whether the androgenic or anabolic effect of testosterone is related to histamine metabolism. Various anabolic agents were compared with testosterone propionate in their effects on the excretion of free histamine, potassium, sodium and total nitrogen in rat urine.

Female albino rats weighing 140–220 gm. were individually placed in metabolism cages and fed 'Complan' diet (Glaxo Laboratories), a blend of dried skimmed milk, arachis oil, calcium caseinate, maltodextrin, cane sugar, essential minerals and vitamins.

During the examination of urinary nitrogen, potassium and sodium, food intake was kept constant by giving either 8 gm. 'Complan' or 8 gm. 'Complan' plus 1 gm. glucose daily depending on body-weight. 8 gm. 'Complan' provides 398 mgm. nitrogen, 2·2 mmole potassium, 1·58 mmole sodium and 36 calories. Tap water containing 0·013 mmole/l. of potassium and 0·04 mmole/l. of sodium was given *ad lib.*

For a test of androgenic activity of testosterone and 'Durabolin' (Organon), castrated male rats weighing 285–385 gm. were used and were fed normal laboratory rat pellets *ad lib.*

Urine was collected in acid (1·5 ml. 1 *N* hydrochloric acid in each collection vessel) over a 24-hr. period. Collection funnels and metabolism cages were sprinkled with distilled water (30–60 ml.). The combined volume of urine and washing fluid was measured and filtered through Whatman paper No. 1. Aliquots of filtrate representing 2- to 4-hr. samples were taken and neutralized. Final volume was made up with Tyrode solution to an appropriate concentration of histamine for assay.

Urinary free histamine was estimated by the biological assay method described elsewhere[2] and expressed in terms of the base.

Total nitrogen was determined by the micro-Kjeldahl method and sodium and potassium by the EEL flame photometer model *A*.

Table 1. EFFECT OF 'DURABOLIN' AND TESTOSTERONE PROPIONATE ON URINARY HISTAMINE OUTPUT

Group	Av. body-wt. (gm.)	Dose (mgm.)	Average free histamine output/μgm./rat/day				Av. body-wt. gain (gm.)
			Control	Day after injection 4th	7th	11th	14th
Control	*(3) 163	—	32	36	43	44	20
'Durabolin'	(4) 180	1·25	31	13	2	3	38
Testosterone propionate	(3) 158	1·25	33	32	37	30	17

*No. of rats used.

Anabolic substances were all administered intramuscularly. Testosterone propionate ('Testoviron', Schering), 19-nor-androste-nolone phenylpropionate ('Durabolin', Organon) and 17α-methyl-17β-hydroxy-androsta-1, 4-diene-3-one ('Dianabol', Ciba) were used as steroid anabolic agents. The effect of growth hormone ('Somar-*A*', Armour) was also examined as an example of a different class of anabolic agents.

A preliminary examination showed that 'Durabolin', a powerful anabolic agent with low androgenic activity, reduced the output of free histamine (Table 1). These results indicated the existence of close relationship between anabolic mechanism and histamine metabolism. Therefore the effects of various anabolic agents on the excretion of free histamine were examined. The results are shown in Fig. 1.

'Durabolin' was the most potent substance in reducing urinary histamine output, and is followed by testosterone propionate. Although 1·25 mgm. testosterone propionate had no significant effect on the urinary histamine as shown earlier (Table 1), a larger dose (2·5 mgm.) produced a reduction (Fig. 1). Reduction of histamine output by 'Durabolin' lasted on the average for 40 days. 'Dianabol' was given in a dose of 1 mgm./rat/day for three consecutive days as it was not very effective in a single dose (1–2·5 mgm.). The effect of 'Dianabol' at this dose-level was similar to that produced by testosterone propionate (2·5 mgm.). Growth hormone was given to two normal females and to two ovariectomized females ; but since the effects observed were similar, both results were pooled to construct the figures shown in Figs. 1 and 2. Histamine excretion reached a minimum after the third injection and showed no further decrease after the fourth and the fifth injections. Neither continued injection for 7 days nor increased dose (2 mgm./day for 3 days) produced any further decrease. 'Heparin' (Leo) (2·5 mgm./day for 5 days) was also tested as it was reported to have an anabolic effect[5], but no significant effect was noted (Fig. 1).

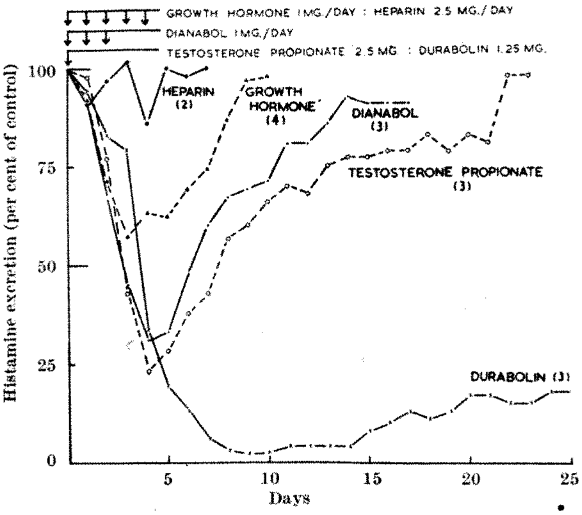

Fig. 1. Effect of anabolic agents on the urinary excretion of free histamine expressed as percentage of control-level (average value of daily histamine excretion during the last three days prior to the administration of drugs). The number in parentheses under the names of test substances indicates the number of rats used

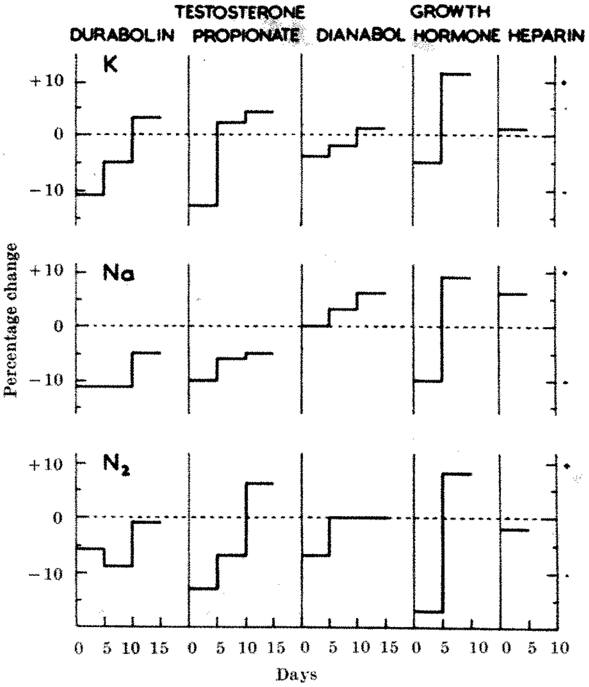

Fig. 2. Effect of anabolic agents on the excretion of urinary potassium, sodium and total nitrogen expressed as percentage change from the control-level. The investigation shown in Figs. 1 and 2 are concurrently carried out on the same rats

Anabolic substances are known to produce a retention of nitrogen, potassium and also sodium[4]. An attempt was therefore made during the investigation illustrated in Fig. 1 to examine whether the anabolic effect as reflected in the excretion of these substances is related to the potency in decreasing urinary histamine output. As shown in Fig. 2, 'Durabolin' showed a prolonged activity in retaining nitrogen, potassium and sodium, although testosterone propionate (2·5 mgm.) had a stronger effect during the first 5-day period. These effects were small with 'Dianabol'. Growth hormone produced a profound anabolic effect during its administration but showed rebound recovery over the control-level on discontinuation. 'Heparin' showed no significant effects indicating the absence of an anabolic effect.

Although the anabolic activity as reflected in the excretion of nitrogen, potassium and sodium appeared to be similar (Fig. 2), 'Durabolin' increased the body-weight more than testosterone propionate, as shown in Table 2. These rats, two in each group, were taken from the series illustrated in Fig. 1. This finding was further supported by the results shown in Table 1 although food intake was not controlled in this work. It should be noted that the absence of anabolic effect of testosterone propionate (1·25 mgm.) as reflected in gain in body-weight coincided with the absence of histamine reducing effect (Table 1).

Fifteen males, castrated 5 months previously, were divided into three groups—control, testosterone-treated and 'Durabolin'-treated. Testosterone- and

Table 2. EFFECT OF 'DURABOLIN' AND TESTOSTERONE PROPIONATE ON GAIN IN BODY-WEIGHT

	Dose (mgm.)	Daily food intake 'Complan' (gm.)	Initial body-weight (gm.)	Wt. gain in 26 days after injection (gm.)
Control	—	8	160	15
		8	165	10 Av. 12·5
'Durabolin'	1·25	8	165	30
		8	177	21 Av. 25·5
Testosterone propionate	2·5	8	175	12
		8	167	23 Av. 17·5

'Durabolin'-treated groups received two 1 mgm. doses of the respective drugs at an interval of 1 week, and the rats were killed one week after the last injection. As shown in Table 3, there was no appreciable effect on the weight of the kidneys; but significantly different effects were noted on the weight of the seminal vesicles. This result confirms the low androgenic effect of 'Durabolin' in comparison with testosterone propionate as reported by Overbeek and de Visser[6]. Therefore, it appears that the androgenic mechanism in the body is not related to histamine metabolism. Gain in body-weight was similar with 'Durabolin' and testosterone propionate.

In this work it is clearly shown that anabolic agents decrease output of urinary histamine. Evidence[2] has already been presented that testosterone propionate increases the capacity for histamine inactivation in rats. It is likely that 'Durabolin' and 'Dianabol' act by the same mechanism, the former more active and the latter slightly less active than testosterone propionate. An anabolic effect is believed to be produced by an increase in the activities of enzymes which synthesize protein. It is possible, therefore, that steroid anabolic agents may exert an effect on the output of urinary histamine through a potentiation of an enzyme system which inactivates histamine. Such an enzyme system might be common to both protein synthesis and histamine inactivation.

Table 3. EFFECT OF 'DURABOLIN' AND TESTOSTERONE PROPIONATE ON THE SEMINAL VESICLES AND THE KIDNEYS OF CASTRATED MALE RATS

Group	Initial body-wt. (gm.)	Wt. gain in 2 weeks (gm.)	Seminal vesicle (mgm.)	Kidney wt. (gm.)
Control	314 ± 10*	-14 ± 6	53 ± 17	2·09 ± 0·12
'Durabolin'	356 ± 6	25 ± 1·6	100 ± 9	2·16 ± 0·09
Testosterone propionate	356 ± 11	24 ± 5·1	237 ± 44	1·94 ± 0·04

*Standard error.

The anabolic effect produced by growth hormone appears to be different from that produced by steroid anabolic agents[7-10]. The anabolic effect of growth hormone showed a different time-course from the steroids tested, and produced an effect on histamine excretion (Fig. 2). This may be taken as further evidence that growth hormone and steroid anabolic agents have different sites of action. Histamine output has been shown to be affected by testosterone propionate more readily in ovariectomized rats than in normal female rats[2]. No such hypersensitivity was noted with growth hormone in ovariectomized rats.

Although the effect of 'Dianabol' on the excretion of urinary total nitrogen was much smaller than that produced by testosterone (Fig. 2), it was shown by others[11] to produce a gain in body-weight equal to that produced by testosterone propionate. Both 'Dianabol' and 'Durabolin' have been shown to have very low androgenic activities at the dose-level used in this work[6,11] (Table 3). It is reasonable to conclude that it is not the androgenic but the anabolic activity of steroid compounds that is related to histamine metabolism.

Heparin in a dose of 2·5 mgm./rat/day for 5 days failed to produce an anabolic effect (Fig. 2). It also failed to reduce histamine excretion in the urine (Fig. 1). Granitsas[5] reported the anabolic activity of heparin in normal rats. The discrepancy between the results of Granitsas and this study is not clear at present and needs further investigation.

My thanks are due to Prof. R. A. Kenney for his kind assistance in the preparation of this manuscript. 'Durabolin' (Organon), 'Dianabol' (Ciba) and 'Testoviron' (Schering) were kindly provided by local agents of the respective firms.

STAINING OF SULPHATED MUCOPOLYSACCHARIDES

By DR. I. D. HEATH
Department of Anatomy, Queen's College, Dundee, University of St. Andrews

METHODS in use at present for detecting sulphated mucopolysaccharides consist of the exhibition of metachromasia with basic dyes, and a method using colloidal iron[1]. These methods tend to be rather unspecific, and nuclear staining tends to obscure the picture.

From the work of Stacey[2] it is apparent that sulphated mucopolysaccharides are found in mast cells (heparin), cartilage ground substance (chondroitin sulphuric acid) and some mucins. In addition, they have been isolated from other sites, for example, skin and cornea.

Previous work[3] has shown that nuclear fast red (Herzberg), when prepared as a 0·1 per cent stock solution in boiling 5 per cent aluminium sulphate solution which is diluted 1 to 2 with further 5 per cent aluminium sulphate solution for use, is a highly selective stain for mast cell granules, cartilage ground substance, and some mucins in tissue sections. This work has now been extended, the earlier conclusions having been confirmed.

Test slides of pure chemical substances dissolved in 5 per cent gelatin were prepared, fixed in formalin vapour overnight and stained 5–10 min. in the dye solution. The substances used included the sulphated polysaccharides; heparin, from ox, sheep and pig, fucoidin[4], and a sulphated polyglucose, and the unsulphated polysaccharides, dextrin, dextran and starch. In addition, other known constituents of mast cells, namely, 5-hydroxytryptamine, histamine and 5-hydroxytryptophan, were used. Only the sulphated polysaccharides and heparin stained (Fig. 1*c*).

Tissues from members of all classes of vertebrates and sites, fixed in a variety of fixatives, both aqueous and alcoholic, were stained, and it was found that only those tissues which contained sulphated mucopolysaccharides reacted, for example, media or aorta, although mast cells when present in the tissues did stain. Only sections fixed in acetic Zenker failed to react in this way.

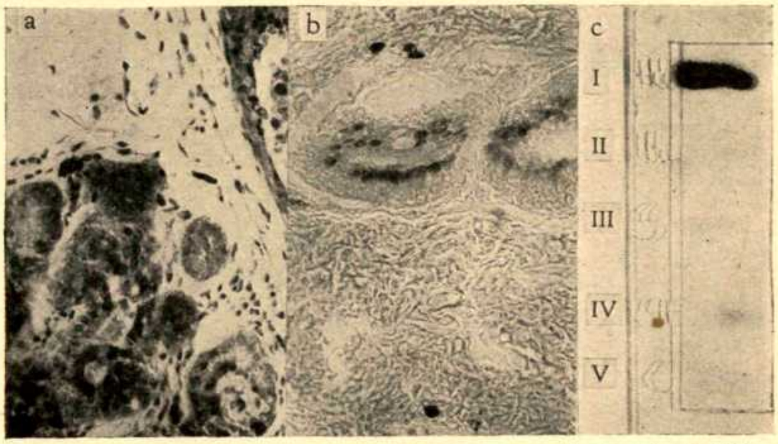

Fig. 1. (*a*) Ox trachea stained with 0·1 per cent aqueous methylene blue (×100). (*b*) An adjacent section stained with 0·1 per cent methylene blue in 5 per cent aluminium sulphate. Note only mucus and mast cells stain (×100). (*c*) Test slide of mast cell constituents in 5 per cent gelatin stained with 0·1 per cent nuclear fast red (Herzberg) in aluminium sulphate. I, heparin; II, histamine; III, serotonin; IV, 5-hydroxytryptophan; V, control gelatin blank

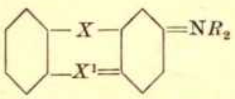
The stock solution of nuclear fast red in aluminium sulphate was buffered, using various buffers, to *p*H values between 0·5 and 7; at *p*H 7 a precipitate was formed. The *p*H did not affect the staining reaction.

These observations were extended to dyes of azo, quinone imine, phenyl methane, xanthine and phthalocyanine groups, in addition to several miscellaneous dyes, which were all prepared in the manner for nuclear fast red mentioned here. 0·1 per cent aqueous solutions were run in parallel as controls. In all, 56 different dyes were used, some of basic and some of acidic nature. The tissues used as test tissues were ox trachea and rat skin fixed in formol–dichromate (*p*H 6) and formol–calcium respectively. 6μ-sections were dewaxed, hydrated and stained for 5–30 min. in the dye solution, differentiated rapidly in 70 per cent alcohol, dehydrated in graded alcohols, cleared in xylene and mounted in polystyrene or Canada balsam.

With basic dyes prepared in aluminium sulphate solution, mast cell granules and cartilage ground substance stain deeply ortho- or metachromatically, depending on the dye used. Skin and mucin stain to a lesser extent and always orthochromatically (Fig. 1*b*). Those dyes which give the best results have the basic formula:



X = O, S, or N, X = C or N, R = CH_3 C_2H_5, etc.

The thiazines, toluidine blue and methylene blue, and the azines, neutral red and nuclear fast red, give the best results. Certain dyes give less specific reactions, staining, in addition, red blood cells, nuclei and all mucines. This is particularly noticeable with the rhodamines, but less with the phenyl methanes and dyes having large substituent groups attached to the benzene rings in the above formula, namely, cresyl fast violet, janus green. Triphenylmethane dyes tend to differentiate out rapidly and for that reason are not as satisfactory as the azines and thiazines. Basic dyes in aqueous solutions stain all the elements mentioned here, but nuclei and the cytoplasm of mucous cells stain too (Fig. 1*a*). Acidic dyes in aluminium sulphate solution stain all tissue elements deeply, including cartilage ground substance, but in aqueous solution the cartilage ground substance remains unstained, although the cell nuclei in the lacunæ stain.

In an attempt to find out what groups, if any, were specific for this reaction, sections containing sulphated mucopolysaccharides were methylated[5] and stained as mentioned. This prevented staining. Methylation has been reported to block various groups in tissue sections[5], including sulphate groups, and this seemed a possible explanation of its effect. This explanation was supported by the finding that sections containing unsulphated mucopolysaccharides, for example, umbilical cord, after sulphation[6] stained a uniform deep colour. It appears, therefore, that the sulphate groups are, in part at least, responsible for the reaction.

Equimolar concentrations of other aluminium salts, either as pure aluminium salts or as alums, were found to confer similar specificity of action on basic dyes, as did a number of salts of other metals. It appears from this that it is the cation which is responsible for the specificity of action, and by using a variety of different compounds it became apparent that only those cations which freely form co-ordination complexes confer specificity on the basic dyes.

It appears, therefore, that by preparing certain basic dyes in aluminium sulphate a highly specific stain for the detection of sulphated mucopolysaccharides in tissue sections is produced. The dye complex produced is probably a co-ordination compound of a suitable metallic cation and the dye, the reaction between the tissues and the complex being similar to mordanting in the textile dye industry.

I wish to thank Evans Medical Ltd., Bengers, Ltd., and Dr. D. M. Shepherd of the Pharmacology Department, Queen's College, Dundee, for supplying the heparins, dextran and sulphated polyglucose respectively.

AN UNREACTIVE TYROSINE RESIDUE IN INSULIN AND THE EXCLUSIVE IODINATION OF THE *A* CHAIN

By DR. P. H. SPRINGELL*

National Institute for Medical Research, Mill Hill, London, N.W.7

IT has been known for some time that it is possible to introduce sufficient iodine into insulin to bring about disubstitution of all the tyrosine residues present[1]. More recently it has been observed that the *A* chain is preferentially iodinated, particularly at lower levels of iodination[2]. The present article describes iodination conditions under which one tyrosine residue of the *B* chain appears to be entirely unreactive and another sufficiently unreactive to facilitate exclusive iodination of the *A* chain.

Iodination of proteins, including insulin, has generally been carried out between *p*H 5 and 10 (refs. 3 and 5). Although there are reports of iodination under more acidic conditions[3,6], no detailed study has been described using insulin. It was found that iodination of insulin by the McFarlane method[5] proceeds almost as well at *p*H 1 as at higher *p*H values, providing only partial iodination is attempted (Fig. 1). Even with larger amounts of iodine no more than about 6 atoms of iodine/mole could be taken up in the first 5 min. of the reaction.

Examination of the distribution of iodine–131 was carried out after disulphide splitting by Swan's method[7], followed by high-voltage paper electrophoresis[8] and autoradiography (Figs. 2 and 3). The figures show that it is possible to iodinate the *A* chain almost exclusively at the 1 atom/mole level at *p*H 1 but not at *p*H 9 (Figs. 2*e* and 3*f*). When more iodine was used, the proportion found in the *B* chain gradually increased (Figs. 2*a–d* and 3*b–e*). If iodination is first carried out at *p*H 1 to the 6 atoms/mole level with inactive iodine and afterwards at *p*H 9 with 2 atoms labelled iodine/mole, then 75 per cent of the radioactivity is associated with the *B* chain (Fig. 3*a*).

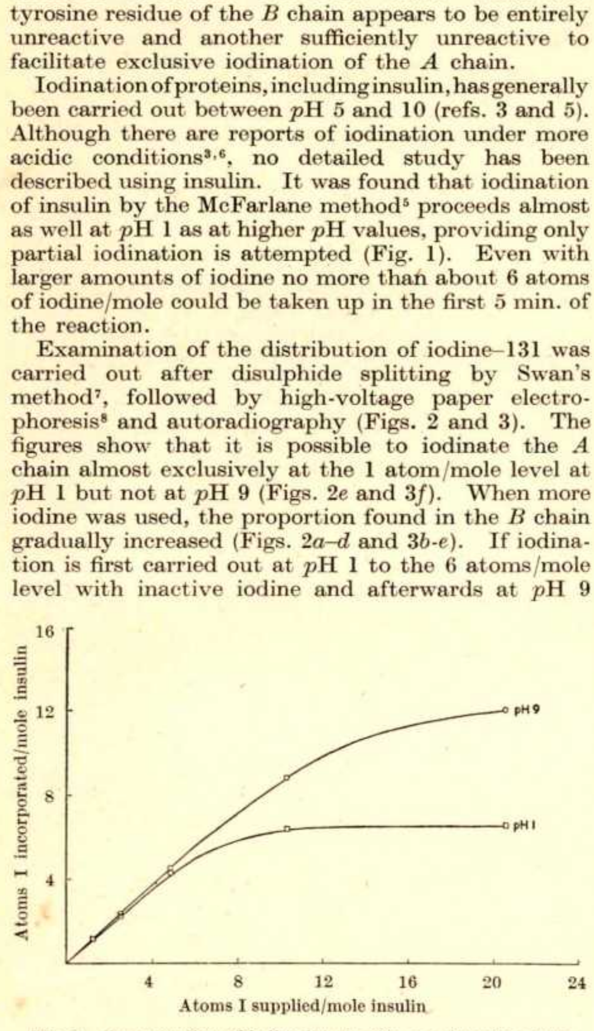

Fig. 1. Incorporation of iodine into insulin as a function of the amount of iodine supplied. Insulin (2 mgm. B.D.H. crystalline) was dissolved in 0·5 ml. 0·1 *N* hydrochloric acid. The following were added: 0·5 ml. buffer (containing per 100 ml.: □, *p*H 1–10 ml. 1 *N* hydrochloric acid + 3 ml. 2 *M* glycine + 12 ml. 2 *M* sodium chloride; ○, *p*H 9–1·3 ml. 2 *N* sodium hydroxide + 9 ml. 2 *M* glycine + 12 ml. 2 *M* sodium chloride), 0·5 ml. 0·1 *N* sodium hydroxide (in *p*H 9 experiments only), water to give a final volume of 4·5 ml. after iodine monochloride addition and iodine monochloride (3·3 μatoms I/ml.)[5] containing between 5 and 50μc. iodine-131 depending on requirements. After 5 min. reaction, 0·5 ml. 100 per cent trichloroacetic acid was added and the protein precipitated. The supernatant was withdrawn and the precipitate washed with 5 ml. 10 per cent trichloroacetic acid. Suitable aliquots of supernatants were counted. (Atoms I incorporated/mole insulin = atoms I supplied/mole insulin

$$\times \frac{\text{added activity} - \text{supernatant activity}}{\text{added activity}}\Big)$$

The uptake of 6 atoms of iodine could lead to the mono-substitution of the 4 tyrosine and 2 histidine residues, the di-substitution of only 3 tyrosine residues, or to di-substitution of some residues and mono-substitution of others. It is evident from the tyrosine and histidine distribution[9] that mono-substitution of all residues would result in an eventual predominance of iodine in the *B* chain. However, scanning for radioactivity in the appropriate regions (Fig. 3*b* and *c*) shows that this is not the case at *p*H 1. Also it is unlikely that histidine is involved since it is known to react much less readily with iodine than does tyrosine under a variety of conditions[10]. Analysis of enzymic digests of the split chains of insulin confirmed the presence of diiodotyrosine. Although monoiodotyrosine was also found, it is uncertain whether it represents a genuine product of iodination. Some of it is almost certainly formed by partial deiodination of the diiodo compound during proteolysis[11] and possibly also during the disulphide splitting reaction.

On the basis of the above it is concluded that *p*H 1 iodination at high iodine-levels probably results mainly in the di-substitution of 3 tyrosine residues, leaving one inaccessible at least for the first 5 min. of the reaction. Another tyrosine group is also iodinated less readily than the other two residues at low iodine-levels. Both these less reactive tyrosine residues are apparently located in the *B* chain.

Iodination of insulin at *p*H 1 brings about opalescence and eventually flocculation as more and more iodine is added. This could be interpreted as resulting from aggregation similar to that observed during formation of fibrous insulin[12]. One site of attach-

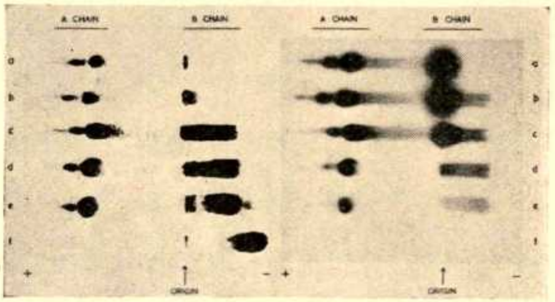

Fig. 2. Electrophoretograms of sulphite-split *p*H 9 iodinated insulin. The insulin precipitate (see legend Fig. 1) was washed with ether to remove trichloroacetic acid, dissolved in Swan's reagent[7], the mixed chains precipitated after the –SS– splitting and the *A* and *B* chains separated by paper electrophoresis (3,800 V., 2·5 hr.) in pyridine : acetic acid : urea as described by Dixon and Wardlaw (ref. 8). After drying and removal of excess urea, the paper was autoradiographed (right) and then sprayed with diazotized sulphanilic acid (Pauly) reagent (left). Amounts of iodine supplied and incorporated (expressed in atoms/mole) are as follows: (*a*) 20·6 and 12·1, (*b*) 10·3 and 8·9, (*c*) 4·8 and 4·5, (*d*) 2·5 and 2·3, (*e*) 1·2 and 1·1. Electrophoretogram (*f*) contains untreated insulin only. Minor components probably represent deamidated products. Because of the higher radioactive content, relatively less of the mixed chains was applied to spots (*a*) and (*b*), which accounts for the apparent reduction in the amount of Pauly-positive material

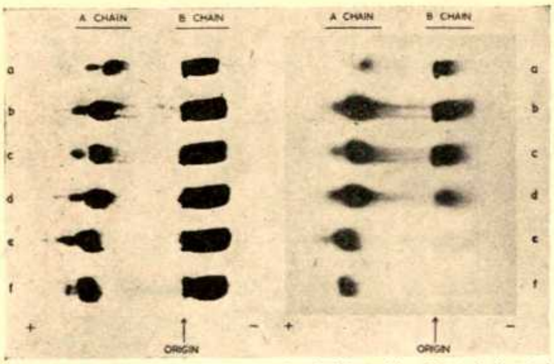

Fig. 3. Electrophoretograms of sulphite-split pH 1 iodinated insulin. The insulin was treated as described in the legend of Fig 2. Insulin in electrophoretogram (*a*) was first iodinated at pH 1 by addition of 20·6 atoms inactive I/mole and then at pH 9 by addition of 2·5 atoms I (containing iodine-131)/mole. At pH 9 2·3 atoms I/mole were shown to be incorporated by radio-assay; at pH 1 presumably 6·6 atoms I/mole were introduced. Amounts of iodine supplied and incorporated (expressed in atoms/mole are as follows: (*b*) 20·6 and 6·6, (*c*) 10·3 and 6·4, (*d*) 4·8 and 4·3, (*e*) 2·5 and 2·2, (*f*) 1·2 and 1·1. Left: After spraying with Pauly's reagent. Right: Autoradiograph

ment during association of insulin monomers may be in the vicinity of those portions of the *B* chains which contain the masked tyrosine residue. In this connexion it is of interest that Porter[13] gave a similar explanation for the observed masking of one of the *B* chain histidine residues.

Although earlier work seemed to indicate that all tyrosine groups of insulin were equally accessible[1,14,15], more recent work indicates that both tyrosyl residues in the *B* chain are hydrogen bonded[16] and that one tyrosyl group may be more strongly bonded than the other[17] within the 6,000 molecular weight unit. Since iodinations were carried out under pH conditions in which internal hydrogen bonding may no longer be taking place[16,18], the hypothesis involving inter- rather than intra-molecular factors is favoured.

Investigation of the masked tyrosine in the *B* chain is being directed towards establishing which of the tyrosyl residues is involved. Distribution of the iodine within the preferentially iodinated *A* chain is also being examined.

A Wellcome research travel grant is gratefully acknowledged. Thanks are also due to Dr. A. S. McFarlane for his interest in this work, Miss D. M. Parr for technical assistance, and Mr. C. D. Sutton for autoradiography.

RELATIONSHIP BETWEEN VELOCITY OF CARDIAC CONTRACTION AND SIZE OF THE HEART: A HYPOTHESIS

By DR. H. FEINBERG*

Cardiovascular Research Department, Medical Research Institute, Michael Reese Hospital and Medical Center, Chicago

A. V. HILL[1] suggested that "cardiac muscle may be able to change its intrinsic speed according to conditions . . . the heart, unlike the skeletal muscle, becomes intrinsically quicker when the frequency of its beat rises". Recently, experiments on cardiac muscle strips and papillary muscle have provided support for this suggestion[2,3]. These findings imply in regard to regulation of performance of the intact heart that cardiac muscle, unlike skeletal muscle, has no fixed length. This fact, considered with the experiments mentioned and the results of recent work on the effect of calcium ions infused into the intact heart of a dog[4], has suggested the following hypothesis.

For a given cardiac load (stroke volume and peripheral resistance), there is a relationship between the velocity of myocardial muscle fibre shortening and the momentary initial length of fibre or initial volume of the intact heart. Thus, an increased velocity of shortening of cardiac muscle fibres is associated with an increased extent of shortening and so leads to a decrease in the end-systolic volume of that beat and a decrease in the end-diastolic volume of the subsequent beat.

The cardiac contraction has been characterized as analogous to a skeletal muscle twitch[5]. Two separate loads for a given contraction must be considered: (1) the initial load, during the isovolumic phase of contraction, as defined by the end-diastolic volume; (2) the 'ejection' or after-load which operates during the auxotonic phase, and is defined by the volume of blood discharged and the aortic pressure during ejection, that is, the pressure-time curve between diastolic aortic pressure and end-systolic pressure. The cardiac contraction is a unique after-loaded performance since the after-load tends to disappear during ejection. This is due to the fact that tension of the wall in a hollow organ decreases proportionally to the cube root of the volume ejected, so that volume shrinkage may more than counteract rise in cavity pressure.

According to the working hypothesis, the final or contracted length, the end-systolic volume, is only a partial function of the initial length, the end-diastolic volume. The extent of shortening of cardiac muscle

* Established Investigator, American Heart Association.

must also be a function of the velocity of shortening for a given load, and the velocity of shortening can be related to the active state, which has been shown to be a discrete period in a muscle twitch. In the case of the heart, the active state would be partitioned between its two phases of contraction. Thus, if the initial load is achieved earlier in the contraction, the potential for further shortening is increased. At the same time, the ejection-after-load is decreased in the ensuing contraction. Thus, the potential for shortening in the heart is greater than would otherwise occur in an ordinary or simple after-loaded contraction.

Skeletal muscle contractile response to a load, the force of contraction, is customarily considered relative to the fixed or *in situ* length, since it has been shown that the maximum force or tension is attained at that length. On the other hand, end-diastolic cardiac volume, the equivalent of initial length of the myocardial fibres, may change from moment to moment in the same individual. There is really no fixed initial length of fibre in the heart. For example, it has been shown that an appreciable decrease in volume of the heart occurs when an individual shifts to the erect from the sitting or prone position[6].

The experiments of Abbott *et al.*[2] and of Sonnenblick and McCallum[3] have established that the velocity of contraction of cardiac muscle for a given after-load may be augmented : (1) by increasing the heart-rate ; (2) by increasing the initial length of the cardiac fibres ; (3) by the application of positive inotropic agents such as the catechol amines and calcium. The results have been interpreted as representing an increase in the intensity of the active state, since the increased velocity of shortening for a given load was shown to occur despite absence of change or even a decrease in the duration of the active state[2].

In relation to the present hypothesis, one of several factors leading to an increase in shortening velocity in the cardiac muscle strip will lead, in the intact heart, to : (1) an earlier attainment of the aortic diastolic pressure-level; (2) an increased velocity of shortening in relation to the ejection after-load ; (3) an increased amount of ejection and systolic muscle shortening, that is, a smaller end-systolic volume, and (4) a smaller end-diastolic volume in the subsequent beat.

Several findings may be cited as evidence for this hypothesis. Wiggers and Katz[7], in the open-chested animal, showed that increasing the aortic resistance at a constant stroke volume resulted in a transient augmentation in initial volume, followed by a subsequent decrease. Sarnoff *et al.*[8], using an *in vitro* preparation operated at constant coronary flow and stroke volume, confirmed this observation and termed it the 'homometric' regulation of the heart to distinguish it from the ordinary 'heterometric' mode. In Sarnoff's preparation the initial length of fibre, as measured with a strain gauge, increased at first when aortic resistance is augmented at fixed stroke input and then decreased. Consistent with the hypothesis presented, these findings are amenable to the interpretation that an increase in initial length of cardiac muscle will initiate an increase in the velocity of its contraction which, at constant stroke input, will result in a decrease in size of heart.

Infusion of catecholamines was shown by Wiggers and Katz[7] to result in a decrease in size of the heart. Recently[4] we found that calcium infusion into the open-chested anæsthetized dog heart operated at controlled cardiac input led to : (1) an increase in the rate of ventricular development of pressure ; (2) a decrease in end-systolic volume of the heart. Table 1 shows the results.

Table 1. EFFECT OF INFUSION OF CALCIUM IONS ON THE HEART OF THE DOG*

	$\Delta P/\Delta T$† mm./sec.	Stroke volume c.c./min.	ΔCircumference‡ per cent of initial
Control	433	7·8	
Calcium ions infused§	622	7·0	—21

* In the open-chested anæsthetized animal, the heart operated at constant cardiac input. (Mean of three animals.)

† Rate of rise in pressure of left ventricle.

‡ Change in left ventricular end-diastolic circumference as measured with a mercury-in-rubber gauge (ref. 10).

§ Continuous infusion of 10 per cent calcium gluconate.

Finally, Rushmer *et al.*[9] has found consistently that exercise in the intact unanæsthetized animal is associated with a relatively constant stroke volume and stroke work and that the increased cardiac output in exercise is due to an increase in heart-rate. Associated with these changes is a decrease in size of the heart. In one experiment it was shown that, if the response of heart-rate to exercise is tape-recorded and used to pace the heart in a resting unanæsthetized animal, a decrease in size of the heart ensued[9]. These findings would fit the hypothesis presented if they were interpreted to imply an increased velocity of shortening.

The cause of an increase in velocity of cardiac contraction in Rushmer's experiments might be due to an increase in heart-rate or an outpouring of catecholamines, or both. There has, as yet, been no unequivocal experimental demonstration, free of filling changes or of changing inotropic influences, that an increase in heart-rate will increase contraction velocity and decrease size of the heart.

The significance of an equilibrium between velocity of contraction, extent of shortening and the volume of the heart is far-reaching and provides an important supplement to the Starling mechanism for cardiac control. Thus, an increase in initial length, heart-rate, and the advent of positive inotropic influences are postulated as an effective counterbalance to factors that require greater initial length to sustain an augmented load. Those factors which initiate stretch of cardiac fibres are still not clearly understood. They may include : (1) metabolic factors, since cardiac work at smaller initial volume is less efficient ; (2) augmented input (diastolic) loads ; (3) negative inotropic factors. Finally, apparent or real changes in contractility and/or distensibility may be involved, both in increasing and decreasing the velocity of contraction and the extent of shortening.

I thank Dr. L. N. Katz for helping me.

ISOLATION AND PROPERTIES OF DEOXYRIBONUCLEIC ACID FROM MAMMALIAN SPERM

By Dr. E. BORENFREUND, E. FITT and Dr. A. BENDICH

Sloan-Kettering Institute for Cancer Research, and Sloan-Kettering Division, Graduate School of Medical Sciences, Cornell University Medical College, New York

MANY of the properties of the deoxyribonucleic acids (DNA) from numerous sources are well documented, yet relatively little is known of the DNA from mammalian spermatozoa despite their central role in the transmission of genetic determinants. Although DNA can be isolated easily from other mammalian cells, and from the sperm of fish and lower vertebrates, such isolation from mammalian spermatozoa has hitherto been extremely difficult, if not impossible[1]. This has probably stemmed from the inaccessibility of the DNA towards rigorous chemical and physical manipulations which appears due largely to the nearly impervious keratin-like membrane surrounding the sperm-head. The DNA of ram and boar spermatozoa, for example, remains insoluble and bound to a residual protein even after contact for 30 min. with 1·0 *N* sodium hydroxide[2]. Similarly the DNA of bovine sperm is inaccessible to extraction with 0·1 *N* sodium hydroxide[3].

In a brief report in 1950[4], a DNA isolated from defatted human sperm by a procedure involving extensive grinding followed by tryptic digestion was described. The physical properties of the product, however, suggested that considerable degradation had accompanied the isolation. When we applied this procedure to bull sperm it failed to yield DNA. The finding of a sulphur-rich, proteolytic enzyme-resistant keratin-like residue in ram and bull spermatozoa (refs. 5 and 6*a*, *b*) and their increased solubility in thioglycollate[3] suggested that prior rupture of protein-sulphur linkages might lead to an appropriate procedure for the isolation of DNA.

Accordingly, the effect of exposure of fresh mammalian sperm to three groups of agents which affect sulphur linkages was studied. These included oxidizing, mercaptide-forming and reducing agents. Use of only the reducing agents permitted the isolation of the DNA. Pretreatment of sperm with 2-mercaptoethanol, thioglycollic acid and British Anti-Lewisite (2,3-dimercaptopropane) at *p*H 7 was effective at a concentration of 0·25 *M*, and cysteine and sodium sulphite were less so. However, this treatment alone was not sufficient, and DNA was released into solution only after subsequent incubation with trypsin. Reversal of the sequence was ineffective.

Several samples of semen from healthy, highly fertile bulls and pooled samples from rabbits were obtained from the New York Animal Breeders' Corp., Ithaca, New York, through the kind co-operation of Dr. H. O. Dunn and Dr. R. H. Foote, of the Department of Animal Husbandry, Cornell University. Sperm-counts and motility-rates were determined prior to shipment of the freshly frozen specimens. Usually, 2–3 ejaculates from individual bulls (12–16 ml., about $1 \cdot 5 \times 10^9$ cells per ml.) were pooled.

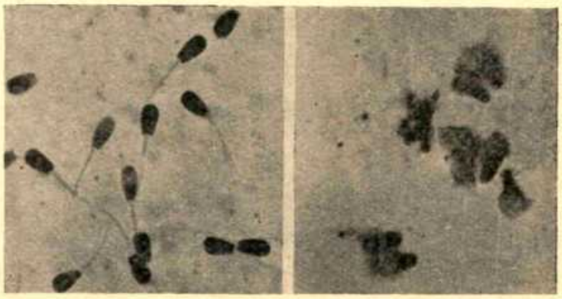

Fig. 1. (left), Bull spermatozoa before treatment. Unstained, unfixed (× 500); (right), bull spermatozoa after exposure to 0·25 *M* β-mercaptoethanol for 2 hr. Unstained, unfixed (× 500)

Δ abs., %	37	36	33	35	33	30

We are indebted to Dr. J. MacLeod, of the Department of Anatomy of Cornell University, for several specimens of semen from normal, healthy medical students. The specimens were processed within ½ hr. of collection. Various methods of homogenization (Potter–Elvehjem, Virtis at 14,000 r.p.m., Mickel's vibrator) and attempts to rupture the sperm cell by freeze-thawing, treatment with deoxycholate or detergents, as well as extraction with phenol or strong salts, failed to release DNA from bull spermatozoa. Similarly, treatment with the enzymes lipase, chymotrypsin, trypsin and lysozyme, or exposure to 9 *M* urea, also failed to release the DNA.

A sperm pellet was obtained by centrifuging the semen for 20–30 min. at 8,000*g* in a refrigerated centrifuge in order to remove the seminal plasma, which is known to contain nucleases[7]. The sperm pellet was washed twice with 0·15 *M* sodium chloride –0·015 *M* sodium citrate and once with ethanol, followed by a 1 : 1 mixture of alcohol–ether to remove the lipoprotein from the capsule[8]. The washings were removed by centrifugation at 8,000*g* for 30 min. To about 100 mgm. of the lipid-free sample were added 20·0 ml. of 0·15 *M* sodium chloride –0·015 *M* sodium citrate containing 2 per cent 2-mercaptoethanol (0·25 *M*) and the mixture incubated for 2 hr. with gentle magnetic stirring in the cold. The effect of this treatment on the morphology of the spermatozoa is shown in Fig. 1. Trypsin (10 mgm.) was then added and the incubation continued for 1 hr. at room temperature. The sample was then centrifuged at 12,000*g* for 1 hr. The supernatant was kept, and the sediment was re-suspended in 10 ml. of saline-citrate containing 5 mgm. of trypsin and incubated for 1 hr. at room temperature and centrifuged. This enzyme step was usually repeated once more, to assure complete release of DNA. To the supernatants obtained after tryptic digestion were added 2 volumes of ethanol, and the nucleic acid fibres which precipitated were removed with a glass rod and redissolved in 0·01 *M* sodium chloride with gentle stirring in the cold room.

* Includes 5-methylcytosine.
† Data from Wyatt, G. R. (ref. 27), recalculated in moles per cent.
‡ Data from Chargaff, E., Zamenhof, S., and Green, C. (ref. 30); base composition is average of two determinations, recalculated in moles per cent.

After the first treatment with trypsin, the preparation was at times so viscous that efficient separation of DNA from the sediment by centrifugation was difficult. In those instances the sample was either further diluted with the saline-citrate or if separation was still not complete the entire mixture was precipitated with 2 volumes of ethanol. The fibres which formed were removed with a glass rod and redissolved in saline-citrate to which a fresh aliquot of enzyme had been added.

Further deproteinization was carried out by the procedure of Kay, Simmons and Dounce[9]. To the 0·01 *M* sodium chloride solution of the DNA, 0·1 volume of 4 per cent 'Duponol' (sodium dodecyl sulphate) in 45 per cent ethanol was added and the mixture stirred at 4° C. for 3 hr. The salt concentration was then raised to 1 *M*, and the stirring continued for 45 min. The mixture was centrifuged for one hour at 13,000*g*, and the DNA in the supernatant precipitated with two volumes of ethanol. In order to reduce the content of protein to less than 0·5 per cent, the level detectable by the method of Ramachandran[10], the preparation was subjected to four or five additional treatments with 'Duponol'. This procedure permits the isolation of about 96–99 per cent of the DNA present in the sperm. This was determined by extracting the remaining tissue sediments after the isolation of DNA with hot trichloracetic acid according to Schneider[11]. These extracts contained less than 4 per cent of the total DNA. DNA, determined by the Burton modification[12] of the Dische reaction, constitutes about 15 per cent of the alcohol–ether-extracted spermatozoa studied.

Phosphorus determinations were carried out acccording to King[13] and the Nessler reagent was used for nitrogen analysis. The atomic nitrogen to phosphorus ratios (N/P, Table 1) are well within the range found for mammalian DNA. Viscosities were determined at various concentrations between 15 and 70 μgm./ml. in 0·2 *M* sodium chloride with a capillary viscometer[14] at shear-rates of 158, 101 and 48 sec.$^{-1}$. Intrinsic viscosities were obtained by extrapolation to zero concentration and zero shear. Solutions containing 0·002 per cent DNA in 0·2 *M* sodium chloride were analysed at 59,780 r.p.m. (259,700*g*) (refs. 15 and 16) in a 'Spinco' model *E* ultracentrifuge equipped with ultra-violet optics, and average sedimentation coefficients, $S_{50\%}$, corrected to 20° C. and water were calculated[17]. With the exception of the DNA from rabbit sperm, which from the sedimentation and intrinsic viscosity values suggest a molecular weight considerably lower than those of the other specimens, the preparations from bull and human sperm showed intrinsic viscosities (η) between 40 and 50 dl./gm. and sedimentation coefficients of about 19–22 *S*. These values are consistent with average molecular weights (Ms and $M\eta$) of about $4–5 \times 10^6$ (ref. 18). Buoyant densities were determined by the method of Meselson, Stahl and Vinograd[19] in a density gradient formed by centrifugation (44,770 r.p.m.) of 8 *M* cæsium chloride solutions to which 2 μgm. of sperm DNA and 1·0 μgm. of a standard DNA–^{15}N from *Pseudomonas aeruginosa* with a density of 1·742 (kindly supplied by Dr. J. Marmur) were added. The buoyant density found for the DNA from bull and human spermatozoa was 1·701, which is about the same as that of DNA from other mammalian tissues[20].

Table 3. CHROMATOGRAPHIC FRACTIONATION OF BULL SPERM DNA*

Chromatographic region	Composition of eluant Molarity, NaCl	Molarity, NH_3	% of original	$S_{20 \cdot w}$
Original			100	20·8
1	0–0·5		41	17·7
2	2·0	0·1	16	20·0
3	2·0	0·1–1·0	10	
4	2·0	2·0	25	22·4
5	(0·5 *M* NaOH)		7	

* Bull sperm DNA (2·5 mgm. in 5·5 ml. of 0·01 *M* phosphate, *p*H 7·0) was applied to a 0·8 × 7·2 cm. column of 'Ecteola'–*SF*–1 and fractionated as described previously (ref. 31). Total recovery of DNA was 96 per cent. The fractions obtained in region 3 consisted of a low, ill-defined band. $S_{20 \cdot w}$ was determined on samples taken from the peak tubes in the regions indicated.

A special heating device attached to the Beckman *DU* spectrophotometer permitted determination of temperature-absorbancy curves according to Marmur and Doty[21]. The midpoint (T_m) of the rise of absorbancy at 260 mμ as a function of temperature averaged about 88° C., and the hyperchromic effect due to temperature, $\Delta_{abs.}$, averaged about 35 per cent. These data indicate a high degree of nativeness. This was supported by the fact that the preparations failed to react with formaldehyde; this is consistent with the behaviour of nucleic acid in the undenatured (double-stranded) form[22]. This is further supported by application of the procedure of Zamenhof *et al.*[23], in which transforming DNA is added to a tissue prior to extraction. When pneumococcal DNA active in transformation to streptomycin resistance was added to bull sperm, and the DNA was isolated by the procedure outlined here, the product still retained its transforming activity.

The values of T_m and buoyant density are consistent with a guanine plus cytosine content of about 43 per cent[20,21]. Base analyses were obtained by hydrolysis with 88 per cent formic acid[24], with 72 per cent perchloric acid[25] and with 6 *N* hydrochloric acid[26]. Wyatt's isopropanol-HCl solvent system[27] was used for paper chromatography. The ultra-violet-absorbing spots were eluted with 0·1 *N* hydrochloric acid and the concentrations of the individual bases determined with the Beckman *DU* spectrophotometer (Table 2)[28].

We feel that the base analyses of the DNA hydrolysed by formic acid are the most reliable. The low

British Flies: Empididae

J. E. COLLIN

The sixth volume—the third to be published—of a series on British Flies inaugurated by G. H. Verrall. This will be the standard work on the British Empididae. The volume is divided into three parts: Tachydrominae; Hybotinae and Empidinae (except *Hilara*); Empidinae (*Hilara* only) and Hemerodrominae. Parts I and II are available; Part III will be ready in October. A complete (clothbound) volume will be published subsequently.

Mechanisms in Biological Competition

EDITED BY F. L. MILTHORPE

The papers in the fifteenth Symposium of the Society for Experimental Biology consider the physical and chemical mechanisms of inter- and intra-specific competition and their consequences in plants and animals. This volume will be of interest to a wide range of biologists, including ecologists, agronomists, and many physiologists and geneticists.

Lectures in Theoretical Physics – Volume III

Edited by **W. E. BRITTIN, B. W. DOWNS** *and* **JOANNE DOWNS,** *Department of Physics, University of Colorado.*
The lectures delivered at the Third Annual Summer Institute for Theoretical Physics, University of Colorado, Boulder, Colorado, June to August, 1960.

Contents:
- Causality and Dispersion Relations
- Selected Topics in Theoretical Physics
- Statistical Mechanics in Irreversibility
- The Scattering of Electrons by Atoms
- Some Applications of the Generating Functional of the Molecular Distribution Functions
- Nonequilibrium Statistical Mechanics
- Quantum Theory of Collision Processes
- Canonical Commutation Relations in Field Theory and Functional Integration
- General Theory of Nonequilibrium Phenomena
- Martin-Schwinger Methods in the Many-Body Problem
- Green's Functions and the Quantum Theory of Fields

Extractive Metallurgy of Copper, Nickel and Cobalt

Edited by **PAUL QUENEAU,** *International Nickel Company of Canada.*
Based on an International Symposium, New York, 1960, sponsored by The Extractive Metallurgy Division of The Metallurgical Society, American Institute of Mining, Metallurgical and Petroleum Engineers (AIME). The papers which comprise this volume provide a good understanding of modern practice in the field; they are divided into five main sections plus an annotated bibliography.

Absorption Spectra in the Ultraviolet and Visible Region

★

Edited by L. Lang

★

Publishing House of the
Academy of Science, BUDAPEST

"The aim of this volume and future supplements is to provide a unified presentation of UV absorption spectra from Hungarian laboratories, capable of continuous expansion as additional data become available, and readily comparable by means of tabulated $\log I_0/I$ values as well as the usual curves of $\log \epsilon$ vs wavelength."

From review in "British Bulletin of Spectroscopy."
See also review in "Nature", February 1961.

Vol. I (2nd Edition) with theoretical and technical introduction in German and English.
170 pp. text ; 414 diagrams & tables ; 1 supplement ;
Cloth. £6 17s. 6d.

Vol. II contains Hungarian and some Polish scientific results. 408 pp. of diagrams. Cloth. £6 0s. 0d.

CAHIERS DE BIOLOGIE MARINE

published by : G. BACCI, C. BOCQUET, P. DRACH, M. FONTAINE, C. LEVI, I. G. POLJANSKY, M. PRENANT, B. SWEDMARK, G. TEISSIER.

The CAHIERS DE BIOLOGIE MARINE, open to authors of any nationality, are devoted to the study of marine organisms and their media.
They do not exclude any of the problems usually studied in a marine laboratory or on an oceanographic ship. Vols. 1 and 2 (1960 and 1961) include Memoranda and Notes set down under headings as varied as :

Study of marine media and their populations in all their oceanographic, ecological, and animal life aspects ;

reproduction and development cycles, the morphology and physiology of marine animals and plants ;

the biometry and genetics of the populations and their applications to systematics.

MECHANISMS IN RADIOBIOLOGY

Edited by **Maurice Errera** *Université Libre de Bruxelles*
and **Arne Forssberg** *Karolinska Institutet, Stockholm*

These two volumes cover the principles of radiobiology, including allied areas in radiation physics and radiation chemistry. The treatise presents a comprehensive treatment of the field, with major emphasis upon those subjects for which review articles are not readily available elsewhere.

Each author is actively engaged in research within the particular field of his contribution. The cooperation of these scientists has produced a work useful as a handbook for the student and as a reference work for the advanced research worker.

IRRIGATION AND CLIMATE

New Aids to Engineering Planning and Development of Water Resources

H. Olivier, C.M.G., Ph.D., M.I.C.E., F.ASCE.

For engineers and agriculturists working on the preparation of water balance sheets and in the planning of new water resources. This book provides relatively simple methods for estimating the quantities and times of crop water requirements for different localities. It is based on the author's wide experience in this field.

Recent Pergamon Books in Chemistry & Astronomy

Printing Inks and Color Vol. I of Advances in Printing Science and Technology

Edited by W. H. BANKS, *PATRA, Leatherhead, England*

Under the Chairmanship of Professor A. C. Zettlemoyer, fifty-eight delegates attended the Fifth International Conference of Printing Research Institutes at Lehigh University, Bethlehem, Penn., U.S.A. Among the papers discussed are the influence of ink, paper and press on colour printing; some aspects of the chemistry and physics of lithographic printing; colour control and instrumentation for colour measurement; control of ink film thickness on the press; and studies of ink transfer in relation to the ink.

Physics and Chemistry of the Earth Vol. III

Editors : L. H. AHRENS, FRANK PRESS, KALERVO RANKAMA and S. K. RUNCORN

Each contributor to this valuable work of reference cites many sources and provides a good bibliography, and the papers include the origin of the elements (discussing types of nuclear reactions which may become involved during the formation of the elements), the distribution of the elements, silicate melt systems, and many other important topics.

464 *pages* £5 *net* ($15.00)

Gases in Light Metals

L. I. SOKOL'SKAYA

Firstly this book clarifies the problems of the reaction of gases with light metals and the methods for the determination of gases in aluminium and magnesium. The mechanism of the formation of defects due to gases in castings, and the influence of gases on the properties of castings are then examined and lastly the origins of the gases and the methods of preventing the formation of gaseous defects are indicated.

The Atlas of the Other Side of the Moon

Edited by N. P. BARABASHOV, A. A. MIKHAILOV, YU N. LIPSKII,
Academy of Sciences of the U.S.S.R.

When the Soviet Union placed the automatic interplanetary station Lunik III round the moon in 1959 the lunar surface invisible from the earth was photographed and pictures transmitted to the earth by radio. This volume is an exact and comprehensive translation of the Russian Atlas of the Far Side of the Moon and contains the best photographs of the moon's hidden surface, a catalogue of the formation thereon, a definitive map and a complete account of the methods used in studying the photographs.

141 *pages* 50*s. net* ($7.00)

Structure of the Moon's Surface

GILBERT FIELDER, *Fellow of the Royal Astronomical Society*

The aim of this book is to produce a largely unprejudiced reference text which brings lunar studies up-to-date. Cross-references may be found rapidly by the use of the List of Contents, the Sectional Numbering at the head of every page, and the Index. A small Chart, for identifying features discussed in the text, has been provided at the end of the book, which is abundantly illustrated with diagrams and plates of the Moon taken by the author at the Pic-du-Midi Observatory.

Telomerization and New Synthetic Materials

R. KH. FREIDLINA and SH. A. KARAPETYAN, *Academy of Sciences, U.S.S.R.*

This is the first book devoted to an exposition of telomerization reactions. The result of intensive Russian research, this reaction makes it possible to obtain the intermediate products for the production of new synthetic fibres, plastics, perfumes and other industrial products from cheap starting materials—for example, from natural and industrial gases. A detailed description is given of the formation and properties of the new synthetic fibre 'enanth' which possesses more valuable properties than caprone and nylon.

Parasitology of Fishes

Edited by
V. A. DOGIEL, G. K. PETRUSHEVSKI and YU I. POLYANSKI

Translated by **Z. KABATA**

This book represents the first attempt at a comprehensive summing up of the problems of fish parasitology, both marine and fresh-water. It is based upon the many years of research by Professor Dogiel and his famous school of fish parasitology in the U.S.S.R., a country which offers within its frontiers an almost full range of the habitats existing on the earth.

It includes discussions on the important problems of parasitology: dependence of the fish parasite fauna on the internal and external environment, host-parasite relationship, specificity, physiology, and the life cycles of the fish parasites. It also contains the first-ever discussion of zoogeography of the fish parasite fauna.

The outstanding value of the book lies in the fact that it presents the principles of an entirely new approach to parasitological problems. **Price 84s. net**

A comprehensive text for students and designers of optical instruments

Instrumental Optics

translated from
G. A. Boutry's Optique Instrumentale by R. Auerbach, B.Sc.

"Professor Boutry's book is of a special nature. Writing mainly for prospective instrument designers, the author describes the practical difficulties which they will have to overcome, and does not present a purely theoretical treatment as found in many instructional works. He first discusses the fundamental principles of geometrical optics, next shows what performance can be expected from a given system, and indicates the boundaries beyond which designers cannot hope to pass because of inherent imperfections of instruments and physiological characteristics of human vision. The physicist will find valuable guidance in the pages of this book to help him arrive at a correct interpretation of observations made with an instrument of a given specification."

From Armand de Gramont's Preface

Tables of Elementary Functions

M. WARMUS, *Nuclear Research Institute, Warsaw Academy of Sciences*

These tables comprise all the important elementary functions. Their characteristic feature is that the estimates of the errors of the values and of the approximate values obtained by linear interpolation are given on every page. Trigonometric functions are given both for degrees and for radians, and the need for conversion from degrees to radians is therefore eliminated. Tables are always given for functions, and their inverses, so that inverse interpolation is unnecessary.

Computing Methods and the Phase Problem in X-Ray Crystal Analysis

Vol. IV of International Tracts in Computer Science and Technology and their Application

Edited by RAY PEPINSKY, J. M. ROBERTSON and J. C. SPEAKMAN

This volume contains the proceedings of the University of Glasgow Symposium, edited by three leading authorities in this field. New and important contributions to two of the most important and fundamental aspects of X-ray crystal analysis—the phase problem, and computational methods—are discussed. Many of the papers are devoted to the programming of electronic digital computers to this task, and to the devising of better and more rapid refinement techniques.

Mathematical Methods for Engineers and Technologists

P. I. ROMANOVSKII

Translation Editor **T. KÖVARY,** *Department of Mathematics, Imperial College, London*

This invaluable book is intended for students of technical colleges and other higher technical education institutes who require a text-book for more advanced courses of mathematics on the following subjects: Fourier series and the Fourier integral; Analytic Field Theory; The Theory of Analytic Functions; Some Special Functions; Operational Calculus; and The Laplace Transforms. The volume is distinguished by the very high level of mathematical rigour, seldom found in this type of book. It fills a definite need and will be welcomed by all who require an intelligently written advanced course in mathematics.

THE WORLD METEOROLOGICAL ORGANIZATION

announces

PUBLICATIONS OF THE IGY METEOROLOGICAL DATA CENTRE

Meteorological Data of the International Geophysical Year (1957/1958) and International Geophysical Cooperation (1959)

Meteorological observations made during the IGY at some 4000 stations were entered on standard forms and sent to the IGY Meteorological Data Centre in the WMO Secretariat. Similar arrangements were made for some of the IGC–1959 observations. This unique collection of nearly nine million observations from all parts of the world constitutes an unbroken and comprehensive record of meteorological data for the 30 months July 1957 to December 1959. The IGY Meteorological Data Centre has been publishing these data in such a way that the various types of observations can be obtained separately for either the IGY or IGC periods or for both together. The original forms are reproduced by photographic methods on Microcards or in loose-leaf publications. With each of these publications a catalogue is supplied with information about the observing stations, their geographical coordinates, elevation and observation programmes.

MICROCARDS OF IGY METEOROLOGICAL DATA

This publication contains the surface and upper-air observations made at 3000 synoptic stations during the IGY. The original forms (about one million) on which the data were entered by the 110 participating countries are reproduced on Microcards of which over 15500 (about 92 per cent of the estimated total) are ready for distribution. This collection of meteorological data from the whole world will be invaluable for many kinds of meteorological and allied research.

The publication consists of four parts :

Part I :	Surface observations—Land Stations	2750 Microcards
Part II :	Surface observations—Sea Stations	2196 Microcards
Part III :	Radiosonde/rawinsonde observations	6317 Microcards
Part IV :	Upper-wind observations	about 5000 Microcards

Subscriptions to complete sets of these data are accepted at the price of US $5,990.00, post paid.

Partial sets may also be ordered for specified regions, periods or types of observations at the price of 50 cents per card of Part II, 40 cents per card of Parts I, III and IV.

MICROCARDS OF IGC (1959) AEROLOGICAL DATA

On 4000 Microcards radiosonde and rawinsonde observations made at over 550 stations are reproduced in a manner similar to that in which the corresponding observations were published in Part III of the IGY Microcards.

This record of the 1959 upper-air observations can be obtained in complete and partial sets.

The subscription price for one complete set is US $1,500.00, post paid. Partial sets of data for specified regions or periods may also be ordered at the price of 50 cents per Microcard.

IGY RADIATION DATA

The collection of over 13000 original forms on which measurements of the various components of the radiation balance were entered is now being published partly in photo-offset and partly on Microcards. This detailed record of radiation measurements made during the IGY at some 600 stations will be of great value to research workers interested in studies of the earth's radiation balance and for all those who are dealing with the application of radiation data to many practical problems in meteorology, agriculture, engineering and other fields.

Subscriptions to complete sets at US $200.00 per set.

Prices of partial sets as set out below :

IGC RADIATION DATA

Radiation measurements carried out in 1959 at some 600 stations will be issued by reproducing the original forms partly in photo-offset and partly on Microcards.

Subscriptions to complete sets of the IGC radiation data can be placed at the price of US $185.00 per set.

Prices of partial sets as set out below :

IGY Prices			*IGC Prices*
US $ 100.00	Part R–1 :	Daily total of radiation components on a horizontal surface and of duration of bright sunshine	US $ 80.00
US $ 9.00	Part R–2a :	Total radiation (sun+sky) on a horizontal surface : Monthly sums for each hour	US $ 9.00
US $ 3.00	Part R–2b :	Diffuse (sky) radiation on a horizontal surface : Monthly sums for each hour	US $ 3.00
US $ 52.00	Part R–3 :	Components of the radiation balance I : Daily sums for each hour	US $ 50.00
US $ 6.00	Part R–4 :	Components of the radiation balance II : Monthly sums for each hour	US $ 5.00
US $ 48.00	Part R–5 :	Instantaneous values of the intensity of direct solar radiation	US $ 45.00

IGY OZONE DATA

The complete record of atmospheric ozone measurements made during the IGY at 57 stations is now available in two loose-leaf publications, which contain the photo-offset reproduction of the original forms collected at the IGY MDC

IGC OZONE DATA

Measurements of atmospheric ozone carried out in 1959 will be issued in two loose-leaf publications containing photo-offset reproductions of the original forms.

IGY Prices			*IGC Prices*
US $ 36.00	Part 0–1 :	Total amount of ozone	US $ 24.00
US $ 3.00	Part 0–2 :	Umkehr observations on clear zenith sky	US $ 2.00

Inquiries should be addressed to : The Secretary General, WORLD METEOROLOGICAL ORGANIZATION,

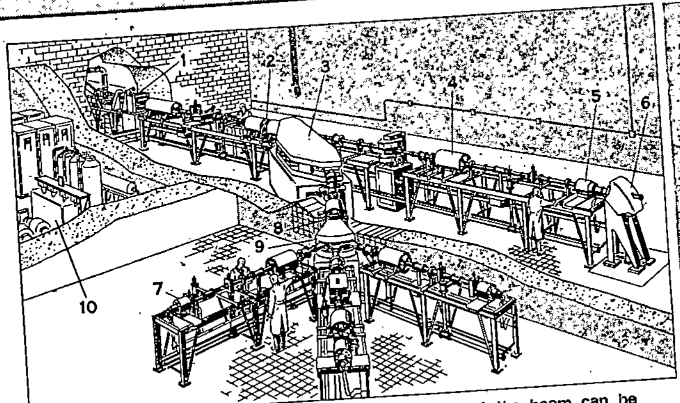
"CHARGED PARTICLES"



Typical high power electron beam analyzing and deflecting system for 10 to 80-Mev, 30 kw linac

1. Linac
2. Positron Target
3. Deflecting Magnet System and Energy-Defining Slits
4. Focusing Lens
5. Neutron Target
6. Terminating Magnet
7. Targets (3)
8. Monoenergetic Gamma Target
9. Switching Magnet
10. Equipment Room

The main features of this analyzing system are: (a) the beam can be delivered to any of three different experimental areas, focused to a small spot or spread out over a large area to facilitate target cooling; (b) net energy dispersion of the beam after deflection is negligible. This means that maximum beam of the desired energy is available because particles of varying energies move along the same center line into target regions; (c) in the deflecting magnet system there is a large energy dispersion at a collimator, which selects the required energy spectrum with a precision of 0.1 per cent or better; (d) the part of the electron beam discarded at this collimator or elsewhere in the system produces x-rays, the major portion of which are directed away from experimental areas; (e) the system can be converted to handle positrons produced in a shower target close to the entrance of the deflecting magnet system.

High Power Linacs

In a recent discussion of *High Energy Linacs,* we indicated that the power of the new accelerators, plus better energy resolution opens up intriguing possibilities for the experimental physicist. One of these possibilities involves production of a monoenergetic gamma-ray beam, with adjustable energy, heretofore just a dream.

Positron annihilation in flight in a thin target produces such a gamma-ray beam. The linac electron beam is used to produce positrons in a wide energy spectrum in a shower target. These particles are energy-analyzed in a deflecting magnet before they impinge upon the annihilation target. Energy selection of the gamma rays is accomplished by varying the magnetic field of the deflecting magnet. The conversion factor is small, so it is essential to have an intense electron beam. It is not essential, however, to have a high degree of beam-energy homogeneity.

An experiment in which beam-energy homogeneity is important is the spectroscopic study of inelastically-scattered electrons from nuclei. Magnetic spectrometers for this kind of experiment can be built with a resolution of better than 0.1 per cent, and the electron beam must be analyzed to this accuracy before it impinges upon the scattering target.

Hot Electron Beams

The high accuracy and power called for in these experiments requires considerable beam-handling ingenuity. The problems may be illustrated: A typical high-energy linac will put 45 kw of high-energy electrons on a one-half centimeter square — this equals 180 kw/cm², enough to vaporize any known material in a few seconds. To make such a system fail-safe requires precisely-protected beam slits and electron scattering devices, and specially cooled vacuum chambers, in addition to the analyzing and collimating equipment. The situation is complicated by an x-ray background which prohibits use of organic materials for coil insulation and vacuum gasketing.

The beam analyzing and deflecting system is an increasingly complex and important part of the linac experimental facility. An inadequate system will greatly reduce the accelerator's research utility. Fortunately, High Voltage Engineering has had years of experience designing and building extremely accurate, magnetic analyzing systems to guaranteed specifications.

Table 4. AMINO-ACIDS RELEASED FROM BULL SPERM DNA*

Aspartic acid	Threonine	Serine	Glutamic acid	Alanine	Valine	Methionine	*Iso*leucine	Leucine	Lysine	Histidine
11·2	8·2	26·0	13·2	6·1	12·4	3·7	2·0	4·4	9·9	2·7

* Determined on a 27 mgm. sample in an automatic amino-acid analyser (ref. 33) after hydrolysis by refluxing with 6 *N* HCl for 24 hr. The glycine was not determined since purines break down under these conditions to give appreciable amounts of glycine.

The results are expressed as moles of amino-acids/100 moles of all amino-acids actually found. Phenylalanine and tyrosine were present as traces. Neither cysteine nor cystine was detected. Together, these amino-acids amount to about 0·1 per cent of the mass of the DNA sample. We are grateful to Dr. M. E. Balis for carrying out the analysis.

thymine value following perchloric acid hydrolysis and the low adenine after hydrochloric acid hydrolysis are consistent with the experience of others who have reported losses of these bases by these procedures[26,29]. The thymine to cytosine ratio (T/C) previously reported[30] for human sperm DNA is considerably higher than the present values (Table 2). The ratios of purines to pyrimidines (Pur/Pyr) are close to 1·0 as found for other mammalian tissues[1].

The DNA from bull spermatozoa was fractionated on a column of the anion exchanger 'Ecteola' using an elution system which yielded DNA in 5 chromatographic regions[31]. The sedimentation coefficients of the DNA in the peak tubes in each region were determined. The results, given in Table 3, show that bull sperm DNA, like that of calf thymus[32], consists of fractions which vary in molecular size and which can be separated on an 'Ecteola' column.

The requirement of the reducing agent used in the isolation of DNA from mammalian sperm suggests the presence of a special sulphur-containing linkage between the DNA (or a component attached thereto) in the sperm nucleus and the protein coat cleavage of which is necessary before the nucleic acid can be released. It is less likely that the protein coat consists of a highly cross-linked, rigid, disulphide-containing protein which merely engulfs the DNA, since release of the DNA should attend the disintegration of the coat, which is brought about by grinding, homogenization, etc.

Accordingly, the DNA isolated from bull sperm was hydrolysed with 6 *N* hydrochloric acid and examined for the presence of amino-acids[33]. The results (Table 4) indicate the presence of protein (or amino-acid) to the extent of about 0·1 per cent, with a remarkably high serine content. The relatively low content of basic amino-acids, the presence of many other amino-acids, and the absence of cystine have also been noted in highly purified DNA from human white cells, spleen and placenta[34]. It is noteworthy that the only sulphur-containing amino-acid detected was methionine, and this was present in small amounts (3·7 per cent). It is possible that sulphur-containing amino-acids may have been removed by the tryptic digestion step. The significance of the amino-acid content is being investigated since this might hold a clue to an understanding of the action of β-mercaptoethanol, which is needed for eventual release of the DNA. This pre-treatment is not required for release of DNA from the sperm of lower forms such as fish, invertebrates and birds, and such differences may therefore be a reflexion of evolutionary development.

These results with sperm DNA are of particular interest since the source material is not only devoid of RNA but consists, presumably, of a homogeneous cell population in contrast to the usual heterogeneous cell-types found in tissues. In addition, sperm is the only reasonably available mammalian haploid cell. Yet, obvious differences with the DNA of diploid tissues are not revealed by the properties given here.

The amino-acids (or protein) which are present in these as well as in so many other preparations described in the literature and which resist rigorous efforts to remove them may be co-valently linked to the DNA. Although these are present to only a small extent, they may play an influential part in the transmission and determination of heritable characteristics and in differentiation. Hence, a critical examination of the amino-acid composition of the DNA and a comparison of preparations from different tissues and sources may reveal an unsuspected basis of the biological activity of these polymers.

We thank Miss I. A. Wright for carrying out the ultracentrifuge runs. This investigation was supported by funds from the National Cancer Institute, National Institutes of Health, Public Health Service (grant No. *CY*-3190), the Atomic Energy Commission (contract No. *AT* [30-1], 910), and the Health Research Council of the City of New York (Contract No. *U*-1096 II *A*).

SURFEN: A QUINOLINE WITH ONCOGENIC AND HEPARIN-NEUTRALIZING PROPERTIES

By DeWITT T. HUNTER, Jun. and JOSEPH M. HILL
J. K. and Susie L. Wadley Research Institute and Blood Bank, Dallas, Texas

SURFEN (*bis* - 2′ - methyl - 4 - amino - chinolyl - 6 - carbamid) has been described as an oral heparin antagonist more potent than protamine sulphate. Experiments were undertaken to ascertain its degree of inhibitory power on heparin *in vivo* and to determine its toxicity. Earlier personal communications have discounted untoward effects following oral administration to rats for 90 days (Dr. Jose Steinhardt, personal communication).

Eighteen mature Swiss mice were fed 'Purina' chow infiltrated with surfen. These animals were divided into groups 1 to 4, receiving a minimum intake of 60, 120, 150 and 300 mgm./kgm./day of surfen, respectively. Groups 1, 3, and 4 consisted of 3 animals each, while group 2 contained 9 animals. Groups 1, 3, and 4 received the diet for 80 days, after which time all animals were autopsied; those in group 2 were fed surfen for only 60 days. All animals were observed daily for evidence of toxic effects. Three untreated animals were autopsied as anatomical controls. The whole mouse colony served as physiological controls. Micro-coagulation times were performed on 3 groups of 2 rabbits given oral surfen before and after heparinization. Two untreated heparinized rabbits were used as coagulation controls.

Mice subjected to prolonged surfen ingestion at dose-levels slightly in excess of those thought to be of therapeutic value developed lymphosarcomata and lesions suggestive of nutritional deficiency (Table 1).

Table 1. MICROSCOPIC CHANGES OBSERVED IN CONTROL AND SURFEN-TREATED MICE

Microscopic observations	Group				Control
	1	2	3	4	
Surfen mgm./kgm./day	60	120	150	300	0
Animals/group	3	9	3	3	3
Lymphosarcoma, per cent animals with tumour	0	33	100	0	0
Per cent animals with lymphocytic infiltrates	67*	33†	0	0	0
Gastric mucosal hyperplasia					
Total thickness	450μ	500μ	500μ	300μ	400μ
Epithelial thickness	24μ	30μ	25μ	2μ	20μ
Polarity of nuclei	absent	absent	absent	absent	present
Pseudostratification	present	present	present	present	absent
Depot fat; lipocyte size	20μ	15μ	10μ	12μ	20μ
Lipid-containing cells/HPF	100	20	20	30	100
Distorted, giant hepatic cells/HPF	1	1	3	5	1
Colloid casts, distal tubules/LPF	1	0	1	0	0

* Two animals showed lymphocytic infiltrations of soft tissue and viscera similar to those seen in incipient mouse leukæmia or severe, generalized viral diseases. Although a virus would have affected the control and group 4 animals with equal probability, the absence of unequivocal sarcoma in group 1 necessitates interpretation as benign.

† Florid lymphocytic infiltrates were encountered in one additional animal. Prominent lymphocytic aggregates were evident in others. Absence of tumour masses necessitated that these cases be classified as 'lymphocytic infiltrates' rather than 'lymphosarcoma'.

The lymphosarcoma in one animal in group 3 became apparent after 55 days on the diet and accounted for the death of the animal on day 71. A second animal in this group showed the tumour at day 70 and the third sarcoma was discovered at autopsy. Those sarcomas in group 2 developed after day 80.

Evidence of dietary deficiency became apparent after only 10 days on surfen. Most marked gross lesions were seen in group 4 about 50 days through the experiment. At this time, the extremities, noses, and tails of all animals became eczematoid and œdematous. Two animals lost portions of their tails following necrosis of distal segments. Trauma was not a factor since physical activity was virtually nil at this time. These lesions partially regressed near the end of the experiment. Hepatic changes consisted of marked pleiomorphism of size and shape of parenchymal cells. Some disruption of lobular architecture was seen, but no necrosis was apparent to account for this. Nuclei were pycnotic and cytoplasm was deplete of glycogen. Severity of dietary deficiency closely paralleled dosage of surfen. Terminal coagulation times were normal.

Rabbits given 300 mgm./kgm. of surfen within 10 min. before, and at any time after, heparinization showed no change in coagulation times when compared with control heparinized animals. However, the feeding of surfen 4–6 hr. prior to heparinization resulted in a moderate depression of coagulation

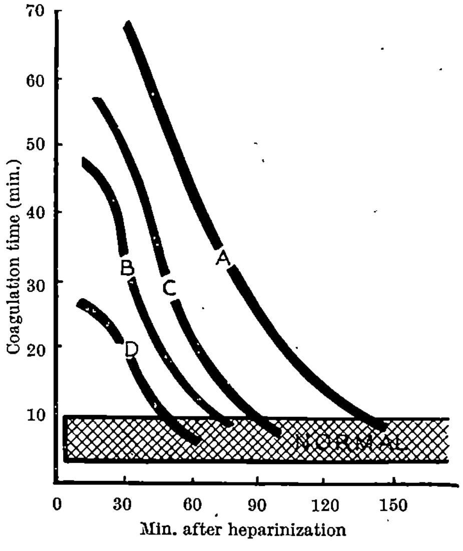

Fig. 1. *A*, Animals receiving 2 mgm./kgm./heparin intravenously. Curves of animals administered oral surfen 10 min. prior to, or at any time after, heparinization were identical with animals receiving no surfen. *B*, same as *A* except for heparinizing dose of 0·5 mgm./kgm. *C*, Animals receiving 2 mgm./kgm. heparin but pretreated with 300 mgm./kgm. surfen 4 to 6 hr. beforehand. *D*, Same as *C* except for heparinizing dose of 0·5 mgm./kgm.

times to about 50 per cent of that seen in controls (Fig. 1).

Although the series is small, presence of lymphosarcoma in a third of the animals in group 2 and all animals in group 3 strongly indicates that surfen is oncogenic at these dose-levels. Based on a spontaneous incidence of one per cent for group 2, p is calculated as 0·000080 and for group 3 as 0·000001.

Absence of sarcomata in group 4 may be explained by the suppressing effect oncogenic substances exert on neoplasia in high doses[4], and by the resistance of malnourished and/or vitamin-deficient animals to tumour development[3]. The findings, in 2 animals of group 1, and 3 animals of group 2, suggest that a prolonged test-period would result in increased tumour induction even at the low dosage in group 1. The oncogenic property of surfen is supported by its hyperplastic effect on gastro-intestinal mucosa. Tumours have not been observed before in this colony of Swiss mice. Although we accepted the manufacturer's chemical description of surfen, we did subject the substance to fractionation in an attempt to disclose oncogenic impurities. The product was homogeneous. Environmental factors would have probably induced neoplasia with equal frequency in the control colony and in group 1. The quinolines have not previously been incriminated in oncogenesis, except in the styryl complex[2], and indeed have displayed oncolytic properties[5].

The other changes observed indicate that surfen interferes with food and/or vitamin utilization. Similar changes are seen in vitamin-deficient animals but not in starved animals[1]. Although the diet was not enriched with vitamins, food intake was sufficient in all groups to maintain health in untreated animals. The liver pathology was suggestive neither of starvation nor of hepato-toxic effect.

Coagulation work performed using heparinized rabbits pre-treated with surfen indicated moderate heparin-neutralizing effects. Surfen is apparently slowly and imperfectly absorbed in the digestive system, and shows activity only if given several hours in advance of heparinization. In this respect, it is inferior to protamine sulphate.

NERVE ENDINGS IN THE MOLE'S SNOUT

By J. ARMSTRONG and DR. T. ANDREW QUILLIAM

Department of Anatomy, University College, London

CONCENTRATED in a small area of hairless skin at the tip of the snout of the near-blind mole are numerous cutaneous nerve endings. In all probability they play an important part in facilitating path-finding and feeding while the animal is either on or below the surface of the ground.

During waking hours the snout is constantly used in a probing fashion (accompanied by head movements) to explore the immediate environment, although the general direction of the animal's movements towards food or away from danger is presumably plotted beforehand in response to olfactory and vibratory sensations. A memory system must also be involved as even when traversing unaccustomed territory the animal may only deviate momentarily from its set course in order to circumvent local obstacles. Observations during life confirm that the snout region is markedly pink in colour and that it is also freely mobile. They also suggest that it is semi-erectile in character since during periods of hyperactivity or stress it assumes a redder hue and becomes more prominent (for example, as during obligatory swimming, when the animal progresses at a great speed and holds its snout well above the water-level). After death, the snout becomes paler and diminishes in size. However, it is not known whether such local circulatory changes could affect the character of responses from nearby nerve endings sensitive to external physical stimuli[7].

At present light-microscope work using *Talpa europaea* has confirmed the classical work of Eimer[4] that there are, in the snout region, many profusely innervated epidermal papillæ passing into the dermis (the so-called 'Eimer's organs'). The presence of encapsulated nerve endings near the deep aspect of Eimer's organs has been recorded by Ranvier[10], Bielschowsky[1] and Boeke[2]. More recently Cauna and Alberti[3] have denied the presence of encapsulated

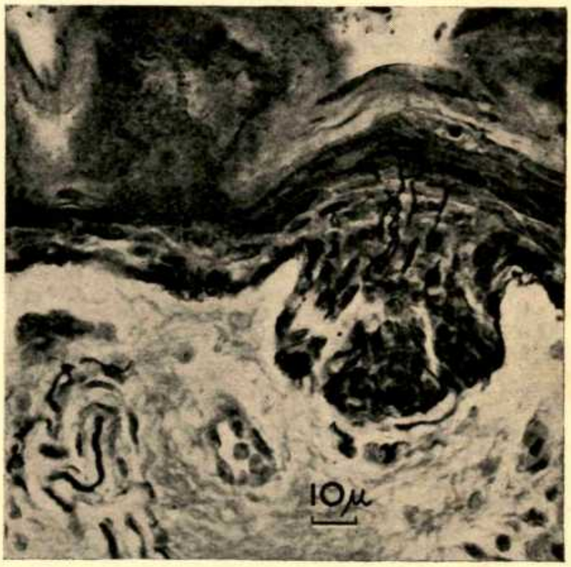

Fig. 1. Vertical section through the skin of the tip of the mole's snout. An Eimer's organ lies to the right. Part of the dermal plexus supplying it and some of the nerve 'terminals' within it can be seen. An encapsulated nerve ending of an unnamed variety lies to the left and intervening between these two structures is a blood sinus. (This material, together with that shown in Fig. 2, was stained by a modified Cajal method)

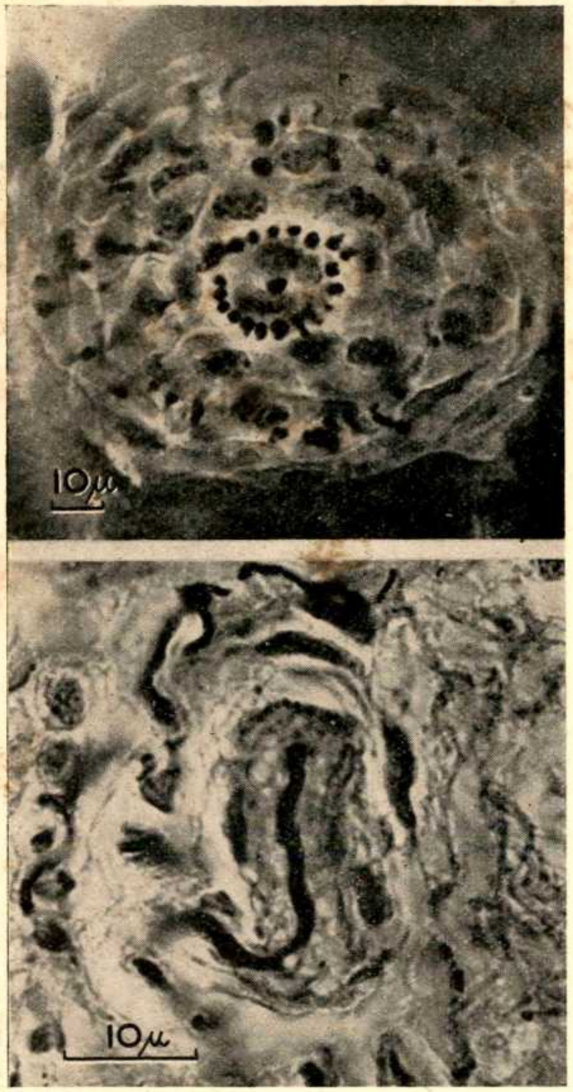

Fig. 2. Above, transverse section through an 'Eimer's organ' showing the axial nerve terminal closely related to paired cells of an inner core. Satellite nerve terminals are arranged circumferentially in a clear annular space. Lying peripherally are the epidermal cells that constitute the bulk of Eimer's organ.

Below, longitudinal section (high power) through an encapsulated nerve ending of an unnamed variety showing a single central axon surrounded by a comparatively simple core and an ill-defined capsule

nerve endings in this region, and have suggested, by implication, that the Eimer's organs are themselves multi-purpose transducers. The present work, together with unpublished electronmicroscopic findings (Quilliam), clearly demonstrate the presence of encapsulated nerve endings of an unnamed variety in the dermis and have considerably amplified the original descriptions and hand-drawn illustrations of them published 35–90 years ago[1,2,10].

The importance of the present findings lies in the fact that it is now no longer necessary to attach an extraordinary functional significance to the Eimer's organs, and in particular, to ascribe to them the unique ability of subserving a comprehensive spectrum of cutaneous sensory modalities.

Fig. 1 shows a vertical section through the skin of the tip of the mole's snout. Above can be seen the undulating profile of the epidermal surface and towards the right is an Eimer's organ in longitudinal section. A few of the fibres of a dermal nerve plexus supplying it from below are visible and a number of ascending nerve 'terminals' (or possibly 'pre-terminals') can be seen traversing it vertically on their way towards the more superficial layers of the epidermis. Located below and to the extreme left is an encapsulated nerve ending the long axis of which in the photomicrograph illustrated happens to be orientated vertically. It is separated from the Eimer's organ previously identified on the right by a blood sinus.

Fig. 2 (above) depicts a typical Eimer's organ in transverse section. A single nerve terminal, axially, is clearly seen to be surrounded by an array of circumferentially disposed satellite nerve terminals. The latter are situated in a clear annular zone that separates the outer core of epithelial cells from the paired cells of the central core which themselves closely invest the axial terminal. The unusually orderly pattern of these grouped nerve terminals may well form a satisfactory structural basis for the fine tactile discrimination that the mole practises during normal activity. Unfortunately, it has not yet proved possible to differentiate histologically between axial and satellite nerve terminals except in respect of diameter measurements and of their relative positions within an Eimer's organ. Consequently, it is not known whether any of the satellite terminals are collaterals of the dermal fibre which is in continuity with the axial terminal. In view of the many bundles of myelinated fibres present in the dermis it would appear likely that every Eimer's organ is innervated by several myelinated fibres. The relatively large number of satellite terminals in an Eimer's organ further suggests that at least some of the dermal fibres supplying it must branch prior to entry into its deep surface—presumably in a subjacent nerve plexus.

Fig. 2 (below) is an enlargement of the encapsulated nerve ending shown in Fig. 1. The capsule is rather poorly differentiated, and the core tissue surrounding the nerve terminal is somewhat scanty. However, nuclei can be made out in the latter on either side of the terminal (at 4 o'clock and 9 o'clock) and several small granules can also be distinguished (at 12 o'clock). The single nerve terminal is almost straight once it has entered the core and ends without visible structural modification. Since some of its morphological features suggest that it belongs to an unnamed type of ending not adequately described hitherto its fine structure will be described elsewhere (Quilliam).

The cellular organization of these encapsulated endings exhibits both certain similarities to and a number of divergences from the pattern typical of the Pacinian corpuscle in the cat. However, it may be tentatively assumed that, functionally, the former behaves like the latter in responding to high-frequency pressure changes[5,6,8].

LETTERS TO THE EDITORS

RADIOASTRONOMY

Spectrum of Galactic Radio Emission

THE general radio emission from the Galaxy has now been accounted for as the synchrotron radiation of high-energy electrons in a magnetic field. An unsatisfactory aspect of this explanation is the relation between the observed radio spectral index α, where radio flux is proportional to (wave-length)$^{\alpha}$, and the expected energy spectrum of the cosmic-ray electrons, the number density of which should also vary exponentially according to (energy)$^{-(1+S)}$. In these circumstances the indices are related by $\alpha = S/2$.

It has been shown by Tunmer[1] that if the electrons are supposed to be generated by the collision of cosmic-ray protons with atomic nuclei, the value of S will depend on the predominating mechanism by which the electrons lose energy. Assuming a proton number density proportional to (energy)$^{-2\cdot5}$, the following values of S will be expected for the various loss mechanisms:

Synchrotron radiation	$S = 2{\cdot}5$
Bremsstrahlung radiation	$S = 1{\cdot}5$
Ionization losses	$S = 0{\cdot}5$

The measured value of $\alpha = 0{\cdot}37 \pm 0{\cdot}04$ for the frequency-range 38–178 Mc./s. (ref. 2) corresponds with a value $S = 0{\cdot}74 \pm 0{\cdot}08$. This value appears to indicate that losses are primarily governed by ionization; unfortunately, Tunmer's paper indicates that the only important loss for the electrons concerned with radiation in this frequency-range is the synchrotron radiation itself. Radiation at 100 Mc./s. is produced by electrons with energy of the order of 10^9 eV. in a field of 10^{-6} gauss. The actual conditions of emission cannot be far different from these, and it seems inescapable that a value of S near 2·5 should be found, corresponding to $\alpha = 1{\cdot}25$.

If the electrons are not formed throughout the energy spectrum, but only at higher energies than those concerned, afterwards falling through the range by synchrotron losses, then a radio spectral index of 0·5 would be found. Even making this extreme hypothesis of the life-history of the electrons, the expected value of α is still greater than that observed.

It is natural to suspect the experimental evidence, and indeed this is now being checked as rigorously as possible. However, some new observations at 408 Mc./s., soon to be published by Pauliny-Toth, support the low value of radio spectral index. The experiment reported by Molozzi, Franklin and Tyas[3], in which galactic radio noise at 3·8 Mc./s. was measured by a satellite-borne radio receiver, also lends some support. Here the measured field-strength E can be related to an effective black-body temperature T by:

$$T = \frac{3\lambda^2}{8\pi kB}\,\frac{E^2}{Z_0}\,\varepsilon^{1/2} \quad \text{(Hugill, in preparation)}$$

For the northern hemisphere, Molozzi's results give $E \simeq 0{\cdot}6$ μV./m., and it seems unlikely that this result is much affected by the ionosphere. Hence $T \simeq 1{\cdot}3 \times 10^6$ °K., while the value to be expected by extrapolating Costain's results from 38 Mc./s. to 3·8 Mc./s. using $\alpha = 0{\cdot}37$ is $2{\cdot}8 \times 10^6$ °K. The indication here is of an even lower value of α at the lower frequencies.

No theory has yet attempted to resolve this problem; the purpose of this communication is merely to point out a serious discrepancy between theory and experiment, which is not apparent from the papers by Tunmer[1] and Hoyle[4]. Further examination of the processes of loss and gain of energy by the electrons of cosmic-ray energies seems to be required.

ASTROPHYSICS

Production of Neon in Stars

WE have recently made certain measurements of the properties of some levels in neon-20 which are related to the production of neon in stars. In particular we have shown that the 4·97-MeV. level has odd parity and $J = 2$. Consequently neon-20 cannot be formed through this level by thermonuclear reactions between helium and oxygen-16 as has been suggested to explain its production in stellar interiors after the hydrogen has been consumed[1,2]. The suggestion arose from the close proximity of the 4·97-MeV. level in neon-20 to the energy of oxygen-16 + α as shown in Fig. 1. For the level to be effective the parity would have to be $(-)^J$ where J is the total angular momentum.

The first evidence that the level has $J\pi = 2-$ arose from γ–γ correlations in the neon-20 $(pp'\gamma\gamma)$ reaction that established the total angular momentum as 2 (ref. 3) and the unexpectedly long life-time of $1{\cdot}9^{+3\cdot5}_{-1\cdot0} \times 10^{-12}$ sec. found by the Doppler shift technique in our experiments[4] using the carbon-12-(^{12}C $\alpha\gamma$)neon-20 reaction. The assignment of negative parity has now been established by our investigations (to be published) of neon-20$(pp'\gamma)$neon-20. In this reaction measurements of the linear polarization[5,6] of the 3·34-MeV. γ-ray by Compton scattering combined with the angular distribution of the γ-ray defined its electric or magnetic character and thereby demonstrated that the levels concerned at 4·97 MeV. and 1·63 MeV. have opposite parity. The parity of the 1·63-MeV. level is positive (ref. 7 and A. E. Litherland and E. Almqvist, D. A. Bromley, J. A. Kuehner and B. Whalen, to be published). A parity of $(-)^{J+1}$ for the 4·97-MeV. level has since been deduced (A. E. L., to be published) from measurements (E. Almqvist, D. A. Bromley, J. A. Kuehner and B. Whalen, to be published) of the α-particle angular distributions in the carbon-12(^{12}C α)neon-20 reaction, and $J\pi = 2-$ has been confirmed by α–γ correlations in this same reaction (H. E. G., A. E. L. and M. A. C., to be published).

The next available level for helium thermonuclear reactions is at 5·63-MeV. This can be formed by the α + oxygen-16 reaction (H. E. G., A. E. L. and

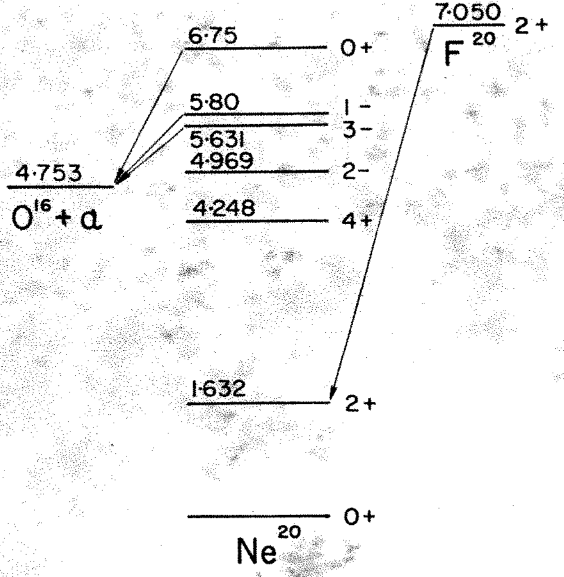

Fig. 1. Diagram for low-lying levels in neon-20

M. A. C. and J. A. Kuehner and E. Almqvist, to be published) and preliminary experiments (A. E. L. and H. E. G., unpublished) on the reaction at an α-particle energy corresponding to this level yield a value of $(2J + 1)\frac{\Gamma_\alpha \Gamma_\gamma}{\Gamma} = 0{\cdot}003 \pm 0{\cdot}002$ eV. The 5·63-MeV. level in neon has now been shown to have $J\pi = 3-$ (J. A. Kuehner, to be published) and $\Gamma_\gamma/\Gamma = 0{\cdot}07 \pm 0{\cdot}01$ (H. E. G., A. E. L. and M. A. C. and J. A. Kuehner and E. Almqvist, to be published). Cameron (private communication) has recently estimated that, under these conditions, neon-20 could be formed through the 5·63-MeV. level at temperatures above 5×10^8 °K. in supernova explosions. He has also pointed out the possibility that the strong neon lines observed in certain stars may be neon-22 formed in the reactions nitrogen-14($\alpha\gamma$)fluorine-18($\beta^+\gamma$) oxygen-18($\alpha\gamma$)neon-22.

The level at 5·80 MeV., which was first discovered in measurements of the sodium-23($p\alpha$)neon-20 reaction[8], has been shown to have $J\pi = 1-$ (J. A. Kuehner, to be published) and $\Gamma_\gamma/\Gamma = 0{\cdot}003 \pm 0{\cdot}003$ (J. A. Kuehner and E. Almqvist, to be published). It would be of great interest to measure $(2J+1)\frac{\Gamma_\alpha \Gamma_\gamma}{\Gamma}$ for this level in the oxygen-16($\alpha\gamma$)neon-20 reaction, since it may also contribute to neon formation in stars.

SEISMOLOGY

Possible Method for increasing the Signal–Noise Ratio in the Detection of the First Motion of a Refracted *P*-Wave

In seismology a method has been developed of examining the focal mechanisms of earthquakes by studying the azimuthal variation of the first movements on seismograms[1]. In extending this method to differentiating between small earthquakes and explosions a basic experimental problem is the detection of the initial movement when its amplitude is of the order of only 10^{-7} cm. in the frequency-range 1–10 c.p.s., and is therefore comparable with the background microseismic noise-level at the quietest sites. The purpose of this communication is to suggest and illustrate a possible technique of increasing the signal : noise ratio.

It is generally considered that the majority of seismic noise consists of surface waves, a characteristic of which is that their amplitude decreases approximately exponentially with depth[2]. The first arrivals at a recording site at distance between 200 and 1,000 km. from a shallow event are P_n waves which have been refracted along the Mohorovičić discontinuity and emerge at the surface with an angle of incidence of about 50°. Allowing for surface reflexion their amplitude varies with depth by a factor of two. Thus, accepting the postulate that the noise is predominantly surface waves, it is immediately obvious that an increase in signal : noise ratio can be obtained by placing the detector deep undergound, typically a factor of 10 being gained at 3 c.p.s. for a depth of 4,000 ft. In this communication we are suggesting that a further improvement of signal : noise ratio can be obtained through the use of two detectors, one at the surface and the other at a depth of, say, a wave-length at the peak recording frequency. The signal at the surface detector is then regarded mainly as noise, and is subjected to a frequency dependent attenuation, higher frequencies being attenuated most, to give the noise signal theoretically expected at the lower detector. The two signals are now subtracted so that the noise is eliminated, and the required *P*-wave signal, slightly modified, remains.

To test the method, model seismic studies have been carried out. The model consists of a 1/16-in. sheet of 'Perspex' 48 in. × 12 in. (Fig. 1). The transmitter at the surface, T_1, generates a burst of 'white' noise, about 750 μsec. in duration, while the 'buried' source, T_2, transmits a 10-μsec. pulse. Two detectors are placed two-thirds of the way along the model, D_1 at the surface and D_2 at a depth of 1 in., corresponding to about one wave-length for a surface

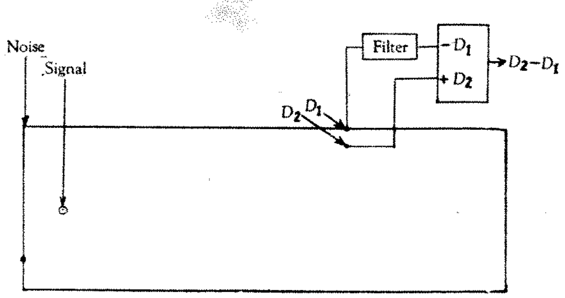

Fig. 1. Diagram of arrangement of transmitters and detectors on model

(b) with noise

Fig. 2

wave with a frequency of 50 kc./sec. which is the dominant frequency of the *P*-wave. The timing of the two transmitted signals is such that the *P*-wave from T_2 arrives at the detectors about half-way through the burst of surface waves from T_1. The signal from D_1 is passed through a filter having a frequency attenuation closely resembling the theoretical surface wave attenuation at the depth of D_2, and this is then subtracted from the signal from D_2 at the appropriate relative gain. (To allow for frequency-dependent phase-changes in the filter, which are approximately linear with frequency, the two detectors are staggered horizontally by about ¾ in.) Typical records are shown in Fig. 2, the gain in signal : noise ratio being readily apparent.

The basic principles behind the method were developed in private discussions with Prof. J. Oliver of Columbia University and we are pleased to acknowledge his help.

PHYSICS

Effect of Ultra-Violet Irradiation on the Electrical Conductivity of Cathodes coated with Barium Oxide

It has been known for some years that irradiation with ultra-violet light can have an important effect on the photoelectric and thermionic properties of a cathode coated with barium oxide. Ultra-violet irradiation at room temperature causes an enhancement of photoelectric emission induced by illumination of the cathode by light of other wave-lengths[1,2], and a pronounced change in the spectral sensitivity curves for photoelectric emission[1-5] and photoconductivity[5] is observed after ultra-violet treatment. The enhancement is only observed at low temperatures and may be removed by heating the cathode to about 700° K. Ultra-violet irradiation may also cause an enhancement of thermionic emission[2]. It is the purpose of this communication to report the results of preliminary observations of the effect of ultra-violet irradiation on the dark electrical conductivity of cathodes coated with barium oxide, as distinct from its enhancing effect on photoconductivity[5].

The experimental tubes employed contained a tubular 'O'-nickel cathode base, provided with an insulated tungsten heater, and coated over a portion of its length with barium oxide. A tungsten thermocouple wire was welded internally to the nickel tube, allowing the measurement of cathode temperature. Embedded in the cathode coating was a helical probe of fine nickel wire. A cylindrical nickel anode with a small circular window pierced in it was mounted coaxially with the cathode. A side-arm attached to the glass envelope of the experimental tube bore a 'Pyrex'-to-quartz graded seal with a plane quartz window at the quartz end, aligned so that the cathode could be illuminated through the quartz window and the window in the anode. The barium oxide coating was prepared by the usual method of pyrolysis of a sprayed barium carbonate suspension. The tubes were submitted to the usual schedules of breakdown, outgassing and activation by drawing thermionic emission current, and after sealing off from the vacuum system an active barium getter was fired.

Measurement of the electrical conductance of the cathode sample could be made by applying small potentials (up to 100 mV.) between the probe and cathode base and measuring the conductivity current on a sensitive galvanometer. The conductivity current-voltage characteristic at any desired cathode temperature T °K. was traced and the conductance σ of the barium oxide sample at that temperature could be obtained by taking the gradient of the characteristic at zero applied potential. The curvature of the characteristic was slight, and only a small error was incurred in later stages of the work when, for the sake of speed of observation, the difference in galvanometer readings for $\pm$ 20 mV. applied between the probe and cathode base was taken as a measure of the conductance.

In determining the effect of ultra-violet irradiation on dark conductivity, the variation of conductance with temperature for the cathode under investigation was first determined before any ultra-violet treatment was applied. The conductivity of well-activated cathodes was sufficiently high to allow measurements to be commenced at a cathode temperature of about 800 °K. and continued down to room temperature. The results are best displayed by plotting $\log \sigma$ versus $1/T$, as shown in Fig. 1*a*. The conductivity plot shows the well-known Loosjes–Vink[6] pattern in which the two linear portions are interpreted as representing a conduction process in which free electron flight across the pores of the oxide coating predominates at high temperatures, and a process of bulk or surface semiconduction through or over the surface of the oxide crystallites operates at low temperatures. In the

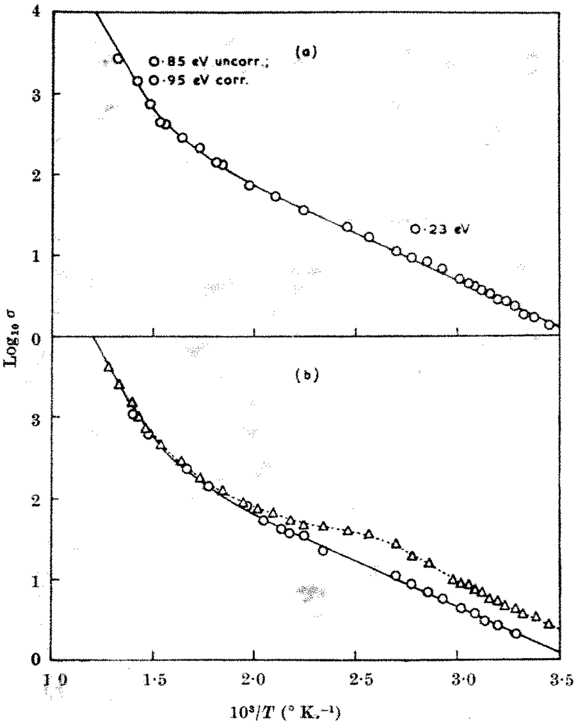

Fig. 1. Effect of ultra-violet irradiation on dark conductivity. *a*, Graph of log σ versus $1/T$ for an activated barium oxide coated cathode before ultra-violet irradiation; *b*, conductivity plots for the same cathode after ultra-violet irradiation: △, points plotted on warming cathode; ○, points plotted on cooling cathode. The conductance σ is expressed in arbitrary units

example given, the activation energy of the low-temperature process is 0·23 eV. and that of the high-temperature process is 0·95 eV., corrected for the parallel low-temperature component. On completion of the conductivity determination the cathode was irradiated through the quartz window with light from a high-pressure mercury arc, containing a high proportion of ultra-violet light, for 1 hr. The dark conductance of the cathode was then redetermined, starting at room temperature and heating the cathode. The effect of the ultra-violet irradiation was to increase the room-temperature dark conductance by a factor of about 2, and as the temperature was increased to about 370 °K. the enhancement increased slightly. From 370 °K. to about 550 °K. it decreased, and at temperatures above about 550 °K. the conductance was the same as that obtained at corresponding temperatures before irradiation. Heating was continued to about 800 °K., and the cathode was then cooled to room temperature. Conductance measurements taken during this process exactly reproduced the values obtained in the initial pre-irradiation determination. The results of this experiment are displayed in Fig. 1*b*; the curve obtained on warming the cathode immediately after irradiation is plotted as a broken line, and that taken on cooling as a continuous curve. For these plots separate current-voltage characteristics were not traced at each temperature, but the conductance was determined approximately, as indicated above. It was found that although the general form of this enhancement of dark conductivity is reproducible, the magnitude of the effect depends on a number of factors, such as the length of ultra-violet irradiation, the temperature of the cathode during irradiation, the period between the end of irradiation and the beginning of conductance measurements, and the rate of heating of the cathode. It was found that any enhancement could be completely removed by heating the cathode to about 600 °K. for a few minutes; on cooling, the conductance would return to the value obtained before irradiation.

This effect may be explained by postulating the existence of normally vacant donor-levels just below the conduction band in the energy-band model for barium oxide. Irradiation of the cathode sample with ultra-violet light may cause the excitation of electrons from the filled band and the occupation of some of these levels. Subsequent warming of the cathode in the dark in the course of conductivity determinations causes thermal excitation of electrons from these occupied levels to the conduction band, and an enhanced conductivity current is observed. Experiments on the enhancement of photo-electric emission by ultra-violet illumination[1-5] have led to the conclusion that such a band of normally unoccupied levels exists at about 2·5 eV. below vacuum potential. Although it is tempting to associate these levels with the enhancement of dark conductivity observed in the present work, there is, as yet, no direct evidence for the validity of such an association.

A Clear Instance of Rheopectic Flow

We have found an instance of rheopectic flow induced by shear in a rotational viscometer. The material exhibiting this rare type of non-Newtonian flow behaviour was a viscous suspension prepared by mixing kaolin clay, precipitated calcium carbonate, oxidized starch, a styrene–butadiene latex, sodium pyrophosphate and water. The total solids of the suspension amounted to 65 per cent.

Characterization of the material as rheopectic was based on shearing stress against time data obtained under conditions of constant shear-rate. A set of these data is presented in Fig. 1. The stress is seen to increase with time until it becomes measurably independent of it. It was ascertained that laminar flow prevailed during measurements.

It appears that this shear-thickening effect is due largely to the presence of calcium carbonate since, when it was replaced by an equal mass of clay, the flow behaviour of the suspension was that of a typically thixotropic material. The longest dimension of the pigment particles in the suspension was smaller than 2μ for the clay and 0·3μ for the calcium carbonate. Clay and calcium carbonate particles were mostly anisometric (length to width ratio for clay about 1·5; for calcium carbonate about 4·0) while the latex particles were essentially spheres (average diameter 0·2μ).

Earlier observations of the rheopectic phenomenon have been mostly visual, qualitative, and confined to certain types of colloidal systems, usually sols[1-5].

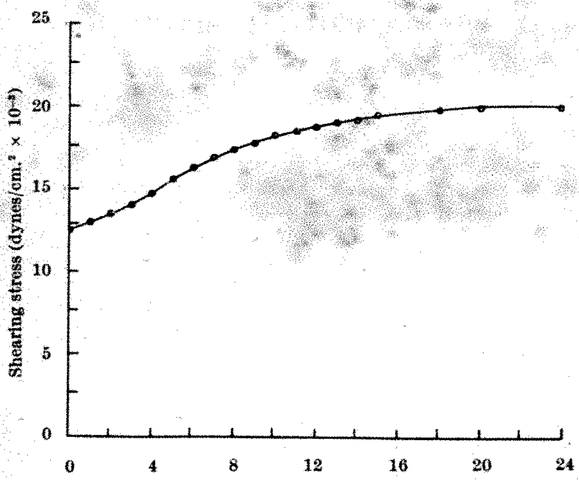

Fig. 1. Variation of shearing stress with time under conditions of constant shear-rate (1,850 sec.$^{-1}$) at 25 ± 0·2° C.

As a probable result of this, an assertion has been made recently that rheopexy is a flow phenomenon where structure build-up is brought about by small shearing-rates only[6], presumably less than about 10 sec.$^{-1}$. However, instances of rheopectic flow have been reported in the literature[7,8] although absolute values of shear-rate at which the phenomenon exhibits itself are not mentioned. Our observations demonstrate that rheopectic flow can develop at moderately high shear-rates (1,500–2,200 sec.$^{-1}$).

METALLURGY

Scattering of Long Wave-length Neutrons by Irradiated Beryllium Oxide

Work on the scattering of long wave-length neutrons by irradiation-induced defects have been carried out by Antal, Weiss and Dienes for graphite[1] and by Antal and Goland for alumina[2]. The method depends on the fact that in materials of low neutron absorption cross-section, neutrons of wave-length greater than the Bragg cut-off are attenuated principally by inelastic scattering (for which the cross-section is a few hundred millibarns) and by the scattering from defects. Application of Babinet's principle shows that each isolated point defect introduces an amount of scattering equal to the free atom cross-section of the material.

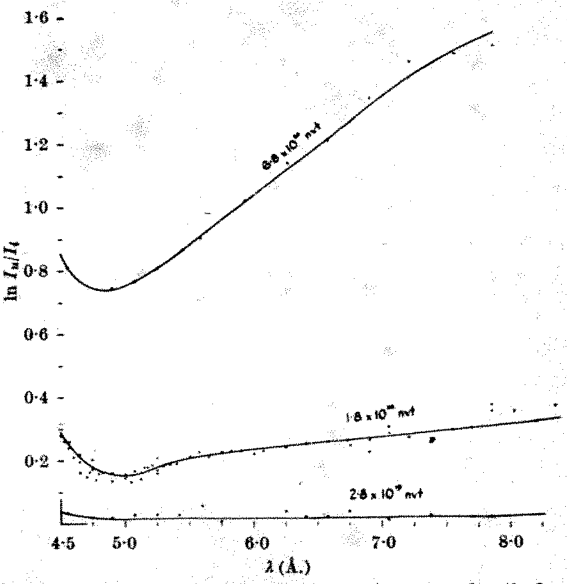

Fig. 1. Transmission ratios versus neutron wave-length for various neutron doses. Top curve, 6·8 × 10^{18} n.v.t.; middle curve, 1·8 × 10^{2} n.v.t.; ; bottom curve, 2·8 × 10^{19} n.v.t.

When the defects are randomly distributed a comparison of the attenuation by identical specimens before and after irradiation can give a direct measurement of the defect concentration. However, if the defects are clustered, interference occurs between the amplitudes of neutrons scattered from different defects within a cluster. In this case it is no longer possible to obtain an unambiguous estimate of the number of defects since the extra attenuation is dependent on wave-length, and the scattering is determined by the number of defects and the configuration of a cluster.

As part of an investigation of the behaviour of beryllium oxide under neutron irradiation, experiments have been carried out on specimens of this oxide irradiated to three different doses in *Hifar*.

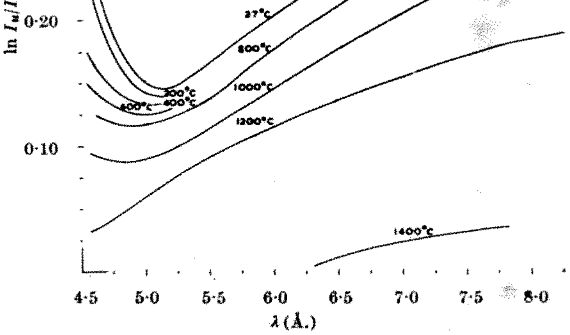

Fig. 2. Transmission ratios versus neutron wave-length after annealing at various temperatures

The neutron spectrometer used was similar to that described by Antal and Goland[2]. A mica monochromator was used with beryllium and beryllium oxide filters. The results are shown in Fig. 1 plotted as $\ln\left(\frac{I_u}{I_i}\right)$ versus wave-length, where I_u is the number of neutrons transmitted by 14 cm. of unirradiated beryllium oxide and I_i is the number transmitted by an identical specimen after irradiation. The doses quoted are the integrated doses over the fission neutron spectrum. It can be seen that the amount of extra scattering due to defects increases with neutron dose. For one set of specimens an annealing study was made by repeating the measurements after annealing the specimens at 200° C. intervals from 200–1,400° C. These results are shown in Fig. 2.

It can be seen that there are two distinct effects, a decrease in attenuation near the Bragg cut-off, which anneals steadily from 200° C. to 1,000° C., and an increase at longer wave-lengths, which anneals between 1,200° C. and 1,400° C.

The initial decrease in extra scattering near the cut-off wave-length could be explained if irradiation broadened the Bragg reflexions. However, this seems unlikely because the X-ray line broadening appears to be insufficient to account for the effect and this line broadening does not anneal until 1,400° C. A defect configuration which would explain the sharp decrease with wave-length is that proposed by Huntington[3] for copper, in which two interstitial atoms appear at each side of a vacant lattice site with an I–V spacing of less than 1 Å.

The theory developed by James[4] for the scattering of X-rays by polyatomic gases has been applied to the increase in scattering observed at long wave-lengths. A model which fits the observed dependence on wavelength is one in which the vacancies are clustered into close-packed groups containing 14 vacancies and the interstitials are randomly distributed. Values for the number of defects have been calculated on this model and these are shown in the Table 1.

Table 1

Specimen	Mean fission neutron dose (n.v.t.)	Irradiation temperature	Fraction of primary collisions	Fraction of displaced atoms	Displacements per primary collision
*X*22	$2\cdot8 \times 10^{19}$	70–75° C.	7×10^{-5}	$4\cdot5 \pm 4\cdot0 \times 10^{-4}$	1–13
*X*4	$1\cdot8 \times 10^{20}$	80–100° C.	$4\cdot5 \times 10^{-4}$	$4\cdot5 \pm 0\cdot4 \times 10^{-3}$	9–11
*X*39	$6\cdot8 \times 10^{20}$	80–100° C.	$1\cdot7 \times 10^{-3}$	$2\cdot2 \pm 0\cdot1 \times 10^{-3}$	12–14

The number of primary collisions was calculated by assuming a cross-section of 2·5 barns as the average of beryllium and oxygen atoms over the fission spectrum.

Further work on X-ray line broadening and other physical properties are being carried out in order to obtain more information on the nature of the defects.

RADIATION CHEMISTRY

Radiation-induced Formation and Reactions of the Formyl Radical Ion

We have recently reported the formation of the CO_2^- radical ion and the related CO_2H radical by the action of ionizing radiation on aqueous solutions of carbon dioxide and bicarbonate[1].

It seemed of interest, therefore, to examine the corresponding reaction with carbon monoxide which should lead, in the first instance, to the CO^- radical ion and the COH radical. Some direct proof for the presence of CO^- in aqueous solutions has been obtained now from experiments in which oxygen-free aqueous solutions containing suitable organic solutes have been irradiated with ionizing radiations in the presence of carbon monoxide. It could be demonstrated that in certain cases the CO^- ion (or the COH radical respectively) could be combined with an organic radical with the formation of the corresponding formylated compound.

For example, the irradiation of aqueous solutions of methanol (10^{-1} *M*) in the presence of carbon monoxide (1 atm.) with Co-60 γ-rays ($1\cdot4 \times 10^{19}$ eV. ml.^{-1}) gave glycolaldehyde with a yield of $G = 0\cdot2$ (molecules/100 eV.) at $pH = 5\cdot4$. The glycolaldehyde was identified by the formation of a coloured derivative with the 2 : 3-diaminophenazine reagent in concentrated sulphuric acid[2].

It is again important that the reaction is carried out in deoxygenated solutions because otherwise the negative polarons $(H_2O)^-$, which are the reducing entities[3] produced by the action of radiation on water, may be scavenged to a greater or lesser extent by the molecular oxygen according to:

$$(H_2O)^- + O_2 \rightarrow O_2^- + H_2O$$

In general, this formylation process depends on the formation of a free radical from the organic solute by the action of the radiation-produced OH or (H_2O^+), for example, in the case of methanol:

$$CH_3.OH + OH \rightarrow CH_2.OH + H_2O \qquad (1)$$

and association of the organic free radical with the COH (CO^-) according to the reaction:

$$CH_2.OH + COH \rightarrow CH_2.OH.CHO \qquad (2)$$

the formyl radical being formed by the reduction of CO according to:

$$CO + (H_2O)^- \rightarrow CO^- + H_2O \qquad (3)$$

$$CO^- + H^+ \rightleftarrows COH \qquad (4)$$

In this way it should be possible to produce some ^{14}C-carbonyl compounds labelled in the CO group.

A Reversible Photochromic Polymer

ULTRA-VIOLET irradiation of chromium, molybdenum or tungsten hexacarbonyls dissolved in donor solvents causes the substitution of one or more molecules of carbon monoxide by solvent. The products are yellow in colour[1].

Methyl methacrylate polymers which contain occluded metal hexacarbonyls behave similarly. On ultra-violet irradiation or on being placed in sunlight, the polymers assume a deep yellow colour when as little as 0·1 per cent of, for example, chromium hexacarbonyl is present. At room temperature, either in air or high vacuum, the colour fades over a period of about 4 hr. The colour vanishes rapidly on warming to 100° but is stable when the specimen is stored in liquid nitrogen.

We believe that, on irradiation, the chromium hexacarbonyl decomposes to give $Cr(CO)_5$ and carbon monoxide. The former molecule may exist as such in the coloured polymer or may be stabilized by interaction with neighbouring ester groups or occluded carbon–carbon double bonds. Since the hexacarbonyl is trapped in the polymer matrix, the carbon monoxide cannot escape even on pumping, and at room temperature it slowly returns to the metal, producing the original colourless hexacarbonyl. Heating to 100° relaxes the polymer matrix and facilitates the reversion to hexacarbonyl.

The infra-red spectrum of the yellow polymethyl methacrylate showed a carbonyl shift of about 40 cm.$^{-1}$ to higher wave-lengths compared with unirradiated samples. No electron spin resonance spectrum other than that normally associated with polymethyl methacrylate irradiated with ultra-violet could be detected. These facts are consistent with the presence of $Cr(CO)_5$ or its addition products.

CHEMISTRY

Fluoride-compensated Substitution of Bivalent Cations in the Magnetoplumbite Structure

$BaAl_{12}O_{19}$ has the structure of the mineral magnetoplumbite[1]. In the hexagonal unit cell, containing two formula units, the aluminium ions are distributed among five crystallographic positions. There are two tetrahedrally co-ordinated positions (4*f* in C_6/mmm) nine octahedrally co-ordinated (2*a*, 12*k*, 4*f*) and one ion surrounded by a trigonal bipyramid (2*b* in C_6/mmm) of oxide ions per formula unit.

The object of this work was to try to introduce bivalent cations, compensated by other foreign ions, in place of the Al^{3+} ions in the structure, in order to study the site preference of these ions in this structure. Cationic compensation (substitution of La^{3+} for Ba^{2+}) and anionic compensation (substitution of F^- for $O^=$) were both used. The latter method was first used for this structure by Frei *et al.*[2], who introduced fluoride into $BaFe_{12}O_{19}$ with concurrent reduction of some Fe^{3+} to Fe^{2+}.

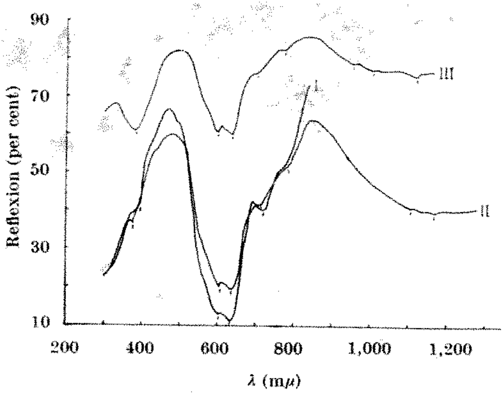

Fig. 1. Per cent reflexion versus wave-length, mμ (magnesium carbonate standard). I, $BaNi_{1·5}Al_{10·5}O_{17·5}F_{2·5}$; II, $BaNi_{2·5}Al_{9·5}O_{16·5}F_{2·5}$; III, $BaZn_2Ni_{0·5}Al_{9·5}O_{16·5}F_{2·5}$

Using cationic compensation, materials having the general formula $Ba_{1-x}La_xNi_xAl_{12-x}O_{19}$ were prepared. For samples where $x \leqq 0·2$, X-ray diffraction indicated the presence of only the magnetoplumbite phase. At values of $x \geqslant 0·3$ a mixture of $LaAlO_3$, Al_2O_3 and magnetoplumbite was found. The samples where $x \leqq 0·2$ were blue in colour; reflectance spectra, taken on pellets pressed from the powders, give the following absorption peaks:

cm.$^{-1}$	Intensity	Site
27,000	Very weak	Octahedral
17,700	Strong	Tetrahedral
16,400	Very strong	Tetrahedral
15,850	Very strong	Tetrahedral
13,950	Medium	Tetrahedral
12,900	Very weak	Tetrahedral

All these absorptions, except the first one, are in good agreement with the spectrum of Ni^{2+} in ZnO (ref. 3) and indicate that almost all the Ni^{2+} is occupying tetrahedral sites. The presence of a small amount of Ni^{2+} in octahedral sites is indicated by a weak absorption at 27,000 cm.$^{-1}$, which is in good agreement with the strongest absorption in $Ni(H_2O)_6^{2+}$ (ref. 3).

Due to the breakdown of the magnetoplumbite phase at $x \geqslant 0·3$, the second method of charge compensation was attempted in order to examine the site preferences as a function of concentration of the bivalent ion.

Materials having the general formula $BaM^{II}Al_{12-x}O_{19-x}F_x$ were prepared by firing mixtures of BaF_2, $BaCO_3$, MO, Al_2O_3 at 1,350–1,400° C. in an atmosphere of dry nitrogen gas.

The first system to be investigated was one in which $M^{II} = Ni^{2+}$ and $x = 0·1$, $0·2 \rightarrow 1$, 1·5, 2·0, 2·5. $BaNiZnAl_{10}O_{19}F_2$ and $BaNi_{0·5}Zn_2Al_{9·5}O_{16·5}F_{2·5}$ were also prepared, using AlF_3 where an extra source of fluoride was needed. X-ray diffraction showed that for all samples where $x \leqq 2·5$, only the hexagonal phase was present; where $M^{II} = Ni^{2+}$ and $x \geqq 1·0$ the *c*-axis was doubled. This effect did not appear where $M^{II} = Zn^{2+}$ or Co^{2+}. At values of $x > 2·5$, the hexagonal phase disappears and is replaced by a spinel phase, probably $Ni_{1+x}Al_{2-x}O_{4-x}F_x$, in the residue after leaching with hot concentrated hydrochloric acid.

The reflectance spectra of the materials the general formula of which is $BaNi_xAl_{12-x}O_{19-x}F_x$, where $x \leqq 2·0$, are identical with the spectra described previously. This indicates that, when substituted for up to 2 gm.-atoms of Al^{3+} (in $BaAl_{12}O_{19}$), Ni^{2+} strongly prefers tetrahedral sites (Fig. 1, curve I).

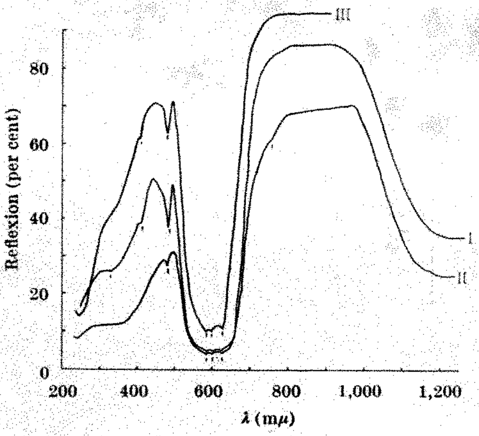

Fig. 2. Per cent reflexion versus wave-length, mμ (magnesium carbonate standard). I, $BaCo_2Al_{10}O_{17}F_2$; II, $BaCo_{2\cdot5}Al_{9\cdot5}O_{16\cdot5}F_{2\cdot5}$; III, $BaZn_2Co_{0\cdot5}Al_{9\cdot5}O_{16\cdot5}F_{2\cdot5}$

At $x = 2\cdot5$ (Fig. 1, curve II) a marked increase is observed in the absorption at 27,000 cm.$^{-1}$, indicating an increase in the amount of Ni^{2+} in octahedral sites. A weak absorption is found at 8,900 cm.$^{-1}$ which also indicates octahedral nickel. The increase in octahedral nickel is caused by the excess Ni^{2+} (greater than 2 gm.-atoms) which is forced to occupy the octahedral or trigonal bipyramid sites. The tetrahedral sites are saturated by the first 2 gm.-atoms of Ni^{2+}. All these samples were blue in colour. Fluoride analysis of $BaNiAl_{11}O_{18}F$ yielded a value of 2·2 per cent by weight of fluoride. The calculated value is 2·0 per cent.

The sample $BaZn_2Ni_{0\cdot5}Al_{9\cdot5}O_{16\cdot5}F_{2\cdot5}$ was prepared in order to see if Zn^{2+} (which has a strong tetrahedral site preference) could displace Ni^{2+} from the tetrahedral sites. Fig. 1, curve III, shows a large increase in the amount of octahedral Ni^{2+} with a corresponding decrease in the amount of tetrahedral Ni^{2+}. This sample had a light blue-green colour.

The next system to be investigated was one in which $M^{II} = Co^{2+}$ and $x = 0\cdot1$, $0\cdot4$, $1\cdot0$, $2\cdot0$, $2\cdot5$. $BaZnCoAl_{10}O_{17}F_2$ and $BaZn_2Co_{0\cdot5}Al_{9\cdot5}O_{16\cdot5}$ were also prepared. X-ray diffraction showed the presence of only one phase (magnetoplumbite). The intensities of the absorptions, of course, vary with composition.

The spectra of all these samples were identical except for that of $BaCo_{2\cdot5}Al_{9\cdot5}O_{16\cdot5}F_{2\cdot5}$. This sample showed a strong absorption in the near ultra-violet region which may be caused by cobalt in octahedral sites. The observed absorption maxima for these materials are:

cm.$^{-1}$	Intensity	Site
24,400	Medium	Tetrahedral
20,900	Medium	Tetrahedral
17,100	Very strong	Tetrahedral
16,800	Very strong	Tetrahedral
16,100	Very strong	Tetrahedral

These values are in fair agreement with the spectrum observed for Co^{2+} in ZnO (ref. 4) and they are in good agreement with the values obtained from the crystal field splittings as a function of *Dq* which were calculated by Low[5]. Curve III (Fig. 2) shows the spectrum of $BaZn_2Co_{0\cdot5}Al_{9\cdot5}O_{16\cdot5}F_{2\cdot5}$. The absorption spectra indicate that Zn^{2+} does not displace Co^{2+} from tetrahedral sites to any appreciable extent.

It has been shown that Ni^{2+} and Co^{2+}, compensated by F^-, have tetrahedral site preferences, in $BaAl_{12}O_{19}$, in all concentrations up to the saturation of the tetrahedral sites. The preference of Co^{2+} for tetrahedral sites has been shown to be greater than that of Ni^{2+}, as tetrahedral Ni^{2+} is displaced by Zn^{2+} and tetrahedral Co^{2+} is not. The tetrahedral site preference of Ni^{2+} (which would normally have an octahedral site preference) may be caused by a Jahn–Teller stabilization. This Jahn–Teller effect may also be the cause of the change of symmetry in the hexagonal unit cell which effected a doubling of the *c*-axis. This effect was not observed with Co^{2+}.

Ultrasonic Velocity in Aqueous Silver Nitrate Solution

We have confirmed the recent report[1] that, in the case of aqueous solutions of silver nitrate, the ultrasonic velocity decreases with increasing concentration over the range of concentration investigated. However, a minimum velocity is observed at approximately 4 *M*; thereafter, increasing concentration up to saturation causes a monotonic increase in ultrasonic velocity, as is usual for aqueous electrolyte solutions. Part of the complete velocity/molarity curve is shown in Fig. 1; these results were obtained with a variable-path fixed frequency (263·3 kc./sec.) interferometer, at 25° C.

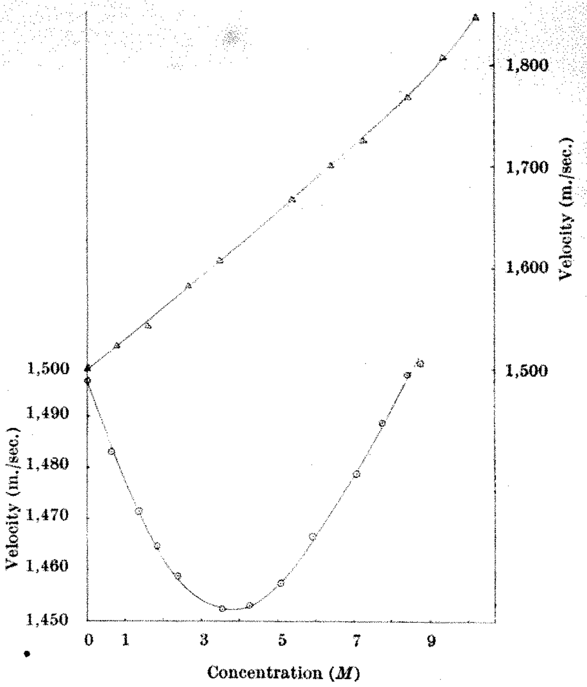

Fig. 1. Variation of ultrasonic velocity with concentration in aqueous solutions of electrolytes. ○, Silver nitrate; △, ammonium nitrate

Although the suggested explanations[2-4] in terms of heavy radicals or complex ions may be correct, it is clear that the parameters directly responsible for the minimum velocity are the density, and the adiabatic compressibility, β, of the solution. These are related by the equation:

$$v^2 = 1/\rho\beta$$

where v is the ultrasonic velocity. The variation in v with molarity may then be expressed:

$$dv/dc = -v/2 . (1/\rho . d\rho/dc + 1/\beta . d\beta/dc) \quad (1)$$

The terms $d\rho/dc$ and $d\beta/dc$ are of opposite sign; hence the relative magnitudes of the terms within brackets on the right-hand side of equation (1) may produce monotonic increase or decrease of v with concentration, or, as in the case of silver nitrate, a minimum velocity.

It is interesting that ammonium nitrate solutions, which show similar variations with molarity of electrical conductance and of mean-ion activity coefficient to those of silver nitrate, do not exhibit a minimum ultrasonic velocity; the curve for ammonium nitrate is included in Fig. 1. Presumably the ion-pairing in these solutions[5] does not always result in a velocity minimum.

Complexes of Vermiculite with Amino-Acids

Organic substances, either as neutral molecules or as cations, form 'sandwich' complexes with the expanding-lattice silicate minerals in which films of the organic substance a few Angstroms thick alternate with silicate layers 10 Å. thick. Recent work has shown that macroscopic vermiculite crystals complexed with butylammonium ions absorb large quantities of water and swell in the direction perpendicular to the plane of the silicate layers[1,2].

We have observed that macroscopic vermiculite crystals complexed with various amino-acids also swell anisotropically to many times their original size. Two apparently different swelling mechanisms are involved, depending on whether the amino-acid is present as the cation or as the dipolar ion; in both instances, swelling is confined to the direction perpendicular to the plane of the silicate layers (Fig. 1). In the jelly-like swollen crystals, the silicate layers remain effectively parallel to one another and, under optimum swelling conditions, may be some hundreds of Angstroms apart.

One type of swelling resembles that exhibited by the butylammonium–vermiculite complexes, and occurs after the amino-acid has been introduced as the interlayer cation replacing the magnesium or other inorganic cations present in the natural minerals. Treatment with 0·5 *M* aqueous solutions of the hydrochloride of the acid for two or three days at 80° C. is usually sufficient for complete exchange with crack-free crystals of dimensions 1 mm. × 1 mm. × 0·1 mm. The amount of amino-acid taken up is close to the cation exchange capacity of the minerals, that is, in the range 120–180 m.equiv./100 gm. Swelling develops when the amino-acid solution, in which the crystals are immersed, is diluted to a critical value which varies with the amino-acid and the vermiculite used. Swelling increases with decreasing solution concentration and is maximal at infinite dilution. The initiation of swelling is thought to coincide with 'hydration' of the interlayer amino-acid cations[2] and their dissociation from the negatively charged silicate surfaces, while subsequent swelling appears to be osmotically controlled. This type of swelling has been observed with ornithine, lysine and γ-aminobutyric acid.

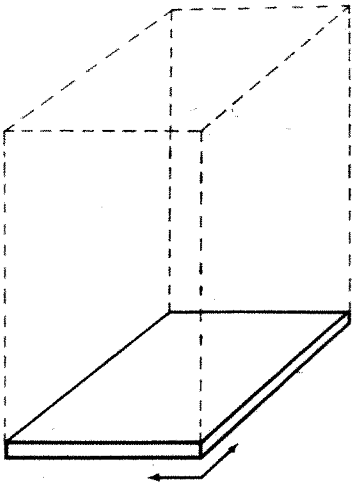

Fig. 1. Representation of the dimensional change in a vermiculite–amino-acid crystal before swelling (full line) and after swelling (dashed line). Silicate layer plane indicated by arrows

A second type of swelling occurs when natural vermiculite crystals are immersed in strong amino-acid solutions containing the acid in the dipolar form. In this type, replacement of the interlayer inorganic cations is inappreciable and swelling may take place at room temperature in a few minutes. Swelling develops only in solutions of sufficiently high concentration and increases directly with concentration. Considerable amounts of amino-acid are taken up into the interlayer regions of the mineral, the intracrystalline concentration being of the same order as that of the external solution. Here the dielectric constant of the immersion solution appears to be the controlling factor. The mechanism is thought to involve the masking of the charge on the interlayer cations so that the effective electrostatic attraction between them and the silicate layers is reduced. Swelling of this type has been observed with solutions of glycine, β-alanine, γ-aminobutyric acid and ε-aminocaproic acid.

Semiconductivity of Chlorpromazine

It has been shown in ref. 1 that chlorpromazine, the common name for phenothiazine-2-chloro-10-(3 dimethyl aminopropyl), is "a quite extraordinarily strong electron donor"; it is "the first substance ever found in which, in its ordinary stable state, the highest filled level corresponds to an antibonding orbital". It thus should be expected that chlorpromazine, also in view of its striking physiological activity, should exhibit some interesting electrical properties.

The parent compound, phenazin, has recently been shown[2] to be an intrinsic semiconductor with an activation energy of 2·1 eV., relating the conductivity σ to temperature T by:

$$\sigma = \sigma_0 \exp - E/2kT$$

We have examined the resistance of the purified substance, melting point 56·85° C., kindly supplied to us by Messrs. May and Baker, Ltd., Dagenham, Essex, England, in the form of glass-like slabs cast from the melt in a 'Perspex' former between roughened platinum electrodes. A thermistor bead was also cast into the slab, but located outside the field, to act as a thermometer. The whole apparatus was placed under thermostatical control. The electrical resistance was found to drift downwards for 20–30 min. after the application of an electric field. Once equilibrium was attained, very little further drift was observed during a period of 3 hr. A time-interval of 20–30 min. was therefore allowed between each reading. The voltage applied was 85 V. d.c.

Data of resistance against temperature were obtained on fifteen runs of heating and cooling cycles, referring to four different slabs. The temperature coefficient of the resistance R was found to reverse sign at 32° C., becoming negative at higher temperatures. A plot of log R against $1/T$ of this transition region is shown in Fig. 1, and a plot of the high temperature region between 34° and 80° C. is shown in Fig. 2.

Chlorpromazine thus appears to be an impurity semiconductor at low temperatures, and an intrinsic semiconductor at temperatures in excess of about 32° C. There is no significant change in either resistivity or value of E on fusion; E remains substantially constant at 2·1 eV. at temperatures between 34° and 80° C. The region of positive temperature coefficient connecting the impurity conductance with the intrinsic conductance regions is considered to be a régime where the concentrations of localized donor- or acceptor-levels nearly equal the concentration of charge carriers. The transition at 32° C. is believed to be associated with a crystallographic change, the substance existing in different modifications below and above that temperature.

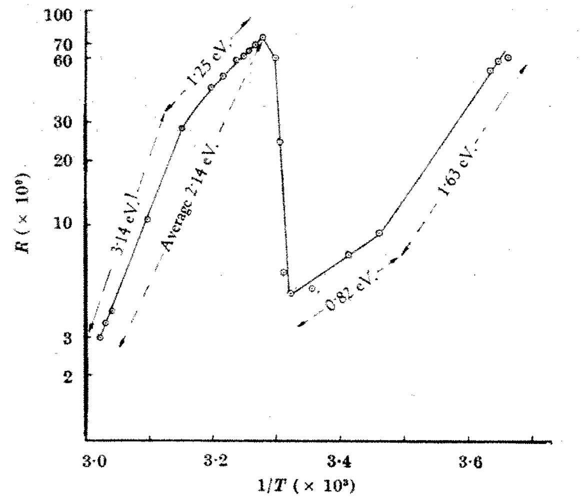

Fig. 1. The resistivity of chlorpromazine, plotted on a logarithmic scale against inverse temperature, showing the transition at 32° C.

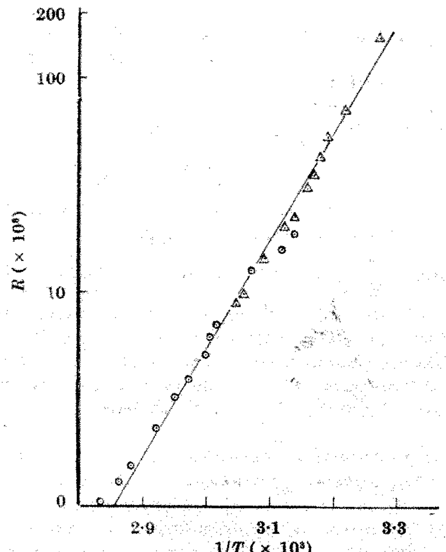

Fig. 2. Resistance of chlorpromazine above the transition. This plot covers the region between 34° and 80° C., the melting point being 56·85° C. There is no significant discontinuity on fusion, nor hysteresis between heating and cooling cycles. △, Heating cycle; ⊙, cooling cycle

There is no evidence for a hysteresis. The points referring to both the heating and the cooling cycle, shown in Fig. 2, are seen to fall on one single straight line.

The conductivity with direct current of chlorpromazine at the transition temperature of 32° C. was found to be $9{\cdot}2 \times 10^{-11}$ (ohm-cm.)$^{-1}$. The value of E found for chlorpromazine, namely, 2·1 eV., agrees with that reported[2] for phenazine; this conforms with ideas put forward[3] on the role of the delocalization of the π-electrons in a ring system. The phthalocyanines are also rather insensitive, so far as E is concerned, to modifications of the molecule which leave the ring structure substantially unaltered, as, for example, by the chelation of metal atoms[5].

Curves closely resembling that shown in Fig. 1 have been reported in ref. 4 for glassy, amorphous selenium. This element also exhibits no change in E on fusion.

Measurements of permittivity and of loss factor at audio- as well as at radio-frequency confirmed the existence of the transition at 32° C.

Direct proof of the existence of a crystallographical change in that region of temperature has been obtained by taking infra-red spectra at temperatures of about 25° C., 36° C. and 55° C.; these temperatures are approximate only, due to heating of the sample by radiation. While no change appeared between the spectra obtained at the two higher temperatures, pronounced differences were observed between those obtained at the two lower temperatures. The changes affect the side-chain as well as the ring system, and are consistent with a steric change in the alignment and the co-ordination of the molecules.

We wish to thank Messrs. May and Baker, Ltd., Dagenham, Essex, for the supply of chlorpromazine, and Dr. R. L. Werner of this Department for his assistance in the interpretation of the infra-red spectra.

Structure of δ-Plutonium

In a recent article[1] a modification to the normally accepted close-packed face-centred cubic structure of δ-plutonium was suggested. The purpose of this was to give a continuous gradation, with increasing temperature, in the amount of covalency in the various plutonium structures; from this was deduced a predicted value of the negative expansion coefficient of about the correct size.

The proposed modification consisted of slight displacements inwards of the face-centring atoms in alternate cells. This structure should give additional weak 'superlattice' lines on an X-ray diffraction pattern in addition to those normally observed. However, we could not detect these experimentally, although calculations showed that the X-ray diffractometer techniques used were amply sensitive. The absence of these lines does not lend credence to the proposed structure.

A full description of the experiments is to be published elsewhere.

Girard *T* Reagent for Carbonyls

The water-soluble properties of Girard *T* hydrazones make the reagent potentially effective for isolation of carbonyls from mixtures soluble in non-polar solvents. In work on the chemistry of rancidity[1], we have found the reagent useful in learning about the distribution of volatile and non-volatile carbonyls in rancid fat. This work indicated possible usefulness of the reagent for investigation of the complex carbonyl anatomy of autoxidized fats. Successful application depends on adaptation to quantitative isolation of very small amounts of carbonyls, and on devising means of controlling the reaction so as to isolate at will free carbonyl and bound or potential carbonyl.

This report deals with certain aspects of the methodology of the Girard reaction. In experiments with known amounts of monocarbonyls, 0·5–1·0 gm. of Girard *T* reagent was reacted in 20·0 ml. of purified anhydrous methanol or ethanol and shaken 3 hr. at room temperature, or refluxed for 1 hr. The reaction mixture was poured into 200 ml. of ice water, and then extracted with petroleum ether to remove non-carbonylic material. The aqueous phase contained the Girard *T* hydrazones. These were converted directly into 2,4-dinitrophenylhydrazones by treatment with 30 ml. of a saturated 2,4-dinitrophenylhydrazine solution in 2 *N* hydrochloric acid[2] and 190 ml. of water. After standing overnight at room temperature, or heating 1 hr. on the steam bath, the 2,4-dinitrophenylhydrazones were removed by successive extractions with carbon tetrachloride and benzene. Monocarbonyl hydrazones were separated by passage of extract residues through hydrated alumina[2]. Total amounts of these compounds were determined by measurement of absorbance at the wave-length of maximum absorption[3–6] in 100 ml. of carbon tetrachloride solution. In the case of mixtures, paper chromatographic methods are available for resolution, identification, and estimation of monocarbonyls[3–6].

Table 1. BLANK DETERMINATIONS

0·5 gm. (purified) RT, 3 hr.	Heated	1 hr.	—	0·310†	—

* Room temperature.
† Purified by treatment with 2,4-dinitrophenylhydrazine and hydrochloric acid.

The above procedure for the Girard reaction gave high blanks which seriously affected determinations of very small amounts of monocarbonyls. The Girard *T* reagent was found to contain hydrazone, which could be removed by several recrystallizations under mild conditions from ethanol. However, the greater part of the blank was found to result from a curious reaction between the primary alcohols used as solvents and both the Girard *T* and 2,4-dinitrophenylhydrazine. The amount of formaldehyde or acetaldehyde hydrazone formed was related directly to the severity of reaction conditions and independent of exposure to air. Apparently, this carbonyl formation is a dehydrogenation and analogous to the formation of osazones from α-keto alcohols. The reaction has been studied on a very large scale by Braude and Forbes[7], who determined that it resulted in a 5–25 per cent yield with primary and secondary alcohols containing two or more ethylenic or phenyl substituents in conjugation with the alcohol group. These investigators stated that derivatives were not formed with monophenyl, α,β unsaturated and saturated alcohols. This has been found not to be completely correct in the case of the two saturated primary alcohols used.

Methanol and ethanol have been the standard solvents used in the Girard *T* reaction since it was first reported[8]. Tertiary butyl alcohol is proposed as a relatively inert solvent for use in the presence of the Girard *T* reagent and 2,4-dinitrophenylhydrazine. The Girard *T* reagent has limited, but adequate, solubility in this alcohol, which is a much better solvent for fats than methanol or ethanol. Blanks found with ethanol and tertiary butyl alcohol are shown in Table 1. Ethanol blanks were substantial, and increased with vigour of conditions of reaction. Both Girard *T* and 2,4-dinitrophenylhydrazine are shown to act on ethanol. Purified butyl alcohol gave negligible blanks when the Girard *T* reagent was recrystallized, except when heated in the 2,4-dinitrophenylhydrazine step. Purification of tertiary butyl alcohol with 2,4-dinitrophenylhydrazine and hydrochloric acid reduced this blank somewhat. This may indicate the presence of a persistent impurity, possibly a ketal. In any event, heating in the 2,4-dinitrophenylhydrazine step was unnecessary for complete conversion.

The use of tertiary butyl alcohol in the Girard *T* reaction gave nearly quantitative results, under mildest conditions of reaction, with *n*-alkanals, *n*-alk-2-enals, and *n*-alk-2,4-dienals. Reaction of methyl ketones with the Girard *T* reagent was less complete (about 80 per cent).

The entire suitability of the Girard *T* reagent for study of total carbonyls in autoxidized fat remains to be determined. Little is known about its reaction with dicarbonyl compounds. In view of its dehydrogenation action on primary and secondary alcohols, the reagent might convert hydroxy compounds produced in the autoxidation into carbonyls. Direct reaction of Girard *T* reagent or 2,4-dinitrophenylhydrazine with fat autoxidation products could result in higher total carbonyl than actually present. There has been some indication that this may occur; such as continual removal of carbonyl on repeated treatments with Girard *T* reagent[1], but further study is necessary. It was considered that the information in this report might be of use to those interested in applications of the Girard *T* reagent.

BIOCHEMISTRY

Immunochemical Distinction between Insulins with Identical Amino-Acid Sequences

Virtually all human subjects treated with commercial mixtures of beef-pork insulin develop circulating insulin-binding antibodies that are readily detectable with insulin labelled with iodine-131 by means of paper or starch electrophoresis, paper chromatography or ultracentrifugation[1]. These antibodies react not only with the specific immunizing insulins but also with horse, sheep and human insulins[2], and with dog, monkey, rabbit and whale insulins (unpublished work) in greater or lesser degree. Harris, Sanger and Naughton[3] have shown that the amino-acid sequences of insulins from four different ungulate species (cattle, pig, horse and sheep) differ only in the 8–10 positions of the *A* chains. Although some human antisera react quite similarly with these four insulins, certain antisera can distinguish clearly among insulins from the different species, generally reacting much more strongly with beef and sheep insulins than with pork and horse insulins[2]. These differences in reaction of the ungulate insulins have been related[2] to the known differences in the 8–10 sequence of the *A*-chain or to possible differences in secondary or tertiary structure.

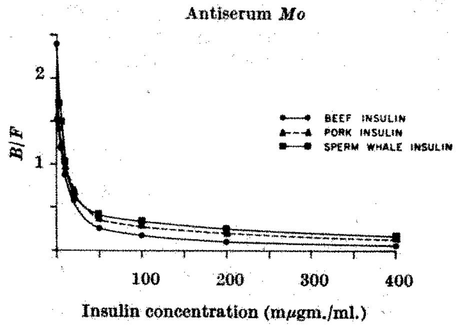

Fig. 1. Ratio of antibody-bound beef insulin-131 to free beef insulin-131 (*B/F*) as a function of the concentration of unlabelled crystalline insulins from various animal species. Human antiserum *Mo* at 1 : 10 dilution

Harris *et al.*[3] found the amino-acid sequences of a whale insulin sample to be identical with those of pork insulin. More recently, Ishihara, Saito, Ito and Fujino[4] established that these sequences are present in sperm whale insulin but differ slightly from those of sei-whale insulin.

The present communication describes experiments showing that certain insulin antisera can discriminate sharply between the competitive inhibition offered by pork and sperm whale insulins to the binding of beef insulin labelled with iodine-131 to combining sites on the antibody molecules.

Crystalline beef insulin labelled with iodine-131 was prepared by methods described previously[1]. Mixtures containing identical trace concentrations of beef insulin-^{131}I, different concentrations of unlabelled crystalline beef, pork or whale insulin and identical concentrations of antiserum (added last in all cases) were prepared at room temperature and allowed to stand for 4 days at 4° C., at the end of which time they were analysed by paper chromato-electrophoresis[1] for the percentage of insulin-^{131}I bound to antibody. Briefly, this determination depends on the adsorption of unbound ('free') insulin-^{131}I to the paper at the site of application[1,5] and the migration of antibody-bound insulin-^{131}I with the inter β-γ globulins[1,6]. The ratio of bound to free insulin-^{131}I is plotted as a function of the concentration of unlabelled insulin present in the mixtures.

Many antisera react quite similarly with crystalline beef, pork and sperm whale insulins. Antiserum from subject *Mo* (Fig. 1) is typical of this group of cases in which not more than about 1·5 times as much sperm insulin as pork insulin was required to reduce the ratio of bound to free insulin-^{131}I for beef insulin-^{131}I to any specified level. Similar results have been observed with antiserum from a guinea pig immunized with beef insulin. In contrast to this relative indifference to the species from which the insulin comes are the results obtained with antisera *Le* (Fig. 2, upper) and *Ge* (Fig. 2, lower), which discriminate sperm whale insulin sharply from pork insulin. More than 150 times as much sperm whale insulin as pork insulin was required to reduce the ratios of bound to free insulin-^{131}I (beef insulin) to

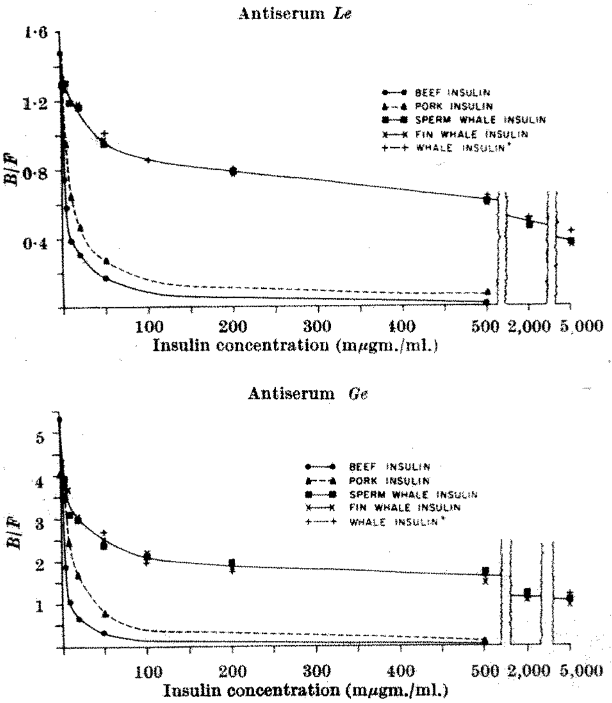

Fig. 2. Ratio of antibody-bound beef insulin-131 to free beef insulin-131 (*B*/*F*) as a function of the concentration of unlabelled crystalline insulins from various animal species. Upper: 1 : 60 dilution of antiserum *Le*; lower: 1 : 400 dilution of antiserum *Ge*. Whale insulin—unidentified as to species, see text

certain levels in *Le* and more than 100 times as much in *Ge*.

Experiments illustrated in Figs. 1 and 2 were carried out simultaneously with the same preparations and the results with antisera *Le* and *Ge* were confirmed repeatedly in several experiments with different preparations of insulin-^{131}I and different dilutions of antiserum and concentrations of insulin.

The differences observed between sperm whale and pork insulins in antisera *Le* and *Ge* can clearly not be attributed to any inherent inactivity or other anomaly of the sperm whale insulin crystals, in view of the essential similarity of reactions of the two insulins in many antisera as typified by antiserum *Mo* (Fig. 1). Furthermore, the procedure employed in purification of the insulin appears to be of no consequence, since three different preparations of beef insulin have been shown to react identically with an antiserum that clearly recognized species differences[2].

Fig. 2 also shows results with fin whale insulin and with a 'whale' insulin kindly supplied by Dr. A. M. Fisher, Connaught Laboratories, Toronto. The latter is not unequivocally identified as to species but may have been the same preparation analysed by Sanger and colleagues. The similarity of reactions of sperm whale and fin whale insulins suggests that these two insulins may have the same structure, but does not establish their identity with respect to amino-acid sequence since the immunochemical reaction does not always differentiate clearly between insulins with different sequences (cf. ref. 2 and Fig. 1). However, the marked discrimination between sperm whale and pork insulins by certain antisera is of considerable interest and would appear to provide the first evidence that two different proteins with identical amino-acid sequences (assuming the absence of any D-amino-acid configurations) may yet possess differences in secondary or tertiary structure. However, the observed species specificities entail differences in the standard free-energy change of binding of the order of only 3–4 k.cal. per mole, whereas the standard free-energy changes themselves are in the range of 8–12 k.cal. per mole[7]. Thus, a relatively small distinction in the structure of whale insulin at a critical site might well account for the lesser degree of complementarity to certain antibodies revealed by these investigations. If confirmed by more direct physico-chemical work, these findings can only mean that the overall protein structure is not determined by amino-acid sequence alone.

Finally, the possible significance of these observations to concepts of genetic transmission of inherited characteristics of protein synthesis is not to be overlooked. It would seem that, in addition to amino-acid sequence, the precise configuration of folding of the protein molecule is determined by the genetic apparatus.

We are indebted to Dr. O. Behrens, Lilly Research Laboratories, for supplies of crystalline beef and pork insulins and to Dr. T. Shibata, Taiyo Fishery Co., Yokosuka, Japan, through the kindness of Dr. Y. Ishihara, Hokkaido University, Japan, for supplies of crystalline sperm whale and fin whale insulins.

Biosynthesis of Hydrastine

LITTLE experimental work has been done on the biosynthesis of the phthalideisoquinoline, the benzylisoquinoline, and the protoberberine alkaloids. All these should be derived, according to biogenetic hypothesis, from two units of tyrosine[1] or two units of shikimic acid[2].

In extracts of *Berberis vulgaris* L. radioactivity from [2-^{14}C]-phenylalanine has been qualitatively detected by autoradiography in a chromatographic spot attributed to berberine[3]. In *Coptis japonica* Makino, DL-[2-^{14}C]-tyrosine gave rise to berberine containing radioactivity of unknown distribution in the nucleus of the alkaloid[4]. Activity from L-[U-^{14}C]-tyrosine was incorporated into papaverine, narcotine and narcotoline in *Papaver somniferum* L.[5]. The distribution of carbon-14 suggested that narcotoline was derived from two tyrosine units, but the evidence was indicative rather than conclusive. In the only detailed investigation to date Battersby and Harper[6] showed by unambiguous degradation of labelled papaverine obtained from DL-[2-^{14}C]-tyrosine in *Papaver somniferum* L. that two units of precursor were incorporated into the alkaloid without randomization.

We have examined the biosynthesis of hydrastine (I) in *Hydrastis canadensis* L. Mature plants were grown hydroponically in aerated nutrient solution[7]

Table 1

	Precursor		Duration of feeding (days)	Products			
				Hydrastine		Berberine	
	Total activity (counts/min.)	Specific activity (counts/min./mM)		Weight (gm.)	Specific activity (counts/min./mM)	Weight (gm.)	Specific activity (counts/min./mM)
DL-[2-^{14}C]-tyrosine	$8 \cdot 68 \times 10^7$	$5 \cdot 15 \times 10^8$	17	0·154	$5 \cdot 17 \times 10^4$	0·330	$12 \cdot 4 \times 10^4$

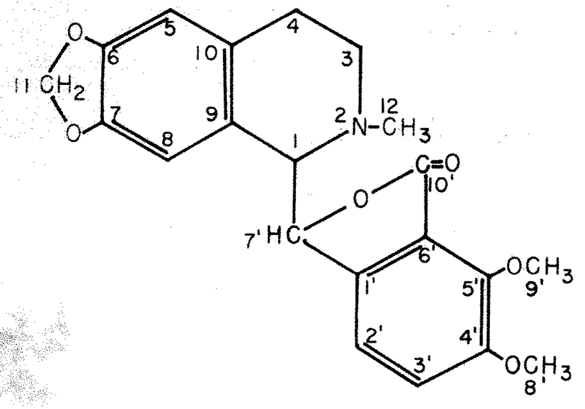
DL-[2-^{14}C]-phenylalanine	$8 \cdot 87 \times 10^7$	$4 \cdot 18 \times 10^8$	8	0·405	$0 \cdot 06 \times 10^4$	0·472	$0 \cdot 42 \times 10^4$
D-[U-^{14}C]-glucose	$8 \cdot 75 \times 10^7$	$8 \cdot 75 \times 10^8$	17	0·506	$0 \cdot 41 \times 10^4$	0·612	$1 \cdot 27 \times 10^4$

containing DL-[2-^{14}C]-tyrosine. Hydrastine and berberine were extracted from the roots. Chemical and radioactive yields are recorded in Table 1. In parallel experiments DL-[2-^{14}C]-phenylalanine and D-[U-^{14}C]-glucose were administered. Radioactive incorporation of these into the alkaloids, also summarized in Table 1, was much less efficient. These results indicate that conversion of phenylalanine to tyrosine is minimal in *Hydrastis* (cf. ref. 8), and suggest that Wenkert's biogenetic hypothesis[2] is not valid in this case.



(I)

Hydrastine from plants grown with tyrosine-^{14}C for 17 days was degraded to locate the radioactivity, which was found, in accord with classical[1], but contrary to Wenkert's[2], biogenetic prediction, exclusively at carbon atoms 1 and 3. Oxidation gave inactive opianic acid (atoms 1′–10′) and active hydrastinine (atoms 1–12). The latter underwent Hofmann degradation to yield hydrastal (atoms 1, 3–11), which was oxidized to 6-vinylpiperonylic acid (atoms 1, 3–11). No loss of radioactivity occurred in these steps. Bromodecarboxylation, accompanied by modification of the vinyl group, gave radioactive 6-bromo-α-hydroxyhomopiperonylbromide (atoms 3–11) and radioactive carbon dioxide (atom 1). The latter was collected as barium carbonate, and then regenerated and converted to benzoic acid by treatment with phenylmagnesium bromide. The homopiperonylbromide derivative was oxidized to 6-bromopiperonylic acid (atoms 4–11), which contained little radioactivity. Radiocarbon was thus confined to carbons 1 and 3 of the hydrastine skeleton. The activities found in hydrastine and its degradation products are summarized in Table 2. The degradation sequence clearly demonstrates that tyrosine serves as a specific precursor of hydrastine, and that, as predicted, two tyrosine units participate in the biosynthesis of the alkaloid.

Table 2

Compound	Atoms of hydrastine	Specific activity (counts/min./mM)	Relative activity
Hydrastine		$5 \cdot 17 \times 10^4$	100
Hydrastinine	1–12	$5 \cdot 10 \times 10^4$	99
Opianic acid	1′–10′	$0 \cdot 04 \times 10^4$	< 1
Hydrastal	1, 3–11	$5 \cdot 16 \times 10^4$	100
6-Vinylpiperonylic acid	1, 3–11	$5 \cdot 02 \times 10^4$	97
6-Bromo-α-hydroxy-homopiperonyl bromide	3–11	$3 \cdot 20 \times 10^4$	62
Benzoic acid	1	$2 \cdot 00 \times 10^4$	39
6-Bromopiperonylic acid	4–11	$0 \cdot 14 \times 10^4$	< 3

The most interesting feature of these results, however, is the unequal labelling of carbon atoms 1 and 3 of hydrastine (relative activity 39 and 60 respectively), indicating differential utilization of radioactive, but not of chemical, precursor for the two segments of the alkaloid molecule. Such a possibility has never been considered, and it has hitherto always been tacitly assumed that biosynthetic utilization of two units of a single radioactive precursor to form the major portion of an end-product would inevitably be associated with equal labelling in the two segments of the latter. Reported work on papaverine[6] and morphine[9] has tended to support this assumption, which, nevertheless, is not generally valid. Equal incorporation of radioactivity into the two segments of such a 'dimeric' product is obligatory only if the 'doubling' step in the biosynthetic sequence is of the type $2A \rightarrow A'-A'$, that is, if two identical units of 'monomeric' precursor combine to yield a true dimer as a biosynthetic intermediate (direct doubling).

If the 'doubling' step were preceded by one or more dissimilar structural modifications of either or both 'monomer' units, such as $A \rightarrow X$, $A \rightarrow Y$: $X + Y \rightarrow X'-Y'$ (indirect doubling), then the ratio of radioactivities in the two segments of the product will depend on a number of factors. The most important of these are (*a*) the number of metabolic steps in each branch of the sequence prior to 'doubling', (*b*) the rate of each of these steps, (*c*) the size of the metabolic pool of each branch intermediate, (*d*) possible utilization of branch and 'dimeric' intermediates for other metabolic processes (leakage), (*e*) possible feed-in of branch intermediates from other, non-radioactive, precursors, and (*f*) the turn-over rate of the product. Equal incorporation into both segments of the product will be approached in a single-dose feeding experiment at infinite time, provided there is no leakage or feed-in of branch-precursors, no leakage of 'dimeric' intermediates, and provided the product continuously accumulates. Unless these restrictions hold, any ratio of radioactive incorporation in the two segments of the product, including a fortuitous ratio of one, is possible. The ratio will vary continuously with time, and its numerical value in any single experiment will depend on the length of time allowed to elapse between initial administration of the tracer and harvesting of the plant.

Although the major portions of each of the two segments of hydrastine (atoms 3–10, and 1, 1′–7′ respectively) are now shown to be derived from a tyrosine unit, the two fragments differ in oxygen substitution (atoms 11, and 8′–9′ respectively). In addition, a one-carbon unit (atom 10′) is required to complete the skeleton of the alkaloid. Any or all of these modifications of the tyrosine units may take place either before or after the 'doubling' step.

Work on the variation of the isotope ratio of the segments with time is proceeding and may throw further light on the dynamic aspects of alkaloid biosynthesis in *Hydrastis*. The systematic degradation of the radio-berberine, isolated from the present feeding experiments, will also contribute to the clarification of the problem.

Ultracentrifugal Differences in Soybean Protein Composition

Soybeans vary widely in size, shape, colour, and chemical composition[1]. Their chemical composition is affected by varietal and environmental factors, and large differences in gross chemical composition are reported. For example, the protein content for 10 varieties over a 5-year period ranged from 36·6 to 53·2 per cent[2].

Little is known concerning the possible variation of the individual components within the protein fraction. The existence of such differences has been suggested on the basis of amino-acid analysis of various soybean protein preparations[3–6], but more direct evidence is desirable. Our results with ultracentrifugal analysis indicate more definitely that some soybean samples differ appreciably in protein composition.

Soybean proteins were extracted at room temperature from 3·0 gm. of dehulled, hexane-defatted flakes by stirring for 30 min. with 100 ml. of potassium phosphate–sodium chloride buffer, *p*H 7·6, $\mu = 0·5$, 0·01 *M* with respect to mercaptoethanol[7]. After centrifuging, the insoluble residue was re-extracted twice for 15 min. with 50-ml. portions of the same solvent. The three extracts were combined, concentrated by pervaporation, and equilibrated against the extraction buffer by dialysis prior to ultracentrifugal analysis.

Fig. 1*A* is the ultracentrifugal pattern for the unfractionated proteins of Clark soybeans grown in 1958 near Farmer City, Illinois. Four fractions are present with sedimentation constants of about 2, 7, 11, and 15*S* and the pattern resembles those recorded earlier[7,8]. Two other American varieties grown in Iowa gave similar patterns.

Fig. 1*B* is the ultracentrifuge pattern for the proteins from Hakuhou No. 1 soybeans grown in 1959 at Miyagi Experiment Station, Miyagi, Japan. (We are indebted to T. Watanabe, Food Research Institute, Tokyo, for supplying the samples of Japanese soybeans.) Again four sedimenting fractions are observed, but there are large differences in the percentages of the 7*S* and 11*S* fractions. Also, the 15*S* fraction is reduced in concentration and is less evident as compared with that fraction in the Clark variety. Patterns similar to Fig. 1*B* were obtained for two other soybean varieties grown at Miyagi. The distribution of components shown in Fig. 1*B* was unchanged when proteins from Japanese soybeans were extracted with water and analysed in the extraction buffer. Furthermore, the ratio of 7–11*S* fraction was not altered in the globulin fraction obtained by acidifying an aqueous extract of soybean meal to *p*H 4·5.

Extractability of soybean proteins depends on variety, age of beans, and possibly location of growth[9]. However, the differences between Clark and Hakuhou No. 1 soybeans cannot be due to differential extraction of the 7*S* or 11*S* fractions since more than 95 per cent of the nitrogenous components were extracted from each sample.

Similarity of the three soybean varieties grown in the same location in Japan tentatively suggests that the differences observed in Fig. 1 are caused by environmental factors.

Variations in protein composition have been detected in corn[10], wheat[11], and barley [12] by a number of methods, including isolation of individual fractions, electrophoresis, and ultracentrifugation. So far as we know, the data we report are the first direct evidence that similar variations occur in soybeans. Further

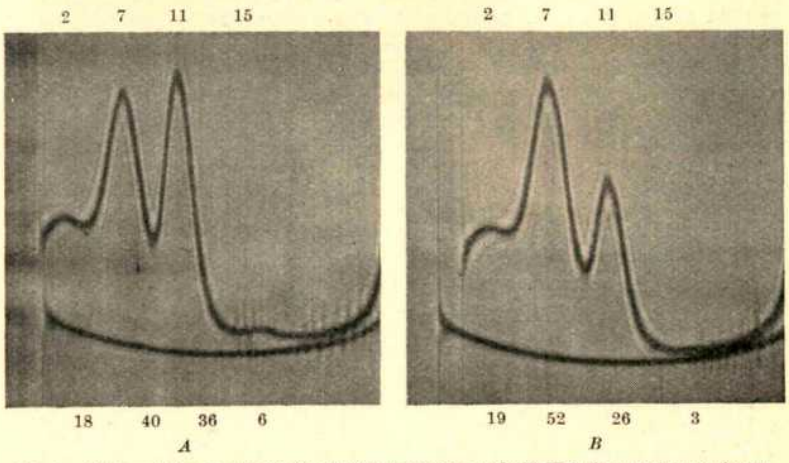

Fig. 1. Ultracentrifugal patterns for (*A*) Clark variety and (*B*) Hakuhou variety soybeans. Numbers across the top of the patterns give sedimentation constants in Svedberg units, across the bottom, the percentage composition. Compositions were determined by area analyses which are corrected for radial dilution. Solutions were analysed in a 30-mm. double-sector cell at 47,660 r.p.m. Protein concentrations ($N \times 6·25$) in gm./100 ml. were (*A*) 1·53 and (*B*) 1·24

work is under way with a number of Japanese and American varieties of soybeans to determine the effects of variety and location of growth on protein composition.

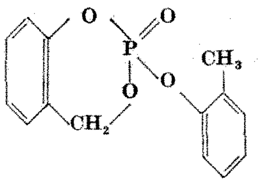
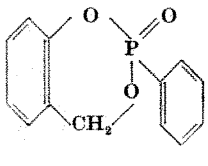
Biological Activity of a Tri-o-Cresyl Phosphate Metabolite

TRI-*o*-CRESYL PHOSPHATE (TOCP) is metabolized *in vitro* and *in vivo* to form potent esterase inhibitors[1–5]. The nature and biological activity of the metabolites were investigated.

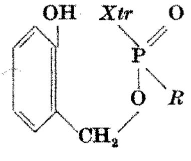
Rats administered radiophosphorus-labelled TOCP were found to excrete radiolabelled di-aryl phosphates, mono-aryl phosphates and phosphoric acid in the urine. Three anti-esterase metabolites were present in the liver, intestine and fæces. Incubation of TOCP with rat liver microsomes fortified with reduced diphosphopyridine nucleotide also yielded three esterase inhibitors of similar chromatographic characteristics to those produced *in vivo*. The major esterase-inhibiting metabolite formed *in vivo* was isolated on silicic acid–'Celite' columns with benzene–ether mixtures. Examination of the infra-red spectrum and hydrolysis products suggested structure I for this metabolite. Reaction of *o*-cresylphosphoryl dichloride with *o*-hydroxybenzyl alcohol yielded 2-(*o*-cresyl)-4H-1,3,2-benzodioxaphosphoran-2-one, b.p. 159–161° C./0·09–0·1 mm. mercury, $n_D^{24.5^\circ} = 1{\cdot}5584$. This compound was identical with the major metabolite in respect to infra-red spectrum, chromatographic characteristics, and anti-esterase activity. One of the other esterase inhibitors appeared to be the *o*-hydroxymethyl derivative of I. The mechanism of esterase inhibition was investigated by reaction of chymotrypsin (*Xtr*) with I and a phenyl phosphonate analogue, II. Both appeared to phosphorylate by opening the cyclic phosphate structure at the P—O— aryl bond to yield III.



I



II



III

An ataxia and demyelination is induced in hens and certain other species by TOCP[6–9]. A similar ataxia in hens resulted from subcutaneous administration of 4–8 mgm./kgm. I, whereas 240 mgm./kgm. II failed to yield ataxia. Preliminary studies indicate a demyelination with I similar to that induced by TOCP. The high activity of I relative to that of TOCP in producing neurotoxicity in hens suggests that the anti-esterase metabolites rather than TOCP *per se* yield the ataxia. TOCP and other ataxia-producing phosphates are known to effect prolonged *in vivo* inhibition of the pseudocholinesterases of hen brain, spinal cord and sciatic nerve[10–13]. The function of this pseudocholinesterase which hydrolyses carboxylic esters of choline is unknown. Experiments with hens established that it also hydrolyses carboxylic esters of thiamine, that is, *O*-acetyl and *O*-propionyl thiamine, an observation consistent with previous reports on the substrate specificity of cholinesterases[14]. The demyelination in hens produced by TOCP is identical with that with certain other organophosphates, and similar lesions appear in hens on a thiamine-deficient diet[8]. Thiamine has been noted as a neuroactive material in peripheral nerves[15] and as a constituent of myelin in peripheral nerves of rabbits[16]. Inhibition of the pseudocholinesterase might result in an accumulation of carboxylic esters of thiamine to impair localized functions of the nerve requiring free thiamine or other thiamine derivatives.

In accordance with this hypothesis, thiamine and other compounds were tested extensively for their effect on the ataxia in hens from TOCP and/or I. Compounds tested alone or in conjunction with thiamine included *O*-acetyl thiamine, tocopherol and cortisone and their acetates, pilocarpine, saponin, and several aldoxime-type cholinesterase reactivators. With varying dosages and multiple administration of these materials before and after the organophosphate, no relief of the neurotoxic symptoms was evident.

TOCP potentiates the toxicity to mammals of malathion (*O,O*-dimethyl S-(1,2-dicarbethoxyethyl) phosphorodithioate)[4,17]. The intraperitoneal LD_{50} for mice was 150 mgm./kgm. for each of I and II. Simultaneous injection of malathion (LD_{50} alone of 1,500 mgm./kgm.) in a 10 : 1 ratio with the cyclic phosphates yielded LD_{50} values of about 1/45th those of either component alone. I and II were similar in this respect, and both yielded marked *in vivo* inhibition of the esterases of plasma and liver hydrolysing the carbethoxy groupings of malathion. The activity of these two compounds in malathion potentiation was greater than that of 120 other di-aryl and tri-aryl phosphates studied which lack the cyclic phosphate structure. The pattern of esterase inhibition in mice resulting from TOCP administration[4] also appeared with I, although the latter acted much more quickly and at a much lower dose.

Metabolic activation occurs with many tri-aryl phosphates containing *o*-methyl, *o*-ethyl, *o*-*n*-propyl and *p*-ethyl groupings[4,5]. *In vivo* hydroxylation of the *o*-methyl and subsequent cyclization to anti-esterase metabolites appears to account for the biological activity of TOCP and certain other tri-aryl phosphates containing *o*-methyl groupings. A similar mechanism involving α-hydroxylation and cyclization might explain the conversion of *o*-ethyl and *o*-*n*-propyl derivatives to anti-esterases. A different mechanism must be involved with tri-*p*-ethylphenyl phosphate.

Publication of this communication is approved by the Director of the Wisconsin Agricultural Experiment Station. The investigation was supported in part by the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation, and by grants from the U.S. Public Health Service, National Institutes of Health (contract *RG*-5304), the U.S. Army Chemical Research and Development Laboratories (grant No. *DA-CML*-18-108-61-*G*-6), and the U.S. Atomic Energy Commission (contract No. *AT* (11-1)-64, Project No. 14).

Isolation of Sterol Esters from Human Fæces

THE importance of obtaining more precise information regarding the sterol excretion pattern in human beings has recently become apparent and has been emphasized by Aylward[1]. The normal clinical laboratory techniques for stools, namely extraction of dried material or wet extraction coupled with saponification make impossible the isolation of any sterol esters which may be present. This difficulty in isolating (as distinct from estimating) sterol esters was indeed common to all lipid extracts until the methods developed by Börgstrom[2], and others, were applied by Fillerup and Mead[3] to extracts from animal tissues. Using silicic acid, they were able for the first time to separate cholesterol esters from triglycerides. We have applied a modification of this technique to the lipids of human fæces and have been able to isolate cholesterol ester fractions; and, using gas-liquid chromatography, have examined the fatty acids present in the esters.

Because the amount of sterol esters in human fæces is very small, it was necessary to extract large quantities of material. Accordingly, collections from five volunteers were arranged for periods of 6–9 days, and the extraction procedure was commenced immediately on the receipt of each sample. Preliminary experiments indicated that fæcal pigments interfered with the chromatographic separations, and it was therefore decided to extract the stools first with 0·9 per cent saline, a procedure which removes some of the bacterial lipids[4]. The solid obtained by centrifugation was then extracted successively by ethanol, ether and petroleum ether; precautions were taken to minimize oxidation by carrying out the procedures, wherever possible, under oxygen-free nitrogen.

Table 1. COMPONENTS OF PETROLEUM ETHER-SOLUBLE FRACTION FROM HUMAN FÆCES, CHROMATOGRAPHED ON SILICIC ACID (ref. 5)

Fraction	Case 1	Case 2	Case 3	Case 4	Case 5
Hydrocarbons and pigments	8·8	5·2	10·8	Nil	6·8
Sterol esters	3·5	7·1	2·0	1·0	13·0
Triglycerides	2·1	7·1	2·0	0·6	3·4
Sterols	77·1	76·7	65·4	93·6	62·0
Diglycerides, monoglycerides, phospholipids and pigment	8·5	3·9	19·8	4·8	14·7

In order to increase the proportion of sterol ester in the petroleum ether fraction to be chromatographed, the free fatty acids were first removed by washing with 1 per cent sodium carbonate solution; the extract remaining was dissolved in the minimum amount of hexane and fractionated on a column of Mallinckrodt silicic acid, the ratio of adsorbent: extract being kept at about 100 : 1·5. Pre-treatment of the silicic acid and the elution system followed Barron and Hanahan[5]. Positive oxygen-free nitrogen pressure was maintained, 25 ml. fractions were collected, and elution of the sterol esters was judged to be complete when a negative Liebermann–Burchard test was given. The solvent from the fractions was removed at 40° C. by means of a vacuum oven, the fractions were weighed, and the residues were dissolved in petroleum ether and combined according to the peaks shown when the weighed residues were graphed.

Neither free fatty acid nor free sterol was present in the sterol ester fraction, and the weight of the fraction agreed with the estimations of sterol ester made on the original petroleum ether-soluble fraction by a colorimetric method. Table 1 shows the amount of sterol esters isolated by this method, calculated as a percentage of the total material recovered.

The acids obtained by saponification of the sterol esters from extracts 1, 2 and 5 were methylated and submitted to gas-liquid chromatography, diethylene glycol succinate, ethylene glycol adipate, silicone oil, and dimethylchlorosilane being the stationary phases. The fatty acids present in the extract in the unesterified form, and those from the sterol ester fraction, were markedly similar in type and distribution and ranged from C12–C20 +, saturated and unsaturated.

We thank Mr. J. Piercy and Drs. Raymond Greene and D. S. Rideout of the New End Hospital for the facilities provided, and the Nuffield Foundation for a research grant (to P. W.).

Effect of Ribonuclease and Deoxyribonuclease on Incorporation of Tritiated Pyrimidine-Nucleosides into Ribonucleic Acid and Deoxyribonucleic Acid in Human Cancer Cells (HeLa) in Culture

AUTORADIOGRAPHIC work in various laboratories on synthesis of nucleic acids in the intact cell has indicated that nuclear RNA is a precursor for cytoplasmic RNA, although different authors have placed different emphasis on the role of the nucleolus and chromatin portion[1–5]. It was suggested that RNA mediates incorporation of pyrimidine nucleotides into DNA, probably through an intermediate fraction[7,8]. In testing and extending these observations, the uptake of tritiated cytidine, uridine, thymidine and deoxyuridine into the various nucleotide fractions was examined for dependence on RNA-ase and DNA-ase, added to the cells in culture before, and at the same time as, exposure to the tritiated precursors.

Tritiated cytidine (specific activity 1 c./m.mole) and tritiated uridine (specific activity 0·62 c./m.mole) were used as common precursors for RNA and DNA at a concentration of 2 μc./ml. of medium. Tritiated thymidine (specific activity 1·9 c./m.mole) and tritiated deoxyuridine (specific activity 4·0 c./m.mole) as specific precursors for DNA at a concentration of 0·4 μc./ml. of medium. RNA-ase was obtained from the Nutritional Biochemicals Corporation in crystalline form, and DNA-ase from the California Corporation for Biochemical Research. Crystalline albumin was obtained from Armour Laboratories, and bovine serum from the Colorado Serum Co.

Leighton tube cultures of HeLa-S_3 cells, either with or without coverslips, containing about equal numbers of cells in the log phase of growth were used. Simultaneously with the addition of tritiated thymidine, or 90 min. before addition of tritiated thymidine, tritiated cytidine, tritiated deoxyuridine and tritiated uridine, the standard culture medium was changed to one supplemented with RNA-ase or DNA-ase (to make a final 0·1, 0·2 or 1 per cent solution), or one containing equivalent amounts of protein in the form of albumin or bovine serum, or one without supplement. The cultures in the various media were incubated at 37° for various lengths of time. At the end of the incubation period, the cells were washed, fixed and extracted differentially with perchloric acid to obtain the different nucleotide fractions (acid-soluble pool, RNA and DNA), or they were fixed with methanol and prepared for autoradiography with or without prior histochemical extraction of RNA with perchloric acid. Details of the methods used have been described in refs. 6 and 7.

Table 1 lists the total tritium activity of the separated nucleotide fractions, soluble pool, RNA and DNA, after 10 min. exposure to the tritiated precursors. The results show that the incorporation of tritiated thymidine and deoxyuridine is depressed in the HeLa cell by RNA-ase and to a smaller extent by DNA-ase. Tritiated cytidine and uridine incorporation into DNA is not inhibited and its incorporation into RNA is slightly enhanced by RNA-ase, in agreement with Ledoux's data on ascites tumour cells[9].

Similar results were obtained autoradiographically (grain counts) and will be reported later. The cells showed morphological changes when 0·2 per cent to 1 per cent RNA-ase was used, as a decrease in basophilic staining property in the cytoplasm as well as in the nucleoli, which often were distorted. The decreased basophilia might be explained in part by a complex formation of RNA with RNA-ase, thus preventing the basic stain from binding[10].

Incorporation of tritiated thymidine and tritiated deoxyuridine into the 'soluble pool' was inhibited by RNA-ase. Tritiated thymidine added to the cells simultaneously with the medium containing RNA-ase was more readily incorporated than when tritiated thymidine was given at 90 min. after addition of the medium containing RNA-ase to the cells. This in addition seems to indicate that the RNA-ase acts not primarily on the cell membrane but intracellularly[10]. The various effects reported for RNA-ase on cells might all be explained by an effect on RNA and not on enzymes, even if they are associated with microsomes[11], nor on energy-delivering reactions[10]. The RNA-ase used at present was tested in the fixed HeLa cell, and was shown to remove selectively RNA, leaving DNA intact.

If one assumes specificity of RNA-ase for RNA also in the living HeLa cell and despite the lack of further results on reactions in the soluble fraction, the inhibition of uptake of thymidine and deoxyuridine by RNA-ase in this work suggests that incorporation of those precursors into the nucleic acids in the HeLa cell may be mediated by, or depend on,

Table 1. TOTAL TRITIUM ACTIVITY OF NUCLEOTIDE FRACTIONS (SOLUBLE FRACTION, RNA AND DNA) IN COUNTS/MIN. AND AS PERCENTAGE OF CONTROL, AFTER 10 MIN. EXPOSURE OF THE CELLS TO DIFFERENT TRITIATED PYRIMIDINE NUCLEOSIDES IN REGULAR CULTURE MEDIUM AND IN MEDIUM CONTAINING RNA-ASE ,OF DNA-ASE, OR EQUIVALENT AMOUNTS OF PROTEIN AS BOVINE SERUM OR ALBUMIN. an RNA, probably in the soluble pool. RNA synthesis *de novo* apparently would not be dependent on this same RNA fraction, since tritiated cytidine and tritiated uridine incorporation was not depressed.

Since the labelling of DNA from tritiated cytidine and tritiated uridine was only slightly altered by RNA-ase and DNA-ase, the depression of the incorporation of tritiated thymidine and tritiated deoxyuridine apparently does not reflect a depression of the rate of DNA-synthesis.

Effect of Boric Acid on the Phosphoglucomutase of Pea Seeds

It has been suggested that a possible role of boron in higher plants is to activate the processes involved in the uptake and movement of sugars, and the manner of operation has been attributed to the facility with which boric acid forms complexes with the *cis*-hydroxyl groups of the sugar molecule. Dugger and Humphrey[1] suggest, as the result of assay of a comprehensive range of enzymes from pea seedlings, that boron inhibits sucrose synthesis from uridinetriphosphate, glucose-1-phosphate and fructose, and stabilizes the level of uridine diphosphoglucose as well as increasing the rate of its formation. They consider that boron inhibits starch phosphorylase, thus increasing the availability of glucose-1-phosphate for the formation of uridine diphosphoglucose. The transfer of the former through the normal glycolytic cycle is considered to be unaffected on the basis of assay of specific enzymes, including phosphoglucomutase. The phosphoglucomutase used was apparently prepared from muscle, and, in fact, it has been shown that low concentrations of boric acid specifically inhibit the phosphoglucomutase of pea seeds[2]. The enzyme can be purified by alcohol fractionation at −5° C. and obtained free of phosphorylase and phosphatases which utilize the substrate and products. The phosphoglucomutase activity is always associated with that of phosphohexoisomerase, but this enzyme has been found to be unaffected by boric acid. Fig. 1 shows the extent of the inhibition by a range of concentration in a preparation of this type. The fall in inorganic phosphorus + phosphorus released by hydrolysis at 100° C. in 1 *N* hydrochloric acid (free + 7′P) is used as a measure of formation of glucose-6-phosphate. When the purified system is used, no increase in inorganic phosphorus occurs during the time required for the system to reach equilibrium, and at this time chromatographic assay indicates the presence of only glucose-1-phosphate, glucose-6-phosphate and fructose-6-phosphate.

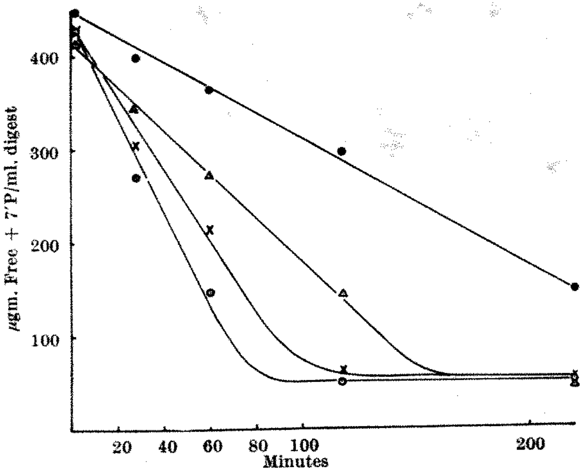

Fig. 1. Effect of boric acid on the activity of a purified phosphoglucomutase preparation from pea seeds. Digest components: glucose-1-phosphate, 13 μmoles/ml., magnesium chloride, 5 μmoles/ml.; glyoxaline/hydrochloric acid buffer *p*H 7·2, 20 μmoles/ml.; enzyme, 0·06 mgm. nitrogen/ml. Concentration of boric acid: 2×10^{-3} *M* (●); 5×10^{-4} *M* (Δ); 2×10^{-4} *M* (×); none (○)

The inhibition of phosphoglucomutase may be complex: for example, Fig. 2*a* shows that there may be an initial lag period, followed by an increase in rate though the final rate is still less than that in the control digests. This type of inhibition can best be explained on the assumption that the inhibitor is rendered ineffective by combination with one of the

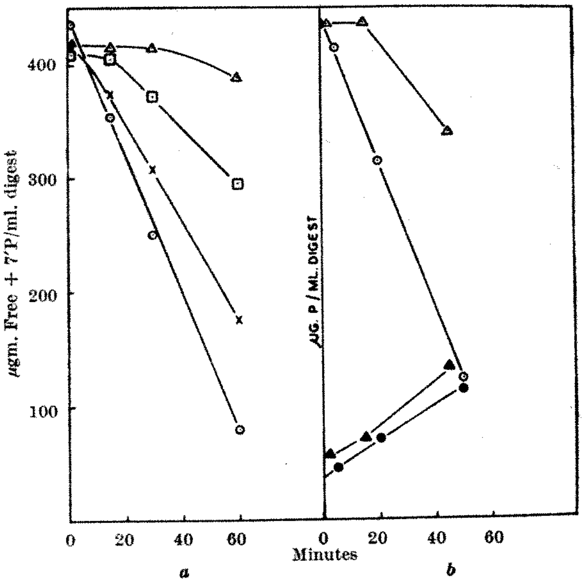

Fig. 2 (*a*) Effect of boric acid on the initial stage of utilization of glucose-1-phosphate by a purified phosphoglucomutase preparation. Main digest components as in Fig. 1. Concentration of boric acid: 5×10^{-3} *M* (Δ); 1×10^{-3} *M* (□); $2·5 \times 10^{-4}$ *M* (*X*); none (○). (*b*) Effect of boric acid on the utilization of glucose-1-phosphate by a crude extract of pea seeds (50 gm. dry seeds soaked and extracted with 100-ml. ice-cold 0·005 *M* neutral cysteine). Main digest components as in Fig. 1, enzyme extracts diluted four-fold. Concentration of boric acid: 1×10^{-3} *M* (▲ and Δ); none (● and ○). Open symbols (free + 7′P); filled symbols (free P)

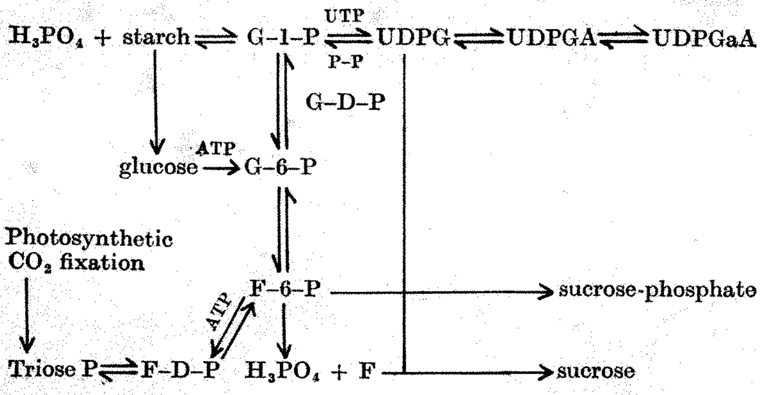

Fig. 3

products of the reaction. This enzyme system involves a low concentration of glucose-1,6-diphosphate as an essential component of the reaction, and on the basis of existing knowledge of the mechanism of action of the muscle enzyme it is likely that phosphorylation of the enzyme occurs; it is at this stage that boric acid possibly has its effect. The crude enzyme is also inhibited by boric acid under conditions in which the contaminating phosphorylase is unaffected as measured by increase in colour with iodine, and release of inorganic phosphate (Fig. 2*b*). The partially purified plant preparations contain appreciable quantities of inorganic orthophosphate as well as bound ketose, and the importance of these components is still under investigation.

The phosphoglucomutase activity is greatest at about *p*H 7·8, but similar percentage inhibitions occur with 0·002 *M* boric acid over a *p*H range of 5·6–8·0. At the *p*H normally used, namely, 7·2, 99 per cent of the added borate would exist as boric acid.

From these results it follows that if utilization of starch is blocked at the phosphoglucomutase stage, two immediate consequences are apparent:

(*a*) The formation of glucose-6-phosphate and hence fructose-6-phosphate and fructose can be prevented by boric acid, thus reducing the amount of fructose-6-phosphate and fructose available for the synthesis of sucrose. Since combined fructose is not normally stored in amounts comparable with glucose polysaccharides, it is reasonable to suppose that fructose arises primarily via the phosphorylated form by the normal glycolytic use of starch.

(*b*) More glucose-1-phosphate is available for synthesis of uridine diphosphoglucose, and in the absence of fructose acceptor it would either accumulate or be available for synthesis of other materials, for example galacturonic acid residues of the cell wall.

At this stage it would be premature to speculate further on the role of boron in higher plants. However, glucose-1-phosphate clearly occupies a key position in the utilization of hexoses, and the scheme of Fig. 3 indicates how the inhibition of phosphoglucomutase by boric acid could be used as a means of regulating closely the diversion of glucose-1-phosphate for different synthetic purposes. It is evident that the mechanism of action of the phosphoglucomutase of pea seeds is similar to that of the muscle enzyme which is unaffected by boric acid[1], so it is unlikely that the inhibiting action is brought about by the formation of complexes with one of the substrates. It is more reasonable to attribute the specific effect on the plant enzyme to the structure of the enzyme protein. The complex nature of the mechanism of action coupled with the type of inhibition shown in Fig. 2 makes kinetic studies difficult, and the elucidation of the type of inhibition involved is obviously necessary before an assessment of the importance of boric acid as a regulatory substance can be critically evaluated.

PHYSIOLOGY

Number and Arrangement of Osteons in Corresponding Regions of Homotypic Long Bones

TETRACYCLINES administered *in vivo* become incorporated into recently laid down rapidly calcifying bone-tissue; the labelled material can be detected by its fluorescence in ultra-violet light[1-5]. This technique represents a very valuable new tool in the investigation of bone growth and reconstruction.

The problem investigated here is whether it occurs, and what is the extent of structural symmetry, in various sectors and levels of the shaft cortex of homonymous long bones in the right and left side, in other words, in portions of osseous tissue which are largely submitted to equal mechanical stresses and undergo a series of parallel changes during bone growth and remodelling. In the present communication, results are reported on the distribution and number of new-forming Haversian systems (secondary or replacement osteons). This work is introductory to a study of the factors which govern bone

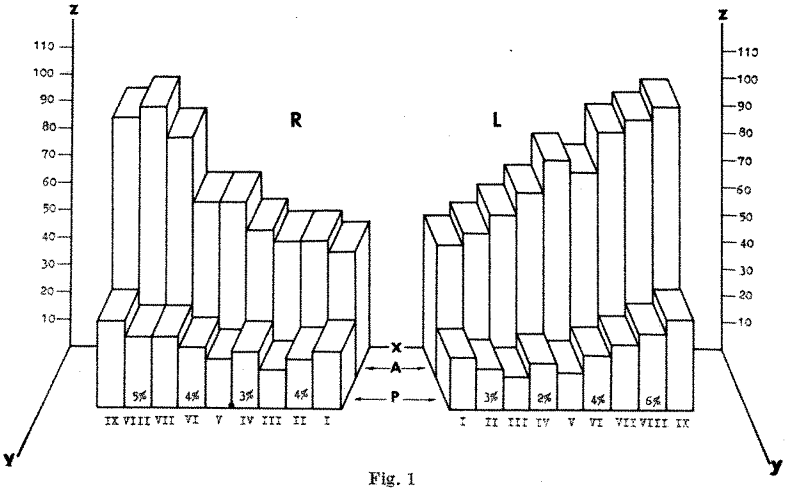

Fig. 1

reconstruction, and has also a practical meaning since the structure of the 'controlateral' bone is generally taken as the normal test of the bone submitted to experimental procedures.

Young growing and adult dogs were given *per os* demethylchlortetracycline ('Ledermycin') 30–40 mgm./kgm. body-weight for 3 days and killed 7 days later. Cross-sections of the entire diaphysis were taken from various long bones of both sides; care was taken to cut out the sections exactly at the same shaft-levels in each couple of homonymous bones. Generally, 5–15 planoparallel cross-sections 1 mm. apart, starting from the middle level of the diaphysis, were serially sawn and ground to a uniform thickness of about 60μ. Photomicrographs were made of each section in ultra-violet light (Ortholux Leitz microscope).

The distribution and number of the osteons labelled by a fluorescent ring were analysed in the photomicrographs of the shaft cross-sections, divided into four 90° quadrants. A rather close symmetrical correspondence in the arrangement of the newly formed osteons resulted in each of the four 90° quadrants of each couple of sections (right and left) at the same level. The 90° quadrants were further bisected and the distribution of the osteons analysed in each 45° sector of the left and right sections. Each 90° quadrant was divided also into an outer and an inner band by means of a line equidistant from the periosteal and the endosteal surfaces of the cortex. When comparing such sectors and zones in the right and left bone, a fairly close symmetry in the distribution of new-formed osteons was still apparent; such a correspondence was no longer found when comparing, on both sides, small areas of the sectors or zones.

The new-formed labelled osteons were counted in the corresponding 90° quadrants and 45° sectors of the right and left bone. The percentage differences in the number of labelled osteons between the right and left bone were as follows: 90° quadrants, max. 14·6 per cent—min. 0·87 per cent; 45° sectors, max. 28·5 per cent—min. 3·4 per cent. An analogous course in the variation of the number of the osteons was recorded in the corresponding 45° sectors of the two sides when studying the series of successive cross-sections from the middle shaft-level to the metaphysis.

An attempt was also made to assess the amount of bone tissue laid down in the osteons forming in corresponding sectors and levels of the right and left bone shafts during the period of tetracycline treatment. The labelled areas were cut out from enlargements (× 110) on photographic paper of constant known weight and their total weight computed as percentage of the weight of the entire area covered by bone tissue in the 45° sectors of the right and left side after removal from the photographs of the areas occupied by non-osseous material (for example, lumina of vascular canals and resorption cavities).

As an example, the results obtained from the analysis of an 18-mm. cylinder of the right and left tibial shaft in a 6-month-old dog are shown (Fig. 1). The number of labelled osteons in the left (L) and right (R) tibia is given as a function of the level of the section and of the position of the 45° sector. On the x axis are plotted the levels of the shaft cross-section in caudo-cranial order, commencing from the centre of the diaphysis (I, II, III, etc.); on the y axis are plotted A, the anterior, and P, the posterior 45° sectors of the 90° antero-medial quadrant; on the z axis are plotted the number of labelled osteons in each sector of every section. The per cent ratios between the amount of the new-formed labelled osseous tissue and all the bone material of the posterior sector P is reported only for four levels.

Altogether it seems that the differences in the distribution and number of Haversian systems (structures of the second order) forming during a given period of time in strictly corresponding regions of compacta of homotypic bones are not much more conspicuous than the differences in the shape and thickness of the cortex (structures of the first order) in the same regions.

Effect of Adrenalectomy and Corticosteroids on Distribution of Radioactivity in Protein of Cell Fractions from Myocardial Slices

Adrenalectomy increases, and cortisone decreases, the incorporation of radioactivity from amino-acids labelled with carbon-14[1,2], and from amino-acid precursors[3], into the protein of isolated rat diaphragm. Implicit in these observations is the possibility that the adrenal steroids alter protein biosynthesis in muscle by an effect on the intracellular protein synthesizing machinery. The experiments to be described are part of an investigation of that possibility. Because of the relative ease with which myocardium is homogenized and fractionated that tissue was selected (in preference to skeletal muscle) for this work.

Adrenalectomy increased, and cortisone depressed, the incorporation of amino-acids into myocardial slices in a way, qualitatively and quantitatively, similar to their effects on skeletal muscle[1,3] (Table 1).

There is no reason to believe, then, that there is a fundamental difference in the effect of adrenal cortical hormone on protein biosynthesis in cardiac as compared with skeletal muscle, and myocardium would appear to be a suitable tissue in which to investigate the mechanism of the effect of corticosteroids on protein synthesis.

In an attempt to identify the locus at which corticosteroids influence protein biosynthesis, heart

Table 1. Effect of Adrenalectomy and Hydrocortisone on Incorporation of ^{14}C-Phenylalanine into Protein of Myocardial Slices

Experimental condition	Radioactivity incorporated into protein (counts/min./mgm.)
Intact	111 ± 9·5
Adrenalectomized	159 ± 6·7
Adrenalectomized, hydrocortisone, 0·4 mgm./day	123 ± 7·0
Intact, hydrocortisone, 4 mgm./day	77 ± 5·1

Male Sprague–Dawley rats of 200–300 gm. were used; adrenalectomy and hormone treatment were carried out as described before (refs. 1 and 3). Rats were decapitated, the hearts excised and sliced freehand on a cold glass surface; endocardial slices were discarded. Approximately 100–200 mgm. of tissue was incubated with 2 ml. Krebs–Henseleit bicarbonate medium, 1·5 mgm. glucose and 0·3 μc. 3-^{14}C-DL-phenylalanine (0·23 mM). Incubation was for 2 hr. at 37° C. in a Dubnoff shaker (152 cycles/min.); the gas phase was 95 per cent oxygen–5 per cent carbon dioxide. At the end of the incubation period the protein was isolated and its radioactivity determined (ref. 4). Each figure is the mean ± $S.E.$ of the mean of six observations. The effect of adrenalectomy ($P < 0·001$) and of 4 mgm./day of hydrocortisone ($P < 0·01$) are significant.

Table 2. DISTRIBUTION OF RADIOACTIVITY FROM ^{14}C-PHENYLALANINE IN PROTEIN OF CELL FRACTIONS FROM MYOCARDIAL SLICES: EFFECT OF ADRENALECTOMY AND CORTISONE (2 MGM./DAY)

Fraction	Condition	Radioactivity incorporated into protein (counts/min./mgm.)				
		0 min.	5 min.	15 min.	30 min.	60 min.

Cell debris	*I*	0	8	16	21	48
	A	0	10	24	46	79
	C	0	6	10	19	33
Mitochondria	*I*	1	5	15	31	40
	A	0	7	36	75	150
	C	1	6	12	28	32
Microsomes	*I*	0	8	23	45	80
	A	0	85	92	210	452
	C	0	6	13	28	70
Soluble	*I*	0	6	25	46	105
	A	0	17	54	116	242
	C	0	5	18	39	75

Approximately 500–700 mgm. of myocardial slices were incubated, for varying periods of time, in 5 ml. of Krebs–Henseleit medium containing 1·5 mgm./ml. of glucose and 0·1 μc./ml. of L-phenylalanine-U-^{14}C (0·01 m*M*). After incubation, two slices were removed for separate analysis and the remainder of the sample was fractionated at 0–4° by a modification of the method used by Zamecnik and Keller for liver (ref. 5). The tissue was minced in 0·35 *M* sucrose containing 0·01 *M* unlabelled DL-phenylalanine, homogenized at 1,200 r.p.m. for 10–15 sec. with a loose-fitting pestle (clearance 0·014–0·019 cm.) and for 20–30 sec. with a tight-fitting pestle (clearance 0·010–0·015 cm.). The homogenate was spun for 10 min. at 700*g* in a Servall *SS*-1 centrifuge. The supernatant was decanted and spun at 15,000*g* in a Spinco model *L* preparative ultracentrifuge for 30 min.; the 15,000*g* supernatant was decanted and spun again at 105,000*g*. The final soluble fraction (supernatant) was retained. The pellets obtained at 15,000 and 105,000*g* were rinsed and drained. Four fractions were obtained in this way: (1) at 700*g* a pellet consisting of unbroken cells, nuclei and myofibrils (hereafter referred to as 'debris'); (2) at 15,000*g* a fraction referred to as mitochondrial, although it is likely some small non-respiratory granules are also present; (3) at 105,000*g* the microsomes, and (4) a final soluble or supernatant fraction. Each figure is the average of two determinations. *I*, Intact; *A*, adrenalectomized; *C*, cortisone-treated.

slices were incubated with ^{14}C-phenylalanine and the distribution of radioactivity in the protein of cell fractions determined. Since the distribution of radioactivity was measured at a number of different time-intervals for intact, adrenalectomized and cortisone-treated animals (Table 2), of practical necessity, only duplicate observations could be made. For this reason the results must be considered to be preliminary.

After adrenalectomy the specific radioactivity of the protein in each of the fractions of heart muscle (debris, mitochondria, microsomes, soluble fraction) is increased (Table 2). The increase, after 1 hr. of incubation, is by far the greatest in the microsomal fraction (448 per cent as compared with 90 per cent in the slice itself). The magnitude of the effect of adrenalectomy on amino-acid incorporation into heart microsomes suggests the possibility that they are the intracellular site at which adrenalectomy acts to enhance protein biosynthesis. This would be analogous to the finding by Korner[6] that it is the liver microsomes, rather than the other participants in intracellular protein biosynthesis, which are stimulated by adrenalectomy. This suggestion—there is no direct evidence for an effect of hormones on microsomes in muscle—needs testing in an *in vitro* system.

Cortisone depressed amino-acid incorporation into each of the cellular fractions of myocardium. In contrast with the changes after adrenalectomy the decrease after cortisone was equal in each fraction (20–30 per cent), and not nearly so great. The distribution of radioactivity in the protein of the several fractions, then, offers no clue to the mode of intracellular action of cortisone in depressing protein biosynthesis; if anything, it suggests the most important effect of cortisone is not intracellular. On this score, there is evidence[7] that cortisone depresses amino-acid penetration into the muscle cell interior, an effect that accounts, at least in part, for the depression of protein biosynthesis; this effect need not be reflected in a selective depression of amino-acid incorporation into any specific cell fraction.

Action of Plasmin on Cartilage Matrix *in vivo*

INTRAVENOUS injection of unactivated papain into young rabbits leads to collapse of their ears due to loss of matrix[1], reduction of the chondroitin sulphate in the ear cartilage[2,3] and the appearance of chondroitin sulphate in the blood and urine[3,4]. Activated papain does not produce this gross effect, and it has been suggested[5,6] that the active enzyme combines with inhibitors in the blood, whereas the inactive papain is activated by sulphydryl groups in cartilage itself and attacks the mucopolysaccharide/protein complex, releasing the chondroitin sulphate.

Lack and Rogers[7] reported the liberation of chondroitin sulphate from cartilage *in vitro* by the blood protease, plasmin. They suggested that the rapid chondrolysis which occurs in joint infections by streptococci and staphylococci might be due to kinases produced by these organisms activating plasminogen in the surrounding fluid. Astrup *et al.*[8] have shown that a diffusable activator of plasminogen is present in synovial membrane and articular cartilage and have postulated that this provides the mechanism for the removal of fibrin from joint cavities after trauma or hæmorrhage.

It now appears that if sufficient plasminogen reaches cartilage *in vivo* there is a sequence similar to that observed with papain. The cartilage matrix is depleted, chondroitin sulphate diffuses out and is afterwards excreted in the urine. As loss of matrix may be demonstrated following immersion of cartilage in plasminogen, it is presumed that the enzyme is activated *in situ* by tissue activator.

In the experiments summarized here we have injected rabbits with crude papain, rabbit plasminogen and human plasmin respectively. We also exposed ears, screened by asbestos from the rest of the body, to 10 min. infra-red radiation, giving 10 min. exposure to each side of the ear. The crude papain was provided by Messrs. A. M. Zimmerman (London), human plasmin by the Blood Products Division, Medical Research Council, and rabbit plasminogen was extracted from fresh rabbit serum by Kline's method[9]. Urines were collected in twenty-four hour periods and stored at −10° until assayed. Their content of acid mucopolysaccharide was measured by the method of Di Ferrante and Rich[10], the results being expressed in terms of the glucuronic acid content of the precipitated acid mucopolysaccharide fraction, as estimated by the method of Dische. Urine was collected for two days prior to injection and afterwards until the glucuronic acid content returned to the pre-injection level. The results obtained are summarized in Table 1.

Table 1. EXCRETION OF ACID MUCOPOLYSACCHARIDES IN RABBIT URINE

No.	Weight of rabbit (kgm.)	Treatment	Acid mucopolysaccharide excretion (mgm. glucuronic acid/24 hr.)		No. of days after treatment to reach excretion peak
			Pre-treatment level	Post-treatment peak	
1	1·5	Papain (3 ml., 2 per cent)	2·2	4·3	1
2	1·3	Rabbit plasminogen	1·3	3·0	5
3	0·8	Rabbit plasminogen	2·3	6·8	3
4	1·4	Rabbit plasminogen + local $CHCl_3$	1·5	4·3	1
5	1·5	Human plasmin	1·5	3·3	1
6	1·0	Infra-red to 1 ear	2·0	3·5	4
7	1·0	Infra-red to 2 ears	1·4	8·0	4

The ears were closely observed during these experiments and it was noted that papain produced greater collapse and also a greater tendency to hæmorrhage around the veins. A rise in the excretion of chondroitin sulphate was not always accompanied by a collapse of the ears: sometimes there was no more than a softening or curling of the tips.

We postulate that plasminogen, diffusing from the blood, is activated in cartilage and attacks the protein/chondroitin sulphate complex in a manner similar to papain; it appears that this may be achieved by increasing local vascular permeability, which allows plasminogen already in the blood to pass through to the matrix.

Cholinergic Transmission in Fish Muscle

IT is known that the enzymes needed for the synthesis and the destruction of acetylcholine are present in fish muscle in large amounts[1,2], and that certain electric organs, probably derived from muscle, are sensitive to acetylcholine[3]. It is therefore usually taken for granted that neuromuscular transmission in fish occurs by a cholinergic mechanism, as in other vertebrates, but there is, in fact, little evidence that fish muscle can be activated by acetylcholine, or that acetylcholine is normally released by motor-nerve-endings in fish.

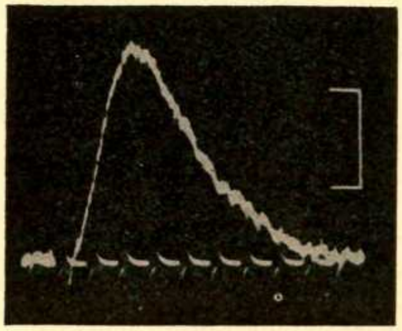

Fig. 1. Acetylcholine potential produced by a 1 msec. (3 *n* coulomb) pulse of outward current, recorded in deep lateral muscle of goldfish. Vertical scale: 1 mV.; horizontal scale, 10 msec.

Although muscle from the goldfish (*Cyprinus auratus*) is not markedly sensitive to acetylcholine injected into the bathing solution, acetylcholine applied from a micro-pipette can have a powerful depolarizing action. The membrane potential of fibres in the deep part of the lateral muscle, at the level of the visceral cavity, was recorded with a conventional glass micro-pipette filled with $3M$ potassium chloride, and acetylcholine was released from a similar micro-pipette filled with $3M$ acetylcholine chloride (Roche Products). When the acetylcholine micro-pipette was brought close to sensitive spots on the surface of the fibre, rapid depolarization could be produced by permitting acetylcholine to diffuse out of the tip; if sufficient acetylcholine was released, the fibre contracted. The effect was best seen by passing short pulses of outward current through the pipette. The resulting potential changes (Fig. 1) resembled normal junctional potentials observed in the same muscle during repetitive stimulation, but their time-courses were much slower (about ten times slower in the case of the potential shown in Fig. 1). The very sensitive regions were extremely sharply localized, as in other vertebrate muscle, and the maximum sensitivity was comparable with that of frog muscle (that is, about 1 mV. depolarization per *n* coulomb of charge delivered through the acetylcholine pipette). Similar observations were made on the deep lateral muscle of catfish (*Ameiurus nebulosus*).

Indirect evidence of acetylcholine-release in fish muscle is provided by the susceptibility of junctional potentials to the blocking action of tubocurarine (10^{-5} w/v) or to potentiation by eserine (10^{-5} w/v). In Fig. 2, eserine is shown to have caused a great increase in the amplitude of spontaneous miniature potentials recorded in a fibre of the deep lateral muscle with an intracellular micro-pipette.

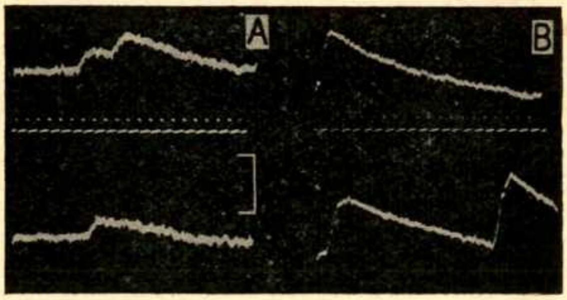

Fig. 2. Spontaneous potentials recorded in a fibre of deep lateral muscle of goldfish: (*A*) control; (*B*) 8 min. after adding eserine sulphate (10^{-5} w/v). Vertical scale, 1 mV.; horizontal scale, 1 msec.

These observations seem to give strong presumptive evidence of cholinergic transmission in at least some fish muscle.

Removal of Milk Constituents from the Mammary Gland of the Ewe

A number of experiments was conducted on the ewe to determine the role of lymph draining from the lactating mammary gland in the resolution of the milk constituents. Lymph flowed continuously for many weeks from a polyethylene catheter inserted into the main lymphatic duct draining the mammary gland. Initial investigations were concerned with the changes in composition of the lymph when the lamb was removed from its mother early in lactation. Plasma and lymph samples were collected at intervals for 7–14 days and the concentrations of free fatty acids, volatile fatty acids, cholesterol, phospholipid, total esterified fatty acids, protein, potassium, calcium and inorganic phosphate were measured. In addition, attempts were made to determine the presence of milk proteins in the lymph by the technique of specific precipitation in agar[1] and also by electrophoresis on cellulose acetate.

In three sheep out of six, the lymph, normally clear, became distinctly milky in appearance when the udder was very distended with milk. The milkiness persisted for as long as 2 days in one of the sheep and for only 4 hr. in another. The milky lymph contained increased concentrations of total esterified fatty acids, calcium, inorganic phosphate and potassium, and microscopic examination of the lymph under dark-ground illumination revealed the presence of particulate fat. Protein peculiar to milk was also identified in the milky lymph by the specific precipitation technique (Fig. 1). This could not be demonstrated electrophoretically. There was no evidence for the presence of this protein, nor significant change in the constituents measured in lymph which was not milky in character. More recent experiments demonstrated that a large proportion of human serum albumin containing iodine-131, which had been introduced into the gland sinus, was removed intact by way of the lymphatics. Under conditions in which the gland became very distended with milk, the radioactivity in the lymph rose to a high level and then decreased exponentially (Fig. 2). Lower levels of radio-activity were found in the lymph draining from mammary glands which did not become very distended with milk.

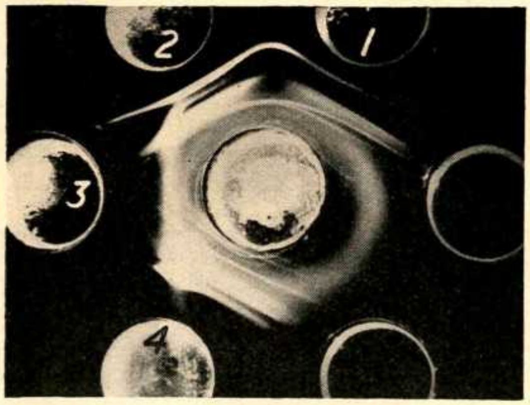

Fig. 1. Lines of precipitation between the central well containing ewe skim milk antiserum and the surrounding wells containing (1) non-milky lymph, (2) milky lymph, (3) diluted milk, and (4) wether's serum. A broad line of precipitation can be seen opposite the well containing milk. This line crosses all the precipitation lines opposite the well containing wether's serum and represents the precipitation between specific antibodies and protein in milk not found in plasma. This broad milk protein line is continuous with a line (often seen divided) opposite the well containing the milky lymph. No such line was found opposite the well containing the non-milky lymph

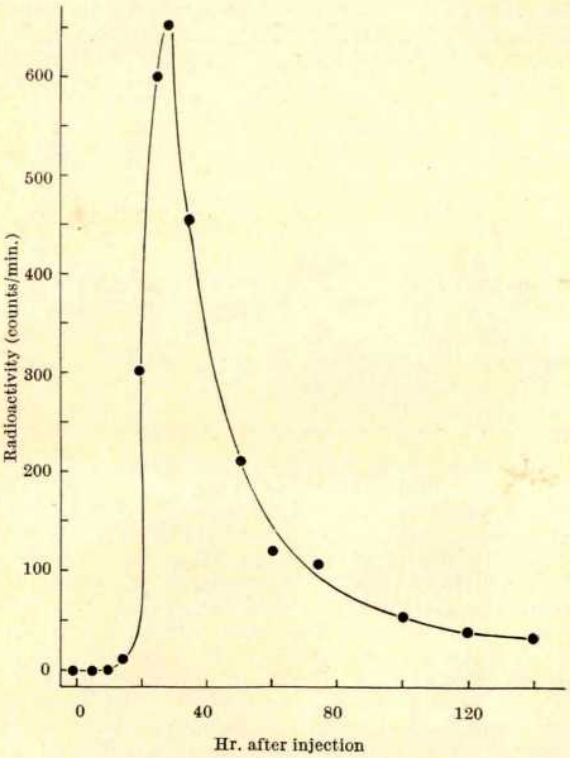

Fig. 2. Appearance of radioactivity in the lymph draining from a mammary gland following the introduction of human serum albumin labelled with iodine-131. Since the radioactivity was found in the trichloracetic acid precipitate it is reasonable to assume that the human serum albumin is being removed intact

These results indicate that fat and proteins of milk may be removed by the lymphatics of the mammary gland. The escape of milk from the gland when the udder is grossly engorged may be associated with the actual rupture of some acini or milk ducts. The finding that the lymph became rapidly milky following the insertion of a hypodermic needle deep into the mammary tissue may be significant in this regard. However, it appears that much of the secreted milk in the udder is removed by less-obvious means. Heyndrickx and Peeters[2], in their studies on the constituents of mammary lymph collected from freshly slaughtered cattle, point out that the lymph collected from the udder which had not been milked out prior to slaughter was excessively turbid, and analysis of this lymph showed that it contained milk constituents. The apparent ease of escape of milk into the lymph under these conditions may be associated with tissue anoxia or it may be a characteristic feature of the dairy cow and related to the higher rate of milk production.

HÆMATOLOGY

Recovery and *in vivo* Survival of Rabbit Erythrocytes

HUMAN and other mammalian red cells have been frozen and thawed with limited hæmolysis using a variety of cooling conditions and protective additives. Slow cooling in high concentrations (30 per cent) of glycerol[1], moderately rapid cooling in plasma containing sugars[2], and ultra-rapid cooling in low concentrations (6 per cent) of glucose[3] have allowed high recoveries (90–95 per cent) of red cells of which 80–90 per cent survive at least 24 hr. when transfused.

Polymeric solutes, including polyvinylpyrrolidone (PVP), dextran, polyethylene glycols, and albumin, afford effective protection for red cells as measured by *in vitro* recoveries[4]. Under conditions of rapid cooling and warming, polymers are the most efficient of all protective agents[5]. To our knowledge, however, only one investigator has reported *in vivo* survival studies on red cells frozen in the presence of polymers. Sloviter[6] observed poor viability (20 per cent) of rabbit and human red cells frozen with polyethylene glycols unless thawed cells were washed free of the polymer. Washing, however, lysed some 80 per cent of the initially recovered cells.

We have observed, in work described in this report, that rabbit blood containing a low concentration of PVP, a neutral, hydrophilic polymer, can be rapidly frozen and thawed with erythrocyte recoveries of greater than 90 per cent. Thawed blood was transfused directly, without removal of the polymer, and the red cells exhibited a 24-hr. survival averaging 93 per cent. Table 1 shows results obtained in four experiments using 24 separate blood specimens.

Rabbit blood was collected in acid-citrate glucose (3 vols. blood, 1 vol. ACD). Polyvinylpyrrolidone of average molecular weight 40,000 (*K*-30 PVP, Oxford Laboratories, San Francisco) in saline was added (4 vols. blood-ACD, 1 vol. PVP) to give a final concentration of 7 per cent in the mixture. Twenty to forty ml. of the mixtures was frozen rapidly in capped aluminium tubes of 17–33 mm. diameter by mechanical shaking in liquid nitrogen. After storage at − 170° C. for several days, samples were thawed by mechanical shaking in water at 45° C.

Recoveries of red cells were determined using hæmatocrits and colorimetric measurements of supernatant and total hæmoglobin as oxyhæmoglobin in 1 : 100 dilutions in aqueous sodium carbonate.

Aliquots of thawed blood were labelled with chromium-51 (ref. 7), (Abbott Laboratories, sterile sodium 'Rachromate') and an accurately measured volume was infused through an ear vein. Total infused radioactivity as red cells was measured on a separate aliquot. All chromium-51 measurements were made by scintillation counting using a Nuclear Chicago *DS*5–5 well counter. Blood samples were taken from the opposite ear into oxalate at 30–60 min. and again at 24 hr. after infusion. The percentage survival of red cells at each sample time was calculated using apparent red cell volumes previously determined on each rabbit by auto-transfusion of labelled unfrozen blood.

Table 1. RECOVERY AND SURVIVAL OF RED CELLS IN RABBIT BLOOD CONTAINING POLYVINYLPYRROLIDONE

Exp.	No. of samples	Container diameter (mm.)	Red cell recovery (per cent)	Red cell survival (per cent) 30–60 min.	Red cell survival (per cent) 24 hr.
1	6	17	92 ± 3	110 ± 15	98 ± 12
2	6	17	87 ± 6	97 ± 4	98 ± 6
3	6	17	93 ± 1	93 ± 16	89 ± 17
4	6	33	96 ± 1	97 ± 7	85 ± 7

In experiment 4, samples also were taken at 2–3 day intervals up to 12 days. Percentage survival at each sample time was corrected for labelled cells removed by previous sampling and chromium elution. Identical measurements were made on six additional rabbits which received unfrozen blood. Frozen cells were lost more rapidly during the first 48 hr.; subsequent rates of loss of frozen and control cells were equal (about 1·8 per cent per day). Approximately 85 per cent of the transfused frozen cells exhibited normal *in vivo* viability.

Results indicate that polyvinylpyrrolidone, long studied as a plasma expander, may prove useful as a protective agent in the low-temperature preservation of whole blood suitable for direct transfusion after thawing.

PATHOLOGY

An Iso-Antigen (γB^A) of Mouse γ-Globulin Present in Inbred Strains

HEREDITARY iso-antigens (allotypes) of rabbit γ-globulin were discovered in 1956 by Oudin[1], and independently in 1958 by Dubiski *et al.*[2]. Since then many publications have appeared reporting the serological, genetical and immunochemical characteristics of rabbit γ-globulins[3-6]. More recently, antigenically different types of serum globulins have been described in guinea pig[7], man[8] and baboon[9].

In the present experiments, two inbred strains (*BALB/c* and *C57BL*) of mice were used; the *BALB/c* mice were first immunized, by Dubiski's method[3], with *Proteus vulgaris* (*X* 19). *Proteus* cells coated with anti-*Proteus* sera were afterwards injected subcutaneously twice a week (15 times) into individuals of the *C57BL* strain. In this way, five pairs of mice were immunized with five individual sera (more particularly the γ-globulin selected by bacteria) of

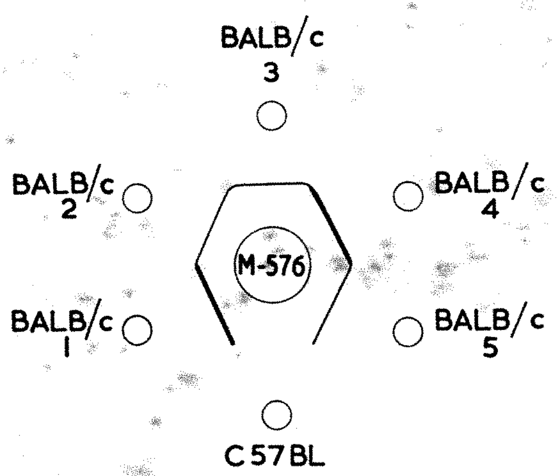

Fig. 1. Precipitation in 1·5 per cent agar gel between a *C57BL* mouse antiserum (*M*-576, in the central well) and sera of six different mice

the *BALB/c* strain. Each serum was therefore used for immunization of two mice. The animals were bled ten days after the last injection.

We tested the immune sera in 1·5 per cent agar gel against the individual *BALB/c* sera used for injections. Only six of ten mice produced precipitating antibodies. They showed an identity reaction varying only in strength. An example of this reaction is illustrated in Fig. 1.

Immunoelectrophoretic analysis showed that the antigen involved in the precipitation is mouse γ-globulin (Fig. 2).

For further investigations, the four strongest antisera were chosen and sera of several mouse strains tested. All four antisera reacted with all sera of individual mice of the strains: *BALB/c*, *C3H/He* and 'Champagne-Glaxo' (Table 1). None of the antisera was precipitated with serum of any *C57BL* mouse, in which strain the antibodies were produced. The experiments showed clearly that the *C57BL* mice lack a γ-globulin antigen, which we will call γB^A, present in each of the other strains of mice tested.

Snell[10] injected *BALB/c* mice with the sperm of *C57* mice and demonstrated an antigen which was absent in the *BALB/c* strain. S. Dubiski (unpublished results) found that rabbit γ-globulin antigens were present not only in the serum but also in the seminal plasma. It seems possible that the antigenic determinants shown by Snell and those described by us are common to serum γ-globulin and sperm and perhaps also seminal plasma.

Since the antisera produced in all *C57BL* mice reacted with sera of every mouse of the other strains, it would be possible in future to use pooled antisera to test a large number of mice belonging to different strains. Further immunization between various strains of mice is necessary to find how many hereditary γ-globulin antigens are present, and which of them are shared by particular strains. It would also be interesting to know if different γ-globulin antigens exist within an inbred strain.

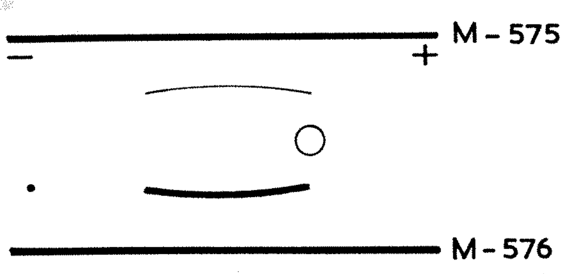

Fig. 2. Immunoelectrophoresis in 1·5 per cent agar gel of a *BALB/c* mouse serum (barbiturate buffer *p*H 8·6, 0·06 *M*, 10 V./cm. for 1 hr.). The antisera in the troughs were produced in *C57BL* mice

Table 1. PRECIPITATION TESTS OF MOUSE ANTI-MOUSE SERA

Mouse antisera (*C57BL* anti-*BALB/c*)	Mouse sera as antigens

Cell Transplants of Avian Lymphomatosis treated with Hydrogen Peroxide

LEUKOSIS is considered to be the most serious disease problem in chickens to-day. After Holman[1] reported his success in destroying implants of Walker 256 adenocarcinoma by replacing rats' drinking water with a dilute solution of hydrogen peroxide, it was decided to see if such treatment would alter the course of leukosis in chickens.

Fleischmann *et al.*[2] reported that survival-time of implanted rats was not lengthened by hydrogen peroxide treatment and hydrogen peroxide did not decrease the size of tumours induced by X-irradiation. Paoletti *et al.*[3] were unable to influence the growth of Ehrlich adenocarcinoma and Walker 256 adenocarcinoma in hydrogen peroxide-treated rats. Ghadially and Wiseman[4] found no difference in survival-time between rats treated with hydrogen peroxide and untreated rats which had been implanted with *RD* 3 sarcoma or Walker adenocarcinoma. Makins and Tanaka[5] prolonged the life of rats with ascites sarcoma to 20 days in contrast to 10 days for controls by intraperitoneal injection of 1 ml. of 2 per cent hydrogen peroxide. Hollcroft *et al.*[6] increased the effect of X-irradiation on regression of transplanted lymphosarcoma by intravenous injection of hydrogen peroxide immediately before X-irradiation, but hydrogen peroxide administered 5 min. before or after X-irradiation did not affect regression. Sugiura[7] was not able to demonstrate any favourable effect on transplanted tumours when the animals drank hydrogen peroxide but there was a moderate inhibitory effect on sarcoma 180 ascites tumour when large doses of hydrogen peroxide were given daily. Jeffree[8] reported no effect on survival-time between hydrogen peroxide-treated and untreated rats. Choraży *et al.*[9] reported no significant increase in survival-time between hydrogen peroxide-treated and untreated animals.

Approximately 4 million *RPL* 12 lymphomatosis tumour cells prepared and counted according to the method described by Mohos and Kidd[11] were injected intramuscularly into 20-day-old Leghorn cockerels. Three per cent hydrogen peroxide was given directly into the crop in one experiment. In the other, the chickens were given a 0·45 per cent solution in drinking water. All birds were kept in batteries and observed daily.

Seventy-six chickens were treated 3 times daily, beginning on the day of implantation, with 1 ml. of 3 per cent hydrogen peroxide directly into the crop. Fifty-two per cent died with lymphomatosis compared with 44 per cent deaths in the control group. A χ^2 test of significance between the treated and check groups resulted in a χ^2 value of 0·658, d.f. = 1, P = 0·40–0·50. The difference was not significant.

Nineteen chickens were not treated until tumours were readily palpable, after which time a 2-ml. dose was given 3 times daily. From the same group, 6 others were given 5 ml. 3 times daily. From the group given 2 ml., 10·5 per cent died, and from the 6, 50 per cent died. In the control group, 64 per cent of 25 died. A χ^2 test for differences between the 2 ml. dose and check group resulted in a χ^2 value of 10·761, d.f. = 1, P = 0·001.

The test indicated the need for further investigation of the effect of hydrogen peroxide. Therefore, a second experiment was initiated in which the dosage and method used by Holman[1] were followed. Hydrogen peroxide at 0·45 per cent level was given continuously in the drinking water to 78 chickens from the day of inoculation until nearly all were dead from tumours. In 78 others, treatment was started 5 days after inoculation when tumours were first palpable. Eighty-two controls were not treated. In the first treated group, 87·5 per cent died with tumours and in the second group, 83·3 per cent died. In the controls, 91·4 per cent died: $\chi^2 = 2·33$, d.f. = 2, $P = 0·30–0·40$.

Since treatment of the transplanted tumours in chickens was not encouraging, it was decided to see if hydrogen peroxide would destroy the cells by direct contact. Portions of tumours were macerated in a Ten Broeck grinder and mixed with 3 parts of 3 per cent hydrogen peroxide. Chickens were injected with 0·2 ml.; tumours developed and destroyed most of the chickens. Tumours were taken from chickens which had been treated with all dosage-levels of hydrogen peroxide and transplanted into other birds. All tumours grew readily and killed the chickens.

In neither instance had hydrogen peroxide altered the activity of the tumour in chickens. Tumours from treated chickens were examined histologically, but there was no difference between tumour cells from treated and untreated chickens.

Hydrogen peroxide was not effective in prolonging the life of chickens implanted with lymphomatosis tumour cells. In the one possible exception where only 10·5 per cent of 19 did die, the possibility of host-resistance cannot be ruled out since some chickens are known to have more resistance than others to this disease. Furthermore, the small number of birds in this group may not have been adequate for a good test.

IMMUNOLOGY

Serum Transferrins in the Genus *Macaca*: Species Distribution of Nineteen Phenotypes

In the genus *Macaca*, rhesus monkeys show a remarkable polymorphism of transferrin, the iron-binding protein, whereas cynomolgus monkeys (the Philippines variety) show only one molecular form of the protein[1,2]. Two-dimensional starch-gel immunoelectrophoresis[3] was used in previous work[1,2] to determine (with the aid of a uni-specific chicken anti-human transferrin serum) the number of transferrin components in the macaque sera. Then comparative one-dimensional starch-gel electrophoresis in the *tris* discontinuous buffer system was used to establish the subtle differences in the mobilities of transferrin, and fifteen phenotypes[2] due to various combinations of eight molecular forms of the protein were detected among rhesus monkeys. These results have now been confirmed by determinations based on the iron-binding property of transferrin. We have also adopted a provisional letter system of nomenclature which has simplified identification of the macaque transferrin phenotypes, thereby making it easier to discover new phenotypes. In this connexion a re-examination of the rhesus sera and an examination of sera from additional macaque species have now revealed nineteen transferrin phenotypes, sixteen being present in the rhesus group alone.

Fig. 1 presents the results of an experiment which involved: addition of iron-59 to rhesus sera representing the fifteen previously discovered phenotypes, analysis of these sera by vertical starch-gel electrophoresis in borate buffer[4], and then demonstration of the iron-binding components by autoradiography[5]. Again the fifteen phenotypes due to the different combinations of the eight molecular transferrins were observed. Each molecular form was assigned a letter, *A* designating the transferrin of slowest mobility and *H* that of fastest mobility. (The mobility increases from *A* to *H* in paper electrophoresis as well as in starch-gel electrophoresis and in the *tris* buffer as well as in the borate buffer.) In lettering the phenotypes it was assumed that when the transferrin genes were homozygous a double dose of a single molecular form of transferrin would be synthesized; but, when heterozygous, single doses of at least two molecular forms

Table 1. SPECIES DISTRIBUTION OF NINETEEN TRANSFERRIN PHENOTYPES IN THE GENUS *Macaca*

Note: The number of sera in each homozygous phenotype is in italics.

would be synthesized. Thus the phenotypes *CC*, *DD*, *GG*, and *HH* are thought to be controlled by homozygous combinations of genes and the other phenotypes by heterozygous combinations. As can be observed in the figure, transferrin *C*, *D*, *G* or *H* has a larger serum concentration in a 'homozygous' phenotype than in a 'heterozygous' phenotype.

The previous suggestion that in the genus *Macaca* there are sharp species differences in the degree of polymorphism of transferrin and in the frequencies of the transferrins[1] is substantiated by the results summarized in Tables 1 and 2. Sixteen phenotypes, four homozygous and twelve heterozygous, have now been recognized in rhesus monkeys (*M. mulatta*) from the Nepal border area of India (77 specimens from three different shipments). One of these phenotypes, a rare one, *BD*, is a new discovery. The transferrin having the highest frequency was *C*. In contrast to the extensive transferrin polymorphism of the rhesus monkeys, only the *D* transferrin has been found in cynomolgus monkeys (*M. irus*) from the Philippines (ninety-five specimens from four different shipments). The pig-tailed macaques (*M. nemestrina*) are again a polymorphic species. Although only seventeen specimens were examined, eight phenotypes (three homozygous and five heterozygous) were observed. Two of these phenotypes, *FF* and *FG*, are new discoveries. The most common phenotype in the rhesus group, *CC*, was not seen in the pig-tailed group. The *D* transferrin had the highest frequency in this group. The stump-tailed macaques (*M. speciosa*), like the Philippines cynomolgus monkeys, may prove to be transferrin homozygotes. The ten specimens examined contained only the H^1 transferrin. This transferrin, another new discovery, was not seen in the other species. H^1 moves faster in electrophoresis than *G*, but not quite as fast as *H*. The physico-chemical nature of the differences in the macaque transferrins and the evolutionary basis for the selection of the phenotypes have yet to be elucidated. In any attempt to do so, it would seem important to investigate the possible role of ecological and geographical factors on the distribution of the transferrin alleles in the genus *Macaca*. In this connexion, *Macaca speciosa* inhabits central India, which is supposed to be quite high in iron content.

Fig. 1. The transferrins of rhesus sera, representing fifteen phenotypes, are compared in vertical starch-gel electrophoresis with the transferrin of normal human serum (far right). Note that the rhesus transferrins migrate faster than the human transferrin. At the top of the figure are the sample designations of the rhesus sera. Many of these samples were used in the original demonstration of rhesus transferrin phenotypes (ref. 1). The Roman numerals designate the phenotypes by the previous nomenclature (refs. 1 and 2). The letters, symbolizing the molecular transferrins, designate these phenotypes by the new nomenclature

We wish to thank Mr. W. Carey Parker for determining the iron-binding components of the rhesus sera by autoradiography and for suggesting the letter system of nomenclature for the rhesus transferrins. We also gratefully acknowledge the valuable help of Dr. P. E. Ayers of the Parke-Dale Unit, Parke Davis and Co., in providing the rhesus and cynomolgus sera, and Dr. R. C. Wolf of the Primate Laboratory, University of Wisconsin, in providing the pig-tailed macaque sera. The stump-tailed macaques, obtained from the Ferndale Pet Shop, were originally shipped from Calcutta, but were captured in central India. A collection of primate sera from Dr. John Buettner-Janusch is now under examination. His collection contains *Macara irus* specimens from Malaya. These specimens, in contrast to those from the Philippines, do show a transferrin polymorphism. This work is being supported by a grant (*G*–14152) from the National Science Foundation.

Products of Mild Acid and Alkaline Hydrolysis of *M*- and *N*-Blood Group Substances

THE preparations of *M*- and *N*-blood group substances obtained by phenol extraction of human erythrocyte stroma are mucoids[1]. They contain, on an average, 10 per cent of hexoses, 6·5 per cent of hexosamines, 1 per cent of fucose, 17 per cent of *N*-acetylneuraminic acid and 7·5 per cent of total nitrogen[1,2].

In an attempt to learn more about the carbohydrate structure of these mucoids, the products of their hydrolysis were studied. The conditions of hydrolysis were similar to those applied to bovine sub-maxillary gland mucoprotein by Gottschalk[3].

Acid hydrolysis: A solution of 15 mgm. of *M*- or *N*-substance in 2 ml. of 0·05 *N* sulphuric acid was heated at 80° for 40 min., afterwards cooled and neutralized with saturated barium hydroxide solution to *p*H 6. Barium sulphate sediment was centrifuged and the supernatant was dialysed exhaustively against distilled water at 2°. The dialysate was lyophilized.

The presence of *N*-acetylneuraminic acid in the dialysate was proved by characteristic reactions (diphenylamine and 2-thiobarbituric acid), paper chromatography in three solvent systems (I: *n*-butanol/*n*-propanol/0·1 *N* hydrochloric acid, 1: 2: 1 v/v; II: *n*-butanol/pyridine/water 6: 4: 3 v/v; III: pyridine/ethyl acetate/acetic acid/water, 5: 5: 1: 3 v/v) and by conversion into 2-carboxypyrrole[3]. After acid hydrolysis of *M*- and *N*-substances, 85–95 per cent of *N*-acetylneuraminic acid was split off and their group activity disappeared completely. In this process also small amounts of dialysable carbohydrate–amino-acid fragments were liberated.

Alkaline hydrolysis: 60 mgm. of *M*- or *N*-substance dissolved in 10 ml. of water was heated rapidly to 80° and saturated barium hydroxide solution was added to a final concentration of 0·02 *N*. The mixture was kept at 80° for 15 min., then cooled and acidified with 1 *N* sulphuric acid to *p*H 6. A further procedure was the same as that after acid hydrolysis.

By means of paper chromatographical analysis and characteristic reactions the following components were found in the dialysate: *N*-acetylneuraminic acid, small amounts of chromogen I, traces of *N*-acetylhexosamine, galactose (in some preparations) and two unknown compounds: C_1 and C_2. The last-named were separated from the other dialysable components by paper chromatography followed by elution of suitable strips of chromatograms; for the separation of C_1, the dialysate was subjected to chromatography in solvent system I, and for the isolation of C_2, in solvent system II.

Compound 1 (C_1): this was homogeneous in the three solvent systems used, gave a distinct colour with benzidine reagent, and a weak colour with direct Ehrlich reagent for sialic acids. Its R_F value was lower than that of galactose. On treatment with acid (0·05 *N* sulphuric acid, 80°, 40 min.) C_1 was split off into *N*-acetylneuraminic acid and galactose (chromatographical evidence). The presence of *N*-acetylneuraminic acid in C_1 was also stated by the methods described here (see acid hydrolysis). The secondary cysteine reaction of hexoses confirmed the presence of galactose in C_1. The amounts of *N*-acetylneuraminic acid and galactose were almost equimolecular.

C_1 was decomposed into *N*-acetylneuraminic acid and galactose after the action of influenza virus strain Lee at 37°.

Compound 2 (C_2): this was submitted to paper chromatography in two solvent systems: II and III gave one spot visible by direct Ehrlich reagent for sialic acids and by direct Ehrlich reagent in the cold (characteristic for chromogens which are formed on mild alkali treatment of *N*-acetylhexosamines[4]) and moved a little faster than *N*-acetylneuraminic acid. C_2, hydrolysed by 0·05 *N* sulphuric acid at 80° for 40 min., yielded only *N*-acetylneuraminic acid; the chromogen part of C_2 was destroyed during this hydrolysis. Chromogen I formed from *N*-acetylglucosamine was also fully destroyed under the same acid conditions. Moreover, *N*-acetylneuraminic acid in C_2 was identified by methods used here.

After the incubation of C_2 with influenza virus Lee at 37° *N*-acetylneuraminic acid and chromogen I (R_F value = 0·6 in solvent system II and positive direct Ehrlich reaction in the cold) were found.

Such disaccharides as *N*-acetylneuraminyl-galactose (C_1) and *N*-acetylneuraminyl-chromogen (C_2), obtained by mild alkaline hydrolysis of *M*- or *N*-substance, show that *N*-acetylneuraminic acid may combine with galactose or *N*-acetylhexosamine in this biologically active material. The linkage of *N*-acetylneuraminic acid in both disaccharides is α-ketosidic because it is labile in acid at elevated temperature and susceptible to virus α-neuraminidase. The mild alkaline hydrolysis of *M*- or *N*-substance repeated several times supplied the same products; it is possible, therefore, that these disaccharides form an essential part of the prosthetic group of *M*- and *N*-mucoids.

I wish to thank Prof. T. Baranowski for his interest and encouragement, and Prof. Zofia Skurska and Mgr. Maria Łobodzinska for preparation of influenza virus strain Lee.

BIOLOGY

Thiabendazole: a Highly Effective Anthelmintic for Sheep

IN the past year, reports on several compounds with outstanding anthelmintic activity against the gastro-intestinal trichostrongyles and strongyles of sheep have been published. Among the anthelmintics tested were the organic phosphorus compound 4-tertiary-butyl-2-chlorophenyl methyl-methyl phosphoramidate[1], a pyridine derivative, 2-(β-methoxy-ethyl) pyridine[2], and one in which an organic phosphorus compound and phenothiazine are stated to act synergistically[3].

Very recently, 2-(4′-thiazolyl)-benzimidazole (thiabendazole) has been reported[4] to have outstanding anthelmintic activity against a wide range of nematode parasites in sheep, cattle and pigs, and some activity against nematodes in dogs.

When thiabendazole was tested in sheep in this Laboratory and in the field in Australia at a dose-rate of 50 mgm./kgm. body-weight, it exhibited a very high degree of anthelmintic activity against *Haemonchus contortus*, *Ostertagia* spp., *Trichostrongylus* spp., *Cooperia curticei*, *Nematodirus* spp., *Oesophagostomum venulosum*, *O. columbianum* and *Chabertia ovina*, but it was not effective against *Trichuris* spp.

In some experiments with penned sheep with a pure infection of either *H. contortus* or *T. colubriformis*, anthelmintic activity was assessed from the results of repeated worm egg counts, but in critical experiments with infections with parasites of the large bowel, the activity was assessed from the ratio of the number of worms passed in the fæces to the number of residual worms found at slaughter a week after dosing. Also, controlled experiments were conducted with penned sheep with naturally acquired mixed infections, an assessment of effectiveness being made by comparing at slaughter the worm counts in treated sheep and in control animals.

In field trials, anthelmintic activity was assessed from results obtained from repeated fæcal examinations, comprising worm egg counts and differentiation of the larvæ recovered from fæcal cultures. In some of the field trials it could be assumed that worm burdens would have been increasing just after the time of treatment, because in control sheep slaughtered at an appropriate time, immature worms were present in large numbers.

The results of all the trials indicated that the worm burdens had been reduced to extremely low levels by a single treatment with thiabendazole, and some treated sheep were found to be completely free from infection when slaughtered. In field trials most of the fæcal examinations made within the two weeks following treatment revealed no eggs, and cultures did not yield any larvæ. In these field trials, it was found that post-treatment egg counts either became constantly negative or remained very low, and it can therefore be assumed that any immature worms present at the time of treatment had also been destroyed.

Results from one controlled trial in penned sheep which harboured mixed infections, shown in Table 1, demonstrate the remarkable anthelmintic activity of the compound.

In one field trial with groups of 50 treated and control lambs, selected at random and held on pastures for fattening, the greater gain in weight in the group treated monthly with thiabendazole showed this drug to be a very effective anthelmintic, and the lambs gained weight at a very high and steady rate. In this trial, 36 per cent of the controls, 44 per cent of the group treated monthly with phenothiazine, and 68 per cent of those treated monthly with thiabendazole attained a weight of 70 lb. or more at 4½ months of age.

— indicates the absence of worms in the aliquot taken for counting; this does not necessarily indicate that no worms were present, but that the total could not have exceeded 50.

In critical trials with *O. columbianum* and *O. venulosum* in Australia, Hebden[5] found that all worms were removed from sheep by treatment. His trials with other species gave results comparable with those recorded in this communication.

Growth Stimulation by High Indole-3-Acetic Acid Concentrations

It is well established that the curve depicting the extension growth of coleoptile sections as a function of indole-3-acetic acid concentration in the surrounding medium (the concentration curve) assumes the shape of an optimum curve. In the case of wheat coleoptile sections the curve ascends at a constant rate until the optimum is reached at approximately 10^{-5} *M* indole-3-acetic acid. The descent of the curve above the optimum is conditioned by the inhibiting effect of higher indole-3-acetic acid concentrations. This clear and distinct picture is found at least when an experimental period lasts 24 hr., while for shorter periods the course of the concentration curve is not so well known.

Foster *et al.*[1] found that the concentration curve is an optimum curve even for short-time experiments. They obtained time curves (curves representing extension growth for different concentrations of indole-3-acetic acid as a function of time), which were straight lines having slope coefficients increasing with indole-3-acetic acid concentrations until 10^{-5} *M*. At higher concentrations they still observed linear curves, but with slope coefficients decreasing with increasing concentration. In later investigations by Cleland[2] it is demonstrated, however, that time curves for different concentrations follow the same course for the first (2–4) hr. of growth. Only after a longer time-interval do the curves separate, showing the usual inhibiting effect of high indole-3-acetic acid concentrations. Working with 10-mm. coleoptile sections (wheat, variety Progress), I could not observe any significant separation of time curves for indole-3-acetic acid up to 10^{-3} *M* over a period of about 3 hr., thus confirming Cleland's results.

To examine more closely the non-appearance of an inhibiting effect of high auxin concentrations during the initial course of the time curves, a special technique was adopted. Attempts were made to let the indole-3-acetic acid act before the actual growth processes commenced. This principle has been introduced by Heyn[3]. The method employed was as follows. During a pre-treatment period (first period) the growth of the coleoptile sections was impeded by either a solution with sufficiently high osmotic pressure (sucrose or mannitol dissolved in McIlvaine's citric acid–phosphate buffer, *p*H 4·6 at 1/100) or by keeping the sections at low temperature (about 3° C.). During the first period treatment with indole-3-acetic

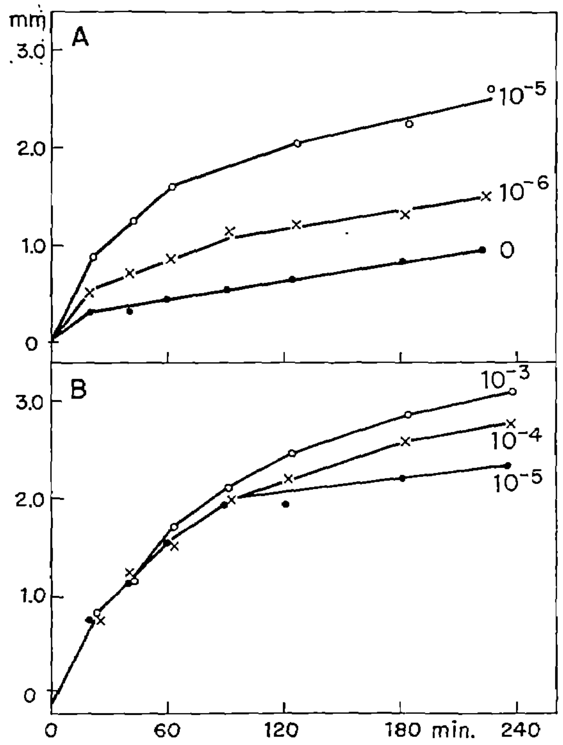

Fig. 1. Growth of wheat coleoptile sections in pure citric acid-phosphate buffer at 23° C. after pretreatment for 2 hr. in growth-impeding sucrose solutions (0·24 M) containing indole-3-acetic acid in molar concentrations as shown in the diagrams

acid was carried out with a concentration series ranging from 0–10^{-3} M. After a washing with buffer solution to remove any adhering sugar and indole-3-acetic acid the coleoptile sections were transferred to pure buffer and the growth period (second period) commenced. All experiments were carried out at 23° C. except for the pre-treatments performed in the cold.

A 2-hr. pre-treatment period in 0·24 M sucrose resulted in a second period of growth as shown in Fig. 1. For practical reasons, only treatment with three concentrations could be included in each experiment (*A* and *B*). The growth increases with increasing indole-3-acetic acid concentrations up to 10^{-3} M. Thus there has been a promoting action by high concentrations normally inducing inhibition when applied during the growth period proper. A repetition of the experiment with a 24-hr. growth period showed similar results.

Low temperature in the pre-treatment period had the same qualitative effect as impeding of growth with sucrose. When mannitol was used as osmotic medium the separation of the time curves for high concentrations could not be observed during the first 4 hr. of the second period, but it appeared distinctly after a period of growth of 24 hr. Prolonging sucrose or low-temperature pre-treatment from 2 to 4 hr. did not alter the results—an increase in growth with rising concentrations up to 10^{-3} M was still observed. This effect disappeared when the pre-treatment was extended to 17 hr. at low temperature. Some of these experiments showed, however, less growth with 10^{-3} M indole-3-acetic acid than with other concentrations. Complete growth cessation could not be achieved with this pre-treatment. Pre-treatment for 17 hr. in sucrose strongly retarded the growth in the second period.

Adding the auxin in the second period following a pre-treatment of 2 hr. in 0·24 M sucrose alone resulted after 20 hr. in a concentration curve with an optimum somewhat below 10^{-5} M indole-3-acetic acid. Without pre-treatment the optimum was at 10^{-5} M. A similar displacement of the optimum was observed by Schneider[4] in experiments with *Avena* coleoptile sections grown in combined sucrose–indole-3-acetic acid media.

Comparison of the concentration curves (20-hr. experiments) for addition of indole-3-acetic acid during the pre-treatment period, and for addition during the growth period, respectively, clearly showed a specific effect of indole-3-acetic acid in the pre-treatment period. The former procedure gave a concentration curve with a distinct minimum between 10^{-6} and 10^{-5} M indole-3-acetic acid while the latter showed a growth optimum in the same concentration interval.

A clear interaction has been demonstrated between indole-3-acetic acid added during the first and indole-3-acetic acid added during the second period. The occurrence of this interaction supports Cleland and Bonner's statement[5] that indole-3-acetic acid can be retained in the tissue from the first to the second period and give rise to a residual effect in the latter.

Agar Disk Method for the Direct Observation of Nematode-trapping Fungi in the Soil

Attempts at the biological control of soil-borne eelworm pests have usually involved a process of green manuring or the addition of some organic amendment to the soil[1–3]. A method has been developed to obtain direct evidence of the effects of such treatments on the predaceous activity of indigenous populations of nematode-trapping fungi in the soil, such work being regarded as fundamental to the investigation of methods using these fungi as agents of biological control.

A weak maize-meal extract agar of the type used for the isolation of predaceous fungi from the soil was used[4]. Disks 1 cm. in diameter and about 3 mm. thick are cut from plates of this medium and placed on microscope slides, four disks usually being arranged in a row on each slide. Each slide is then buried singly in 15-cm. Petri dishes containing soil so that the disks lie about 1 cm. below the soil surface. At weekly intervals the slides are removed and replaced by others bearing fresh disks. On removal from the soil the disk surfaces are washed with a strong, fine jet of water from a wash-bottle. The disks adhere to the slide and can be examined immediately, unfixed and unstained, under the microscope.

During the decomposition of cabbage leaf tissue, glucose and sucrose, a diversity of nematode-destroying fungi (both trap-forming predators and endozoic parasites) appear in the predaceous phase on the disk surfaces. The disks are in effect used as micro-quadrats recording to some extent what is happening in that region of the soil in intimate contact with their surfaces.

The soil is used fresh after being passed through a 7-mm. mesh sieve, thus retaining its microflora and microfauna. Its moisture content is held constant throughout the course of any investigation. By varying the type and quantity of amendment added to the soil, and estimating the nematode population each time the disks are examined[5], the behaviour of the fungi under various conditions and their relationship with free-living nematodes can be studied. Usually four replicate dishes, each holding one slide with disks, are used for each treatment used in any experiment.

It is hoped to enlarge on the details of the relationships between nematode-trapping fungi, organic amendments and nematode populations in a later communication. The above work was carried out during the tenure of an Agricultural Research Council studentship.

Pneumodermopsis paucidens in the North Sea

Clione limacina Phipps is the only gymnosomatous pteropod normally found in the North Sea, but *Pneumodermopsis ciliata* Gegenbaur has been recorded occasionally from Shetland waters[1,2]. In 1960, however, *P. paucidens* Boas was recognized for the first time in the North Sea, where it appeared in collections taken with the small Plankton Indicator[3] and the Continuous Plankton Recorder[4], both sampling in the upper 10 m. It was first recorded in mid-June to the east of the Orkney Islands and, at about the same time, off the north-west coast of Ireland and to the south of Iceland. Thereafter it was found over a wide area (Fig. 1) until early December, with peak numbers of about 10 per m.[3] at the beginning of September. Previously this species has been recorded only from the North Atlantic and off the coast of Ireland[5].

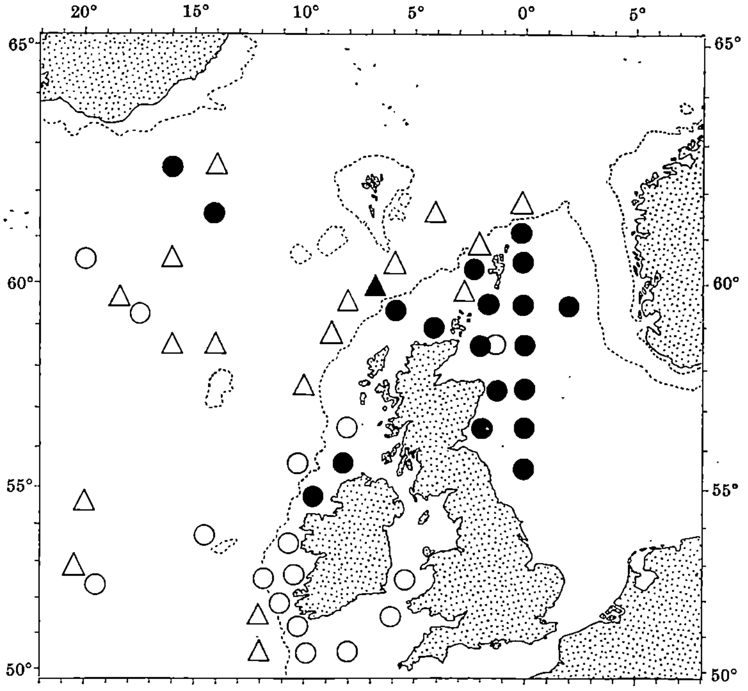

Fig. 1. Chart showing the location of *Pneumodermopsis paucidens* (●) and *P. ciliata* (▲) found in Recorder and Indicator collections in 1960. Previous records from Recorder and Indicator collections in 1956–59, and from the available literature (refs. 1, 2, 6 and 7), are shown as open symbols. Each symbol indicates the centre of a statistical rectangle (1° lat. by 2° long.) in which the species has occurred

Specimens of *Pneumodermopsis* have been re-examined from the collections taken during 1956–59 by Plankton Indicators, in the north-western North Sea, and by Plankton Recorders, throughout the area shown in Fig. 1. Of the total (including those found in 1960) some 700 were *paucidens;* only one of these was taken in the North Sea before 1960. All had the typical radula formula 2:1:2, six hooks and, when they were visible, the characteristic arrangement of the suckers on the median arm. Very few *P. ciliata* were found. These had a radula formula of 6:1:6, many hooks (30–40) and the distal pair of suckers of the median arm had the characteristic "spout at the margin"[6]. Both these species had a range in size of 1–5 mm.

Fig. 1 shows that in Atlantic coastal waters and in the northern North Sea *P. paucidens* was found, whereas in the waters to the west of the continental shelf, both *P. ciliata* and *paucidens* were present.

We are indebted to Dr. J. H. Fraser of the Marine Laboratory, Aberdeen, who confirmed the identification.

Chemical Character of the Pigments in a new Nitrogen-fixing Micro-organism

SOME time ago one of us (Gy. N.) published a communication[1] on a nitrogen-fixing micro-organism from the root nodules of *Lupinus luteus*. By analogy with leghæmoglobin, a red-coloured porphyrin pigment isolated by Virtanen[2] from root nodules of soya beans, Németh presented a working hypothesis of the hæmoglobin-like structure of his red pigment. Interpretation of ultra-violet spectroscopic measurements[1] seemed at the first glance to support this assumption. Furthermore, Matkovics and Tárnoki[3] reported to have isolated—whenever in impure state—a porphyrin methyl ester from root nodules of *Lupinus luteus*. As forecast by Németh[1] more extensive studies were still needed to support this assumption. We wish now to report on our ultra-violet absorption spectral examinations with pigments from strain *Pr-E*/3 of Németh, independently of the work by Schneider, and by Matkovics[6]. On the other hand, paper chromatographic investigation of the acidic extracts prepared from this micro-organism has also been carried out.

In order to separate pigments of different types and structure, before taking up spectra of the strain, *Pr-E*/3 cultivated on a bean agar when air-dry was powdered by quartz sand and, in turn, extracted with pyridine. This sample should contain practically all the pigments as well (Fig. 1, curve 1). Another sample was extracted with ether, the solvent removed very carefully in a nitrogen atmosphere and the residue dissolved in pyridine (Fig. 1, curve 2). A third sample was treated as the second one and then dissolved in *n*-hexane (Fig. 1, curve 3).

The substance which did not dissolve in ether was taken up in pyridine (Fig. 1, curve 4). For the sake of comparison an authentic bovine hæmoglobin dissolved in pyridine (Fig. 2) and paprika carotenoids were investigated spectroscopically in pyridine as well as in *n*-hexane (Fig. 3). Careful measurements of the solutions prepared as given above showed the following spectral results: the ethereal extract showed, when dissolved in pyridine, spectra very characteristic of carotenoids (Fig. 3); no comparison with pyridine-hæmochromogene can be made. The curve of the substance obtained after having been extracted by ether lacks any peak characteristic to carotenoids, but no trace of a pyridine-hæmochromogene could be detected either. The same holds true for the solution of the original pigment in pyridine.

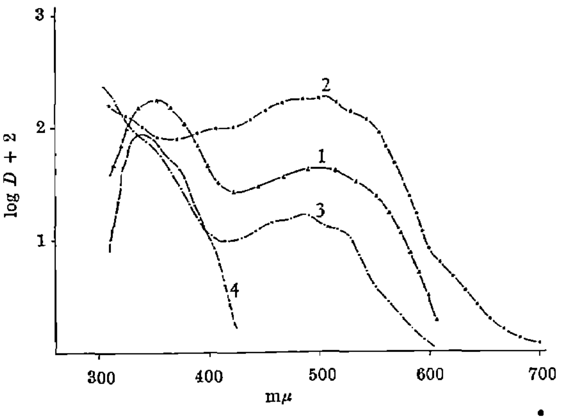

Fig. 1. 1, Strain *E*/3, pyridine extract; 2, strain *E*/3, ether extract, evaporated and dissolved in pyridine; 3, strain *E*/3, ether extract, evaporated and dissolved in *n*-hexane; 4, substance, insoluble in ether, extracted with pyridine

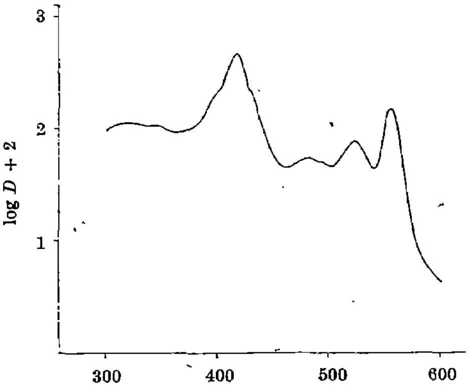

Fig. 2. Bovine hæmoglobin in pyridine

The spectra of the genuine pigment indicate absorption maxima in the range 340–360 mμ (Fig. 4). This can scarcely be ascribed to carotenoids, however; pyridine-hæmochromogene does not absorb in this spectral range either. Accordingly, the chromophore giving rise to this absorption still needs identification. The presence of carotenoids in yeasts is to be expected; for the micro-organism under consideration it has been recorded by others[6].

The red pigment of the strain *Pr-E*/3 could be dissolved quantitatively within a few minutes by distributing by 2 *N* hydrochloric acid and chloroform. The chloroform layer obviously contains fats and carotenoids while the aqueous one proteins of alkaline character and the products of their partial hydrolysis. The aqueous solution has been investigated chromatographically in order to separate amino-acids, porphyrins and flavonoid pigments. Details of this work will be published elsewhere. We shall refer only to the fact that according to the method of Bate-Smith[4] for flavonoids and anthocyanidines with Benedict's reagent a spot characteristic for flavonoids has been found in the case of *E*/3 strain pigment.

In conclusion, the strain *Pr-E*/3 cannot contain considerable amounts of any porphyrin pigments.

The mechanism of nitrogen fixation brought about by these micro-organisms must take quite a different course from that occurring in root nodules of soya beans caused by leghæmoglobin.

Whether carotenoids which are very widespread in micro-organisms, particularly in yeasts, may contribute in any way to nitrogen fixation requires more extensive investigation. Nevertheless, according to

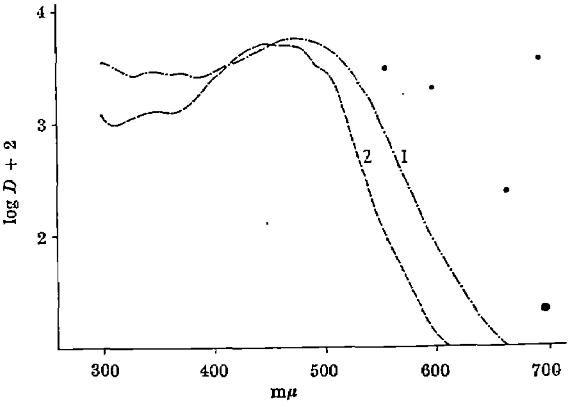

Fig. 3. 1, Paprika carotenoids dissolved in pyridine; 2, paprika carotenoids dissolved in *n*-hexane

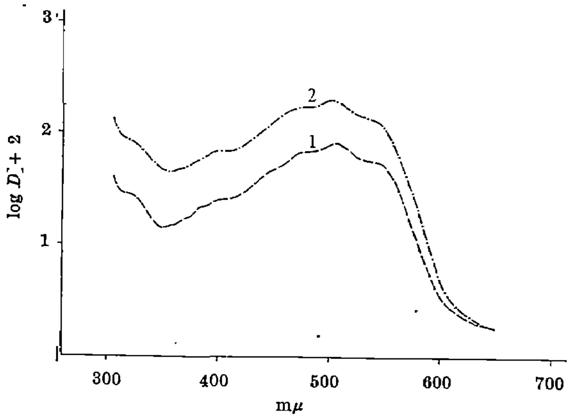

Fig. 4. 1, Pyridine extract of strain *E*/3 raised on a culture medium in distilled water; 2, ether extract of strain *E*/3 raised on a culture medium in distilled water, evaporated, then dissolved in pyridine

Cholnoky *et al.*[5], carotenoids play an important part in oxygen transport in higher plants. It cannot be excluded that oxygen transfer and nitrogen fixation in the yeasts are in some way connected in this case as they are with leghæmoglobin[2].

A more detailed investigation of the pigments of strains *Pr-E*/3 involving flavonoids awaits further investigation.

Indigotin Content of Woad

BEFORE the general introduction of oriental indigo into Europe in the sixteenth century, woad, the product of the woad plant (*Isatis tinctoria*), was the only commercial source of a blue dye, and its production was the basis of a widespread and important industry. It was the result of a lengthy process involving the crushing of the leaves in specially designed mills, air drying the pulp obtained, grinding the dried material to a fine powder, wetting this, and allowing it to undergo spontaneous fermentation, during which it was kept moist and was frequently turned over. This last process took several weeks to complete, and the material became very hot while the fermentation was active. When cool, the mass was allowed to dry and, after re-grinding and sieving, constituted 'finished woad' ready for the dye-vat. The agricultural operations involved in growing the crop and details of the manufacturing process have been fully described by Hurry[1] and others.

It has long been recognized that the essential dye-stuff of woad was identical with that of indigo derived from various species of *Indigofera*, namely, indigotin, and that the former has a much lower indigotin content than the latter, but no estimate of their relative values based on chemical analysis has ever been made. In the absence of any possibility of obtaining a specimen of the medieval preparation it seemed of interest to grow some of the plant in order to determine its indigotin-yielding capacity and, from this, to arrive at a reasonable approximation to the relation.

In both cases indigotin is derived from a glucoside of indoxyl contained in the leaves. Beijerinck[2] has shown that the glucoside of woad is not identical with that of the species of *Indigofera*, but, since indoxyl results from the hydrolysis of both, the same methods of estimation apply. Methods of manufacture depend, in each case, on the activity of a glucosidase which comes into action when the temperature of the plant material is raised or the normal synthetic activity of the enzyme is reversed by some other means. In the case of indigo manufacture this was brought about by steeping the plant in water at about 90° F. for some hours. The solution of indoxyl thus obtained was then drawn off and oxidized by air, whereby a crude preparation of indigotin was precipitated. In the case of woad the necessary heat was produced in the fermentation process and the indigotin deposited in, or on, the finely divided vegetable material.

The glucosides are readily extracted without change if the operation is conducted in briskly boiling water. Indoxyl may be determined quantitatively in such extracts by hydrolysis with a mineral acid in the presence of an oxidizing agent, followed by sulphonation of the precipitated indigotin and titration of the disulphonate with permanganate. Rawson's ammonium persulphate method, as modified by Bergtheil and Briggs[3], was used for the determination in woad. Plants were grown from seed collected from stock descended in a continuous line from that of one of the few professional growers of woad who was still growing it in England in the early 'thirties of the present century. (Dyeing with woad alone had been abandoned long before this. The survival for so long of the cultivation of the plant on a small scale was due to a demand for it by indigo-dyers, who still used the organic fermentation process to reduce their indigo, since it was thought that its presence in the dye-vat led to the production of richer shades. The amount of indigotin contributed to the vat by the woad must have been negligible relative to that supplied by the indigo, but the finely divided vegetable matter involved doubtless facilitated the fermentation.) Only mature foliage was taken for analysis since neither very young nor very old leaves were used in the industry. Samples were taken at intervals throughout the summer. They showed an average indigotin-yielding potentiality of 0·05 per cent, and very little variation occurred between early July and late September. This is extremely low compared with the poorest *Indigofera* leaf, the analysis of which is recorded (0·54 per cent for *Indigofera sumatrana*). It is noteworthy, however, that in the case of woad there is a much higher proportion of mid-rib in the leaf than in those of indigo plants (roughly 50 per cent in the former as compared with 2 or 3 per cent in the latter) and this contains practically none of the glucoside. But even if the figure for woad leaf were doubled it would still remain very low by *Indigofera* standards.

Fresh woad leaf contains about 90 per cent water. If we assume that it was completely dry, and that the process of manufacture was fully efficient, the finished product would thus have contained about 0·5 per cent indigotin. The poorest-quality natural indigo which came on the market contained about 30 per cent indigotin, the best some 70 per cent. If we take the mean of these figures as standard we find that finished woad contained only about a hundredth part as much indigotin as average indigo.

It is difficult to understand how, with so little indigotin in the product, dyers were able to produce anything like as dark a shade of blue as we are accustomed to associate with indigo-dyed goods. If they did so, it must have necessitated repeated dippings with intervals for oxidation between them and constant renewals of the dye stocks in the vats. The amount of inert matter involved must have been enormous.

A Poikilohydrous, Poikilochlorophyllous Angiosperm from Africa

THE sedge, *Trilepis pilosa* Boekl, a primary colonizer of rock surfaces on granitic inselbergs in West Africa, has been found to possess the property, most unusual in an angiosperm, of becoming dormant by losing most of its intracellular water during the dry season, with subsequent recovery on moistening. Plants with this property are found mainly among the lower groups (bacteria, fungi, algae, lichens and bryophytes); the word 'poikilohydrous' being first used by Walter[1] in this connexion. Some pteridophytes also exhibit this property: for example, Iljin[2] described drying out and recovery of the fern *Notochlaena marantae* R.Br., and I have found *Selaginella njam-njamensis* Hieron., which colonizes thin soil mats on West African inselbergs, and the epiphytic fern *Platycerium stemaria* (P. Beauv.) Desv., which is sometimes epiphytic on *Trilepis*, to be poikilohydrous.

Richards[3] remarked that the leaves of *Trilepis* last for one season and are green only during the wet months. He also remarked on the rapid development of new green leaves following the early rains. On the rock domes, however, the patches of *Trilepis* are seen to be of various shades of yellow and green following one of the infrequent dry-season showers. With the onset of the rainy season during April, a number of the old, apparently dead leaves nearest the apex of a plant become green. In the laboratory, detached leaves which were so dry as to be brittle and containing approximately 8 per cent water (normal green leaves contain about 56 per cent water), were found to become green and flexible within 24 hr. of moistening under normal conditions of illumination. Similarly the leaves of entire plants became green progressively from the base when the plants were watered; greening did not take place in plants watered and kept in the dark for up to a week; yet it occurred when these were returned to normal daylight conditions.

The colour of the adaxial side of dormant leaves is pale buttercup yellow ($5/_2$) (ref. 4), while the abaxial surface is palest yellow ochre (o$7/_3$). The dormant leaves may be distinguished by this coloration from the buff-coloured dead leaf blades (which are persistent near the stem apices until they decay during the rainy season), and the dead apical regions of the oldest of the dormant leaves. It must be emphasized that the plants appear 'completely dead' in the dry season, as Richards described them; the brittle straw-like texture of the leaves heightens the illusion that they are dead. On moistening, the yellow colours (which are due to carotenoid pigments in the 'chloroplasts') immediately brighten to a deep buttercup yellow ($5/_1$), gradually giving away to green: sulphur yellow ($1/_1$), citron green (7 $63/_1$) and fern green (o*8* $62/_2$) being successive colours recorded for a detached leaf floated on water for thirty hours. At maturity the leaves are a deep green colour, cf. lettuce green (*8* 61).

Dormant plants of *Trilepis* have been found to retain their viability for at least a year when stored in an air-conditioned room (at ambient temperatures between about 18° C. and 28° C., and relative humidity of about 45 per cent). In the dormant condition the protoplasm is less liable to high- and low-temperature injury, as would be expected from Levitt's[5] summary of work on the limits of high- and low-temperature hardiness. Green *Trilepis* plants rapidly cooled to − 10° C. and kept at this temperature overnight rotted on moistening, while similarly treated dormant plants became green in the normal manner. The lower limits of injury by heat appear to be much higher in the dormant plant than in plants in the hydrated condition; work on this aspect is still in progress. Single leaves will not become dormant—they dry green—and the apical tuft of leaves on a short exised stem may behave likewise: it appears that only with an intact plant or a long portion of stem is dormancy possible under normal conditions. The stem bears a thick 'armour' of dead leaf bases and fibres which loses water rather slowly; this slow drying out of the plant as a whole being possibly connected with the intracellular changes associated with dormancy.

Trilepis leaves have thus been found to last for more than a single rainy season. Their poikilohydrous nature, together with the water-absorbent armour of the stem, enables a rapid start of growth with production of new leaves to be made at the beginning of the wet season (an entire dry plant, in a heavy shower, takes up more than its own weight of water in less than 5 min.). Flowering and production of fruits take place very early in the rains; the nutlet germinates within 24 hr. of moistening, and the young plants thus have a maximum chance of becoming established in their rocky habitat before the onset of the dry season in November.

Trilepis is the second angiosperm found to be poikilohydrous, and closely resembles in its loss and gain of chlorophyll another member of the family Cyperaceæ, *Carex physodes* M. Bieb., described by Vassiljev[6] from the desert flora of Central Asia. Vassiljev mentions the brittleness of the brown, dried-out leaves in *C. physodes* which, as in *Trilepis*, is lost with moistening. The word 'poikilochlorophyllous' is now suggested to describe plants, such as these two angiosperms, which completely lose and regain their chlorophyll following natural variations in environmental conditions. Poikilohydrous members of the lower groups, including ferns (for example, *P. stemaria*), usually retain their green colour when dormant and may, in contrast, be described as homoiochlorophyllous.

Further work on the ecology of *Trilepis* and other poikilohydrous species from West Africa will be published elsewhere.

I wish to thank Prof. Richard Biebl, of Vienna, for kindly supplying me with references to literature on drought tolerance.

Enzymic Breakdown of Stigmatic Cuticula of Flowers

ENZYME preparations from different micro-organisms are able to break down the leaf cutin of different plants[1,2]. Furthermore, the incompatibility reaction in Cruciferae occurs on the surface of the stigma papillae: pollen tubes are unable to penetrate the cuticle of the stigma cells[3] after self-pollination. Therefore we tried to determine the activity of an enzyme preparation from *Penicillium spinulosum* Thom. on cutin preparations of several sources and especially on stigma cutin isolated from about 10,000 stigmata of black mustard by shaking with pectinase solution following the method in ref. 4, and treatment with ethanol. The results are listed in detail in Table 1. From this it is clear that cutin from mustard stigma is attacked more than material from the pistil of *Petunia* and much more than cutin from leaves and fruits. The breakdown is measured by titration of the enzymically liberated fatty acids following a new method[5]. The differences in enzymic decomposition of cutin should depend on a specific state or a special composition of the high-polymeric, reticular substrate. For the first time it has been possible to demonstrate the enzymic breakdown of stigma cutin.

Table 1

Object	Origin of cutin	Enzymically liberated ml. equivalent 0·01 normal fatty acids
Gasteria verricuosa (Mill.) Duval	Leaf epidermis	$3{\cdot}4 \times 10^{-3}$
Solanum lycopersicum L.	Fruit epidermis	$8{\cdot}2 \times 10^{-3}$

MICROBIOLOGY

Mycobacteriophages isolated from Persons with Tuberculous and Non-tuberculous Conditions

IN a recent communication[1] certain effects of mycobacteriophages on acid-fast bacilli were described. They consisted of the lysis of phage-susceptible bacteria, and of biological changes in the phage-resistant elements of the bacterial population. The phage-resistant bacteria were lysogenic. They showed changes in morphology, in the pigmentation of their colonies, in their susceptibility to mycobacteriostatic drugs, in their antigenic composition and in their pathogenicity for laboratory animals.

These *in vitro* observations raised the question as to whether or not similar changes may occur *in vivo*. Any work along this line had to start by demonstrating the occurrence of mycobacteriophages in the human or animal body.

Bacteriophages active on acid-fast micro-organisms have been isolated so far only from soil, particularly fertilized soil[2-8]. Hnatko[2] attempted to isolate mycobacteriophages from specimens of sputum and of stool from tuberculous patients, but he could not detect any phage activity in his filtrates.

Fifty specimens of stool from hospital patients with pulmonary tuberculosis were examined for the presence of mycobacteriophages.

10-gm. amounts of the specimens were emulsified in 200 ml. of Proskauer and Beck synthetic medium modified by Youmans and Karlson[9]. To this suspension were added 1-ml. amounts of actively multiplying cultures from 12 test strains of mycobacteria. These test strains included pathogenic and saprophytic mycobacteria. They were chosen because they apparently were free of prophages, that is, they did not show spontaneous or ultra-violet irradiation-induced lysogeny. After 10 days incubation at 37° C., the suspensions were filtered on membrane filters and the filtrates were added to fresh culture media inoculated with the test strains. After five such passages, the filtrates were spot-tested to determine lytic activity on any of the test strains. The technique for this screening procedure was described by Froman *et al.*[3] and modified by Takeya and Yoshimura[6].

Table 1 shows the lytic activity of ten mycobacteriophages which were isolated from ten of the fifty specimens of stool that were included in this study.

It is interesting to note that only one mycobacteriophage, isolated repeatedly from specimens of stool from patient D.W., is active on pathogenic mycobacteria. While at the time the specimens were collected the sputum cultures of the other nine patients yielded typical *M. tuberculosis*, those of patient D.W. consisted of atypical chromogenic acid-fast bacteria.

Specimens of stool were then collected from 50 patients with pulmonary conditions of non-tuberculous ætiology. Table 2 shows the bacteriolytic spectrum of five mycobacteriophages isolated from this group.

Patient McL., from whom a mycobacteriophage with a large lytic spectrum, including the virulent human strain $H_{37}Rv$, was isolated, came to this hospital to undergo resection for bronchogenic carcinoma. No history of tuberculosis was given. Four phages were isolated from patients with a diagnosis of sarcoidosis. From eight other patients

ith the same diagnosis no mycophages were isolated m stool specimens.

The presence of mycobacteriophages in the stool certain patients could either be temporary and cidental or it could be determined and maintained y infection with mycobacteria. In an attempt to pproach this question, the following experiment was ndertaken:

Five groups of 20 mice each (Rockefeller strain) ere inoculated intravenously with either of two rains of mycobacteria. Three groups of mice were oculated at the same time and by the same route ith filtrates of mycobacteriophages to which the cteria were susceptible, as follows:

Group 1 with *Mycobacterium smegmatis*.
Group 2 with *Mycobacterium smegmatis* and *Bacteriophage smegmatis* (courtesy of Dr. E. Vandra, Budapest).
Group 3 with the virulent human strain $H_{37}Rv$.
Group 4 with $H_{37}Rv$ and *Bacteriophage D*29 (courtesy of Dr. S. Froman, Olive View, California).
Group 5 with $H_{37}Rv$ and *Bacteriophage* D.W.

The amount of bacilli inoculated was 0·5 mgm. r mouse. The phage filtrates, from which 0·2 ml. re inoculated, contained 10^8 lytic particles per ml.

Specimens of stool were collected from each group mice and were examined for the presence of mycoacteriophages. *Mycobacteriophage smegmatis* (Group) was lost: no phage could be recovered from these animals 48 hr. or more after inoculation. Specimens of stool from Groups 4 and 5 contained phages up to nine weeks after infection. According to their plaque morphology and their activity on mycobacteria, these phages were identical with *Mycobacteriophages D*29 and D.W., respectively.

When autopsies were performed on these animals nine weeks after infection, it was established that Groups 1 and 2, which were inoculated with *M. smegmatis*, did not show any gross pathology, whereas the mice inoculated with $H_{37}Rv$ showed lesions in kidneys and/or lungs.

The results of these animal experiments suggest that under certain conditions mice may remain infected with mycobacteriophages for long periods of time. One of the conditions appears to be the presence of multiplying mycobacteria in the tuberculous lesions.

I gratefully acknowledge the technical assistance given by Mrs. M. Liivak and Mrs. S. Dernuet.

Release from the Feedback Inhibition controlling the Biosynthesis of Isoleucine

HAYASHI *et al.* have found that a large quantity of L-isoleucine was accumulated in the cultured medium of *B. subtilis* strain 14 when α-aminobutyric acid (designated as *AB*) was added to the medium containing glucose, peptone, urea and mineral salts[1]. The apparent conversion ratio of *AB* to accumulated isoleucine reached 70 per cent when 1 per cent of the former was added to the medium. In spite of the nature of *AB* as a possible precursor of isoleucine, incorporation of the added *AB*-1-^{14}C to produced isoleucine was observed only at the initial stage of the culture[2]. As the culture proceeded to the accumulation stage of isoleucine, the specific activity of isoleucine tended to be decreased, which means that isoleucine thus accumulated was derived from glucose. On the other hand, it is well recognized in yeast, *Neurospora* and *E. coli* that threonine is at first deaminated to α-ketobutyric acid, which then converts to isoleucine through several biosynthetic steps[3-8]. Further, it was depicted that biosynthesis of isoleucine was controlled by a feedback mechanism within the cells of *E. coli*[7,9].

We have examined the presence and the nature of threonine deaminase in *B. subtilis* strain 14, since it is one of the important enzymes in the most probable pathway of isoleucine biosynthesis, and in addition it was ascertained by Hayashi *et al.* that hydroxyacetyl butyric acid was converted to isoleucine by this strain[1].

An appreciable activity of threonine deaminase is detectable as compared with *E. coli*, and, indeed, specific activities (defined in the table) reached 2·0 to 3·0 in this strain compared with 9·0 in *E. coli* strain *K*12. Cells grown in the medium containing *AB* (*AB* cell) have usually lower activity as compared with those grown in the medium without *AB* (normal cell). Specific activities of the enzyme obtained from *AB* and normal cells, which were collected from 48-hr. cultures, ranged from 0·01 to 0·28 and from 0·13 to 0·63, respectively. In spite of this fact, which suggests that *AB* might repress or inhibit this enzyme through a certain mechanism, the enzyme activity was enough stimulated in either normal cells or *AB* cells when *AB* was added to the system of enzyme assay. In contrast, the enzyme activity was completely inhibited by the addition of 10^{-3} *M* isoleucine, as Umbarger pointed out a similar inhibition in *E. coli*[9]. An inhibition curve of sigmoid type was obtained between the rate of inhibition and the concentration of added isoleucine. As shown in Table 1, when isoleucine and *AB* were added simultaneously at various concentrations, the recovery from the isoleucine inhibition was observed according to the given concentrations of *AB*, where the inhibition curves by isoleucine shifted towards its higher concentrations. Leucine and valine, on the other hand, did not indicate any significant effect on the enzyme activity itself, but gave the similar effect as did *AB* on the inhibition by isoleucine.

Table 1. α-AMINOBUTYRIC ACID, LEUCINE AND VALINE AS RELEASER OF THE INHIBITION BY ISOLEUCINE OF THREONINE DEAMINASE

Concentration of α-aminobutyric acid (*M*)	0	10^{-3}	10^{-2}	10^{-1}
Concentration of isoleucine (*M*)				
0	100*	105	118	132
10^{-4}	30·1	37·0	57·9	82·1
5×10^{-4}	2·1	3·7	4·5	48·8
2×10^{-3}	0	0	0	4·2
Concentration of amino-acids (*M*)		0	Leucine 2×10^{-3}	Valine 2×10^{-3}
Concentration of isoleucine (*M*)				
0		100†	80·7	104
5×10^{-5}		57·0	72·8	77·6
10^{-4}		26·6	65·8	63·8

* Figures represent relative activities to specific activity of 2·4.
† Specific activity, 1·93.

The cells were grown for a period of 24 hr. at 30° C. on a reciprocal shaker, using a medium of following composition: glucose, 10 per cent; peptone, meat extracts, each 0·2 per cent; urea, 0·5 per cent; K_2HPO_4, 0·07 per cent; $MgSO_4.7H_2O$, 0·03 per cent; $FeCl_3.6H_2O$, 0·005 per cent. In the case of *E. coli*, 1 per cent $CaCO_3$ was added to the medium.

The cells were collected by centrifugation, washed twice with 0·1 *M* phosphate buffer (*p*H 7·5) and suspended in the same buffer.

Deaminase activity was assayed at 37° C. in a 1-ml. system containing 40 μmoles of DL-threonine, 100 μgm. of sodium deoxycholate, 0·03 ml. of toluene, 0·4 ml. of cell suspension which contained 2–5 mgm. of dry cells and 40 μmoles of phosphate buffer (*p*H 7·5), and appropriate volume of inhibitor and releaser. After 1 hr. incubation, the reaction was stopped by the addition of perchloric acid. The extent of deamination was followed by determining the keto-acid formed using the modified method of Friedemann and Haugen (ref. 10). Specific activities are expressed in μmoles of keto-acid formed per hr. per 1 mgm. of dry cell.

From the results obtained here, it is postulated that the negative feedback mechanism in the biosynthetic process of isoleucine may exist also in *B. subtilis* strain 14, and the interference with this feedback mechanism may occur in the presence of *AB*, leucine and valine, but only *AB* and not leucine or valine leads to isoleucine accumulation. Moyed and Friedman indicated that feedback mechanisms controlling the biosynthesis of tryptophan and histidine had been lost in such mutant strains of *E. coli* resistant to their analogues[11]. Further, Adelberg indicated that mutant strains of *E. coli* resistant to thienylalanine or *p*-fluorophenylalanine, an analogue of phenylalanine or tyrosine, excrete a large amount of phenylalanine or tyrosine[12,13]. Another example of metabolite excretion was indicated by us, in which a type of releaser from the feedback inhibition may cause the excretion of a metabolite, which is usually supplied moderately by the feedback mechanism for further synthesis. *AB* is not an analogue of isoleucine, nor does not lead a resistant mutant in the above-mentioned medium (unpublished work).

As to the control mechanism, such as the negative feedback loop which may control the rate of biosynthesis of metabolite, it might not be allowed to act in such a simple manner *in vivo* as conceived from the results obtained *in vitro*, since many agents interfering with this mechanism would have to exist within the cell as indicated above.

Spore Dispersal in *Chaetomium globosum* (Kunze)

IN the genus *Chaetomium* the fruit-body, a perithecium, is ornamented with a large number of apical hairs which are either spirally coiled or dichotomously branched. The ascospores are released within the perithecium by breakdown of the ascal walls and the spores ooze out of the ostiole and either form a spore tendril or become entrapped in the apical hairs. Hitherto the mechanism of spore dispersal has been obscure, but recent experiments have shown that entire fruit-bodies as well as spores can be dispersed by falling water drops.

Target disks, 2 cm. in diameter, were cut from a three-week-old agar culture of *C. globosum* having approximately 150 perithecia per sq. cm. Disks were placed on glass slides and surrounded by small glass sheets. A single drop of water 5 mm. in diameter was allowed to fall from varying heights, up to 2 m., on to the centre of each target. This drop, on breaking up, cleared most of the perithecia from an area 0·5–1 cm. in diameter. The dispersed fruit-bodies were found scattered on the glass sheets either singly or in groups of up to twenty. The longest distance of dispersal recorded was 17 cm. The majority of perithecia were found in splash droplets, but others were dry and had obviously remained dry during dispersal. Other drops were found to contain ascospores and the maximum distance recorded for spore transport was 33 cm.

The ease with which perithecia can be dispersed by water is related to the very superficial position and loose anchorage of the fruit-body on the mycelium. The anchorage though loose is, however, resistant to wind. Experiments using a small wind-tunnel showed that with wind speeds up to 10 m./sec. the perithecia remained attached; the spores, however, were readily blown away from the spore masses trapped in the apical hairs.

The dispersal of perithecia in splash droplets and as dry fruit-bodies is probably related to the water-repellent nature of the fruit-body. Colonies of *Chaetomium* can be gently flooded with water without wetting the perithecia, the apical hairs retaining a bubble of air. The falling drop, however, has sufficient kinetic energy to break through the terminal hairs and to wet the perithecia at the point of impact. The unwetted perithecia are probably picked up as the impact drop breaks up into the splash droplets. These small drops would strike the perithecia laterally, the latter being carried on the surface of the drop from which they may be shed during the free flight.

This method of splash dispersal involving whole fruit-bodies appears to be unique in the fungi. Falling water drops act as the agent of dispersal in many bacteria and slime-spored fungi[1] and work by Gregory *et al.*[2] has established the basic mechanics involved. Comparable examples of the splash dispersal of larger units are few and are confined to the dispersal of the lenticular peridioles in the Nidulariales and the sclerotial balls of *Aleurodiscus minnsiae*[3].

GENETICS

Fracture and Fusion of Coccid Chromosomes

Unlike gene mutations the expression of which may be subject to considerable modification, chromosomal changes will remain the same whether they occur as sporadic aberrations or become incorporated in the karyotype of a species. If the complements of two closely related species differ, spontaneous chromosomal mutations paralleling the karyotypic differences should be demonstrable in the same group of organisms.

In the Coccoidea, the haploid chromosome number ranges from 2 to 20 (ref. 1). Since the basic number for the superfamily is in the range of $n = 5$ to 7, both increase and decrease have occurred in the evolution of the karyotype. The chromosomes of the coccids lack localized centromeres and fragments perpetuate themselves during successive mitotic cycles[2]. Thus, simple breakage can provide the basis for increase in chromosome number unless a breakage-fusion-bridge cycle intervenes to eliminate the breakage products. Fragmentation with and without subsequent bridge formation has been previously reported[2]. When bridges are formed, either spontaneously[3] or after high-dosage irradiation[4], they are unmistakably identifiable in my preparations. Their absence in other circumstances indicates that fracture *per se* need not lead to a breakage-fusion-bridge cycle.

Related coccid species may vary in number by one or two chromosomes or by exact doubling. The latter changes, similar to polyploidy, are complex problems and will not be considered here, but parallels of structural aberration and karyotype change are now evident for the simple increases and decreases.

Spontaneous chromosome breakage occurs ubiquitously in the coccids[illegible]; there is [illegible] abundant availability of ruptured chromosomes for increase in number should chance or selection so dictate. Three cases are now known in which karyotypes of related species differ in the manner expected from fragmentation. On the basis of relative measurements, the karyotype of *Africaspis fici* with $n = 6$ chromosomes appears derivable by simple fragmentation from that of *A. chionaspisformis* with $n = 4$ (ref. 5). In this instance, the chromosomes of *A. fici* varied considerably more in size than those of its congener; however, size variation can be achieved through unequal translocation while breakage of the longest chromosome of a complement could lead to more nearly uniform sizes in the derived karyotype. A Mexican species with $n = 6$ is now known from the *Aspidiotus-Hemiberlesia* series and is the first departure, other than that of a highly atypical genus[6], from the basic diaspidid number, $n = 4$, among the numerous species of Aspidiotini examined (Fig. 1*A*). Among the endemic Hawaiian pseudococcids, the genus *Pedronia* is noteworthy for its association with ferns[6]. In two of the species studied cytologically, the basic number of the pseudococcids, $n = 5$, was found while in a third the number was 7 (Fig. 1*B*). In the last two examples, the increase of the haploid number by two required, on a minimal assumption, the rupture of two chromosomes to yield four breakage products. On the basis of size criterion, no breakage products can be identified in the Mexican species and only one or two in the *Pedronia* example; in both cases, therefore, breakage would have had to occur in the longer chromosomes of the antecedent karyotypes. Forms related to the Mexican species are as yet unknown, but the complements of the two *Pedronia* species with $n = 5$ show the expected size variation.

Fusion of the major portions of two chromosomes by means of a reciprocal translocation at sub-terminal points of breakage and loss of the small residual chromosome will reduce the chromosome number by one. The 'double-length' chromosome will be detectable in the karyotype unless its size is reduced afterwards by additional translocations or the original fusion involves two especially short chromo-

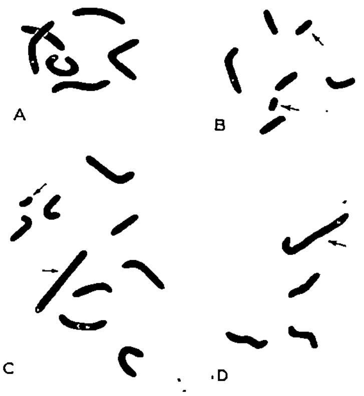

Fig. 1. Structural alterations of coccid chromosomes. *A*, Aspidiotine species, *Aspidotius-Hemiberlesia* complex, $n = 6$. *B*, *Pedronia cibotii*, $n = 7$; arrows, possible fragmentation products. *C*, Aberrant strain of parthenogenetic sp., *Howardia biclavis*, $2n = 10$; arrows, 'double-length' and residual chromosomes from unequal translocation. *D*, *Pseudococcus adonidum*, $n = 4$; arrow, 'double-length' chromosome

somes. A spontaneous change of this sort has been reported for an ovarian mosaic of an armoured scale [illegible] with a residual product undoubtedly too large for tolerable loss, has now been found in a collection of the parthenogenetic armoured scale, *Howardia biclavis* with $2n = 10$ (Fig. 1*C*); because öogenesis is here essentially mitotic, the occurrence in the sample of several individuals with the aberration is a reflection of the clonal type of reproduction. In the *Pseudoparlatoria* complex in North America, species have been recorded with $n = 4$, and one member of double length, and with $n = 5$ (ref. 5). There is no definitive evidence to show the direction in which the change occurred; although 4 is the basic diaspidid number, the 4-chromosome complement in question is highly distinctive and was most likely secondarily derived. A much simpler example is provided by *Pseudococcus adonidum* with $n = 4$; this, the only reduction yet known from the basic number, $n = 5$, of the pseudococcids, is accompanied by a double-length chromosome (Fig. 1*D*). In the armoured scale genera, *Protodiaspis* and *Ancepaspis*, species with $n = 4$ and $n = 3$ have been discovered, and in both cases a disproportionately long chromosome occurs in the species with the lower number. These two genera present an interesting phylogenetic problem.

The method of accounting for karyotypic changes on the basis of the evidence from spontaneous alterations in the same group seems to afford a better understanding of the evolutionary process than inferences from work with dissimilar organisms, no matter how conclusive they seem in themselves.

This work has been aided by a grant from the National Science Foundation.

Discriminant Analysis in Biometrical Genetics

SEVERAL notable attempts have been made to analyse and interpret the inheritance of polygenic characters in terms of simple Mendelian factors giving the familiar ratios in segregating generations[1,2]. More recently, Weber[3,4] proposed his so-named discriminant analysis technique, in which two or more component measurements of a character that may individually appear to be normally distributed are combined into a discriminant function which, in contrast, might assume generally a bimodal frequency distribution suggesting this linear compound measure to be simply inherited like qualitative traits. He illustrates this method for the cotyledon size i tomato by using a linear function of length/widt ratio (x_1) and area (x_2), $x = b_1x_1 + b_2x_2$, and showin x to have a bimodal frequency distribution in F_2 tha simulated a segregation ratio of 3: 1 in one case and o 9: 7 in the other. Apparently, Dr. Weber consider this method of analysing quantitative characters t be useful in general as he argues[3], "this total measurement of discriminant function has no dimensiona designation; it is without dimension in the physica sense, like the term red or white colour".

While this new analysis in biometrical genetics may have some appeal, for its empirical value in particular to those used to thinking only in terms of simple gene models and Mendelian ratios, it is, however, open t criticism on such grounds as the applicability of the method in general and its genetic implications. L statistical theory, it is well known that a linear function of several normal variables is also distribute normally, so that a bimodal distribution of the discriminant function such as that observed by Weber for the cotyledon size in tomato would seem to be very unlikely unless the sampling errors were rather large or the component characters were actually non-normal variates. In any event, this method might be applicable to some very rare examples merely fo expediency rather than as a real solution. Mor over, it seems quite inexplicable how several polygen systems governing the inheritance of various ind vidual components could be made to behave like on or two genetic units by merely considering the segregation together. This, in fact, appears contra to the usual approach of breaking down a comple character such as yield into its components that ma involve relatively simpler genetic situations[5]. Here, Dr. Weber perhaps argues that it is the total impression of a character which is under genetic control while the dimensional measures are artefacts from the viewpoint of genetic determination. Obviously, such an argument would seem to imply the non-existence of a polygenic mode of inheritance of many of the quantitative characters. Thus, it appears that a critical evaluation of this method of discriminant analysis is quite in order in view of an important issue on the polygenic inheritance being involved, and that many more examples need to be investigated before even its empirical usefulness is well demonstrated.

FORTHCOMING EVENTS

(Meeting marked with an asterisk (*) is open to the public)

Tuesday, October 3

Institution of Chemical Engineers, South-Eastern Branch (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Calderbank: "The Origins and Purpose of Chemical Engineering" (Inaugural Lecture).

Tuesday, October 3—Thursday, October 12

Electronic Computer Exhibition (at Olympia, London).*

Wednesday, October 4

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5 p.m.—Ir. A. R. Thatcher: "Some Results on Inventory Problems".

Institute of Petroleum (at 61 New Cavendish Street, London, V.1), at 5.30 p.m.—Mr. H. G. Priest: "The Packaging of Lubricants".

British Institution of Radio Engineers, London Section t the London School of Hygiene and Tropical Medicine, Keppel reet, Gower Street, London, W.C.1), at 6 p.m.—Mr. D. A. Drew: lethods Used for the Study of Vibration in Aero Engines".

Institution of Mechanical Engineers, Railway Engineering roup (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m. Dr. F. T. Barwell: "Some Speculations on the Future of Railway echanical Engineering".

Thursday, October 5

Institution of Electrical Engineers (at Savoy Place, London, V.C.2), at 5.30 p.m.—Mr. G. S. C. Lucas: Inaugural Address as resident.

Thursday, October 5—Friday, October 6

Biochemical Society (joint meeting with the British Bio- hysical Society, in the School of Pharmacy, University of London, runswick Square, London, W.C.1).

hursday, October 5

At 11 a.m.: "The Physical Chemistry of Phospholipids".

iday, October 6

At 10.30 a.m.: "Phospholipids and Sulpholipids".

Society for Analytical Chemistry (at the Institution of Mech- nical Engineers, Birdcage Walk, Westminster, London, S.W.1), at .30 p.m. on Thursday and 10.30 a.m. on Friday—Meeting on "Ad- ances in Analytical Chemistry—Selected Topics Originating from nalytical Requirements in the Field of Nuclear Technology".

Friday, October 6

Photoelectric Spectrometry Group (in the Department of hysics, Imperial College of Science and Technology, Prince Consort oad, London, S.W.7), at 2.30 p.m.—Annual General Meeting. 3.15 m.—Meeting on "Absorption Measurements at Wave-lengths Below 0 mμ".

Society of Chemical Industry, Fine Chemicals Group (in the llcome Building, Euston Road, London, N.W.1), at 2.45 p.m.— eeting on "Approaches to the Chemotherapy of Virus Diseases".

Institution of Electrical Engineers, Medical Electronics scussion Group (at Savoy Place, London, W.C.2), at 6 p.m.— cussion on "What is *p*H and Its Measurements ?" opened by Dr. Mattock and Mr. G. R. Taylor.

Saturday, October 7

Biochemical Society (at the Westminster Hospital Medical School, Horseferry Road, London, S.W.1), at 10 a.m.—Ordinary Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (with a good honours degree in electrical engineering and preferably with special interests in electrical machinery) in Electrical Engineering—The Registrar, King's College (University of London), Strand, London, W.C.2 (October 6).

Demonstrator (with medical qualifications registrable in this country) in Anatomy—The Registrar, The University, Manchester 13, October 7).

Experimental Officer or Senior Experimental Officer, to ssume responsibility for the supervision and maintenance of electronic ontrol, computer and digital equipment associated with the radio elescope and other apparatus at Jodrell Bank—The Registrar, The University, Manchester 13 (October 7).

Lecturer and Administrative Officer (with a university degree in science and with good qualifications in physics, preferably with a knowledge of Welsh) in the Faculty of Education—The Registrar, University College, Cathays Park, Cardiff (October 7).

Assistant Chief Officer (with a degree in botany, agricultural botany or agriculture or equivalent qualifications, and preferably experience of seed improvement and staff administration) at the Official Seed Testing Station—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (October 9).

Assistant Lecturer or Lecturer in Genetics—The Registrar The University, Sheffield (October 14).

Lecturer or Assistant Lecturer in the Department of Pure Mathematics—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (October 14).

Research Fellows (2) (with an honours degree and three years postgraduate experience in a relevant field) in Seismology in the Department of Astronomy, for the investigation of local structure and local earthquakes, and the interpretation of dispersed seismic waves—The Secretary, The University, Edinburgh (October 14).

Lecturers or Assistant Lecturers (with a good honours degree or equivalent qualification, preferably with teaching and/or research experience) in Geology at the University, Kuala Lumpur, Malaya—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 15).

Assistant Lecturer (with a good honours degree in zoology and preferably a special interest in the arthropods) in Invertebrate Zoology—The Registrar, King's College (University of London), Strand, London, W.C.2 (October 16).

Experimental Officer or Senior Experimental Officer in the Department of Metallurgy, to operate, maintain and develop an electron beam micro-probe analyser—The Registrar, The University, Manchester 13 (October 16).

Senior Lecturer and a Lecturer in Mechanical Engineering at the University of Cape Town—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, October 23).

Lecturer or Senior Lecturer in Pure Mathematics at the University of New England, Armidale, N.S.W., Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 27).

Curator (with a qualification in zoology and preferably experience of a teaching museum) of the Zoology Museum—The Registrar, University College of North Wales, Bangor, North Wales (November 30).

Lecturer/Senior Lecturer (with a particular interest and qualifications in the philosophical and/or sociological aspects of education) in Education at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 30).

Lecturer in Pure Mathematics at the R.A.A.R. Academy, which is affiliated with the University of Melbourne—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 31).

Lecturer (with an honours degree in mining engineering or equivalent, and considerable experience in metalliferous mining) in Metalliferous Mining—The Registrar and Secretary, King's College (University of Durham), Newcastle-upon-Tyne 1 (October 31).

Nuffield Research Fellow (preferably with an interest and experience in theoretical or experimental neutron physics)—in the Department of Physics—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (October 31).

Reader (with teaching and research experience and with published work in the field of economic statistics, preferably with a knowledge of econometrics) in Economic Statistics at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (October 31).

Food Technologist (preferably with a Ph.D. in food technology or postgraduate experience in this field) in the Fruit Research Division, D.S.I.R., Stoke, near Nelson, New Zealand, for the investigation of problems arising in the processing of fruits and vegetables, and the development of new products from these crops—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. B.13/18/2 (November 16).

Lecturer in Philosophy at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 18).

Lecturer in Education at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (November 20).

Plant Physiologist (with postgraduate experience), to undertake studies on the growth of the tobacco plant—The Director, Tobacco Research Board of Rhodesia and Nyasaland, P.O. Box 1909, Salisbury, Southern Rhodesia (November 30).

Analyst (B.Sc.(chemistry) and preferably G.R.I.C. or equivalent qualifications), for the operation and care of optical equipment including infra-red and nuclear magnetic resonance spectrometers—Mr. W. A. Wightman, School of Chemistry, The University, Leeds 2.

Assistant Experimental Officer (with a pass degree, preferably in zoology and chemistry) in the Unit for Biochemical Research on Fisheries' Problems—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Berks, quoting Ref. 61/24.

Assistant Lecturer in Chemistry—The Principal, National College of Food Technology, St. George's Avenue, Weybridge, Surrey.

Assistant Lecturer (with a good honours degree and preferably with research and/or industrial experience) in Physical Chemistry—The Academic Registrar, Hatfield College of Technology, Hatfield, Herts.

Editorial Assistant (with a degree in science and preferably editorial experience) for the *Biochemical Journal*—The Editorial Board, The *Biochemical Journal*, 133–135 Oxford Street, London, W.1.

Lecturer (B.Sc. (chemistry and biology) and preferably with a teaching diploma), in Nigeria to teach science subjects to pharmacy students—The Recruitment Secretary (Overseas), Northern Region Recruitment Agency, Nigeria House, 9 Northumberland Avenue, London, W.C.2.

Lecturer (graduate of a British university) in Physiology in the Department of Health Education—Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Physicist (with an honours degree and preferably with appropriate research experience), to take part in a programme or work concerning the physical properties of milk—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 61/27.

Research Assistant (preferably with research experience) in the Department of Genetics, to work in collaboration with Prof. J. A. Roper on nucleo-cytoplasmic interactions in fungi—The Registrar, The University, Sheffield.

Research Worker (with a qualification in chemistry and preferably previous experience in polymer chemistry) in the Isotope Unit, for work in the field of polymer reaction mechanisms—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

Senior Technician or Technician (with experience and training in electronics) in the Pharmacology Department—The Secretary, Royal Free Hospital Medical School, 8 Hunter Street, London, W.C.1.

REPORTS and other PUBLICATIONS

(*not included in the monthly Books Supplement*)

Great Britain and Ireland

British Association for the Advancement of Science. Annual Report, 1960–61. Pp. 31. (London: British Association for the Advancement of Science, 1961.) [148

Ordnance Survey, Chessington. One-inch Map of Great Britain, Sheet No. 190: Truro and Falmouth. (National Grid—Seventh Series.) (Chessington, Surrey: Director General of the Ordnance Survey, 1961.) 5*s.* 6*d.* net, paper. [148

Committee of Privy Council for Medical Research. Report of the Medical Research Council for the year 1959–1960. Pp. viii+326. (Cmnd. 1422). (London: H. M. Stationery Office, 1961.) 15*s.* 6*d.* net. [148

Office of the Minister of Science; Ministry of Health; Department of Health for Scotland; Ministry of Health and Local Government for Northern Ireland. Code of Practice for the Display of Sources of Ionizing Radiations at Exhibitions. Pp. 6. (London: H.M. Stationery Office, 1961.) 6*s.* net. [148

Production Engineering Research Association of Great Britain. Report No. 49: Grinding Carbide Turning Tools—a Comparative Study of Methods. Pp. 14. (Melton Mowbray: Production Engineering Research Association, 1961.) [148

Central Sterile Supply. Edited by Brian Watkin. Pp. 58. (London: Macmillan and Co., Ltd., 1961. A *Nursing Times* publication.) 4*s.* 6*d.* [148

Privy Council. Medical Research Council Monitoring Report Series No. 2: Assay of Strontium-90 in Human Bone in the United Kingdom—Results for 1960, Part 1, with some further results for 1958 and 1959. Pp. ii+13. (London: H.M. Stationery Office, 1961.) 1*s.* 3*d.* net. [148

Ministry of Housing and Local Government. Fourth Progress Report of the Standing Technical Committee on Synthetic Detergents. Pp. 19. (London: H.M. Stationery Office, 1961.) 1*s.* 6*d.* net. [148

Department of Scientific and Industrial Research. Report of the Tropical Products Institute 1960: The Report of the Tropical Products Institute Committee, with the Report of the Director of the Tropical Products Institute. Pp. viii+40. (London: H.M. Stationery Office, 1961.) 3*s.* net. [148

Year Book of the Royal Society of Edinburgh 1961, (Session 1959–1960). Pp. 138. (Edinburgh: The Royal Society of Edinburgh, 1961.) 20*s.*; 3.50 dollars. [148

Ferranti, Ltd. A Review of Ferranti Activities. Pp. 24. (Hollinwood, Lancs.: Ferranti, Ltd., 1961.) [148

Royal Observatory Bulletins. No. 33: Radial Velocities Observed with the Mount Wilson 60-inch Telescope. By D. H. P. Jones and R. v.d.R. Woolley. Pp. E121–127. 2*s.* net. No. 39: Time Service 1960, October–December. Pp. B61–77. 3*s.* net. (London: H.M. Stationery Office, 1961.) [148

British Standards Institution. British Standard 1991: Recommendations for Letter Symbols, Signs and Abbreviations. Part 2: Chemical Engineering, Nuclear Science, and Applied Chemistry. Pp. 46. 10*s.* net. Part 3: Fluid Mechanics. Pp. 36. 7*s.* 6*d.* net. Part 4: Structures, Materials and Soil Mechanics. Pp. 50. 12*s.* 6*d.* net. Part 5: Applied Thermodynamics. Pp. 30. 7*s.* 6*d.* net. (London: British Standards Institution, 1961.) [148

The Nuclear Energy Industry in the United Kingdom. Second edition, revised. Pp. iv+67. (London: United Kingdom Atomic Energy Authority, 1961.) [148

The Kent Incorporated Society for Promoting Experiments in Horticulture. East Malling Research Station Annual Report, 1960, (Forty-eighth year), 1st October 1959 to 30th September 1960. Pp. xxiv+148. (East Malling, near Maidstone: East Malling Research Station, 1961.) 17*s.* 6*d.*; 2.50 dollars. [148

Other Countries

World Health Organization. Technical Report Series, No. 221: Scientific Meeting on Rehabilitation in Leprosy, Vellore, Madras State, India, 21–29 November 1960—Report. Pp. 37. (Geneva: World Health Organization; London: H.M. Stationery Office, 1961.) 2 Swiss francs; 3*s.* 6*d.*; 0.60 dollars. [148

Meddelanden från Oceanografiska Institutet i Göteborg. Nr. 29: Remarks on some Cenozoic Core Sequences from the Central Pacific, with a Discussion of the Role of Coccolithophorids and Foraminifera in Carbonate Deposition. By Eric Olausson. Pp. 35. Nr. 30: Optical Measurements in the Eastern North Atlantic ("Discovery II" Expedition of August and September 1959). By N. G. Jerlov. Pp. 40. (Göteborg: Elanders Boktryckeri Aktiebolag, 1961.) [148

Organization for European Economic Co-operation: Office f Scientific and Technical Personnel. Television for School Scienc Report on an O.E.E.C. Seminar, Ashridge (England), July 196 Pp. v+181. (Paris: Organization for European Economic Co-opera tion, 1961.)

American Society for Testing Materials. Special Technical Publica tion No. 297: A Five-Attribute System of Describing Visual Appearance. By Deane B. Judd. Pp. iv+15. (Philadelphia: American Society for Testing Materials, 1961.) 1 dollar. [148

Research Council of Alberta. Information Series No. 33: Alberta Subbituminous Coals as Drilling Fluid Thinners. By E. J. Jensen Pp. 25. (Edmonton: Research Council of Alberta, 1961.) [14

Colony of Mauritius. Annual Report of the Meteorological Department, 1960. Pp. ii+17. (Port Louis: Government Printer, 1961.) 25 cents. [148

United States Department of Agriculture. Index-Catalogue o Medical and Veterinary Zoology. Supplement 11: Authors A to Z. By Mildred A. Doss, Judith M. Humphrey and Dorothy B. Segal. Pp. i+409. (Washington, D.C.: Government Printing Office, 1961 1.50 dollars. [1

Smithsonian Institution, Washington. Uniform Regulations for t Army of the United States 1861. (Illustrated with Contempor Official War Department Photographs.) Pp. 61. (Publication 44 (Washington, D.C.: Smithsonian Institution, 1961.) [1

Smithsonian Miscellaneous Collections, Vol. 143, No. 1: Locom Mechanisms of Birds. By Frank A. Hartman. Pp. i+91. (Public 4460.) (Washington, D.C.: Smithsonian Institution, 1961.)

American Philosophical Society. A Catalogue of Instruments Models in the Possession of the American Philosophical Socie Compiled by Robert P. Multhauf, assisted by David Davies. I xi+80 (26 figures). 1.50 dollars. (Memoirs of the American Philosoph Society, Vol. 53.) A Catalogue of Portraits and other works of art the Possession of the American Philosophical Society. Pp. viii+1 (59 figures). 2.50 dollars. (Memoirs of the American Philosophica Society, Vol. 54.) (Philadelphia: American Philosophical Society, 1961.) [148

New Zealand: Department of Scientific and Industrial Researc New Zealand Geological Survey. Paleontological Bulletin No. 3 The Fossil Decapos Crustacea of New Zealand and the Evolution of th Order Decapoda. By Martin F. Glaessner. Pp. 79 (7 plates (Wellington: Government Printer, 1960.) 16*s.* 6*d.* [14

Forschungsberichte des Landes Nordrhein-Westfalen. Nr. 932: Di Anomale Diffusion in dem System Polystyrol-Toluol. Von Prof. Dr. Ernst Jenckel und Dr. Alfred Nogaj. Pp. 42. (Köln und Opladen: Westdeutscher Verlag, 1961.) 13.50 D.M. [148

Journal of the Geological Society of India, Vol. 1, 1959. Pp. 166+6 plates. (Bangalore: Geological Society of India, 1959.) Rs. 15. [158

Geological Survey of Uganda. Report No. 3: Explanation of th Geology of Sheet 69 (Lake Wamala). By Dr. R. J. Johnson. Pp. iii+35+3 plates+map. Shs. 15. Report No. 4: Explanation of the Geology of Sheet 76 (Buhwezu). By Dr. A. W. Reece. Pp. vi+73+7 plates+map. Shs. 20. (Entebbe: Government Printer, 1960 an 1961.) [152

United States Department of Interior: Geological Survey. Bulletin 1082–L: Tertiary Geology and Oil-Shale Resources of the Piceance Creek Basin between the Colorado and White Rivers, Northwestern Colorado. By John R. Donnell. Pp. v+835–891+plates 48–59. Bulletin 1091: Investigations of some Clay Deposits in Washington and Idaho. By John W. Hosterman, Vernon E. Scheid, Victor T. Allen and I. G. Sohn. Pp. iv+146+9 plates. (Washington, D.C.: Government Printing Office, 1961.) [159

United States Department of the Interior: Geological Survey. Bulletin 1146–A: Geophysical Abstracts No. 184, January–March, 1961. By James W. Clarke, Dorothy B. Vitaliano, Virginia S. Neuschel and others. Pp. iii+170. 40 cents. Water-Supply Paper 1459–H: Microbiologic Factors in the Solution and Transport of Iron. By Eugene T. Oborn and John D. Hem. Pp. i+213–234. Water-Supply Paper 1535-E: Chemical Degradation on Opposite Flanks of the Wind River Range, Wyoming. By Charles H. Hembree and Frank H. Rainwater. Pp. iii+9. Water-Supply Paper 1586-A: Water Quality and Hydrology in the Fort Belvoir Area, Virginia, 1954–55. By C. N. Durfor. Pp. v+57. 25 cents. Professional Paper 353-C: Effect of Sediment Characteristics on Erosion and Deposition in Ephemeral-Stream Channels. Pp. iii+70. (Washington, D.C.: Government Printing Office, 1961.) [158

Annales de l'Institut de Physique du Globe de l'Université de Paris et du Bureau Central de Magnétisme Terrestre, Tome XXX. Pp. 190. (Paris: Institut de Physique du Globe de l'Université de Paris et du Bureau Central de Magnétisme Terrestre, 1960.) [158

Osservatorio Astrofisico du Arcetri, Firenze. Relazione Sull' attività dell Osservatorio per il 1960. Pp. 20. (Firenze: Osservato io Astrofisico di Arcetri, 1961.) [158

Canada: Department of Mines and Technical Surveys. Geological Survey of Canada. Paper 60–24: Tectonic Framework of Southern Yukon and Northwestern British Columbia. By H. Gabrielse and J. O. Wheeler. Pp. ii+37. (Ottawa: Queen's Printer, 1961.) 50 cents. [158
